Blood group-specific substances A and B are commercially available.* They are supplied in 10 ml. sterile vials. The contents of 1 vial (10 ml.) are added to 500 ml. of group O blood and mixed **just prior** to use in transfusions. Because of the danger of stimulating increased antibody formation in female patients potentially capable of childbearing, use of group O blood modified by group-specific substances should not be permitted except in the face of an emergency. Instead of using group O blood treated with group-specific substances, remove the plasma and use the remaining cells, meanwhile carrying out proper blood grouping and cross-matching tests. To render this even safer, the donor blood should also be Rh negative. Tisdall et al.[271, 272] concluded with respect to this entire matter as follows:

1. As little as 25 ml. of group B plasma containing a high titer of isoagglutinins may cause a hemolytic reaction when administered to a group A recipient.
2. A-like and B-like group-specific substances will reduce a high isoagglutinin titer of bivalent antibodies to low levels. Unger points out that it will in no way affect the titer of univalent anti-**A** and anti-**B**, and therein lies one of the dangers of using such substances.
3. A and B specific substances are capable of antibody stimulation even when in combination with anti-**A** and anti-**B** agglutinins of group O blood. This calls for some caution in administering such material to women potentially capable of childbearing.
4. For use as universal donor blood in civilian hospitals, Rh-negative group O blood, selected for its low natural isoagglutinin titer, is preferable to random group O blood to which group substances have been added to reduce the isoagglutinin titer. The plasma should be removed before administering the blood.

Goebel technic for preparing group-specific substance A[267]

1. Dissolve 450 gm. peptone (Difco Neopeptone) and 180 gm. sodium acetate ($3H_2O$) in 1350 ml. distilled water.
2. Precipitate the crude fraction containing the A substance by adding 3375 ml. 95% alcohol.
3. Collect the precipitate in centrifuge tubes the following day and redissolve in 270 ml. distilled water.
4. Discard the undissolved sediment after centrifugation.
5. Collect the insoluble fraction again by adding

---

*Sharp & Dohme, Philadelphia, Pa.

45 gm. sodium acetate and 675 ml. alcohol.

6. Repeat a third time, using 150 ml. distilled water and 24 gm. sodium acetate, and precipitate with 2.5 vol. alcohol.
7. Redissolve the precipitate in 180 ml. water.
8. Add 27 gm. sodium acetate.
9. Adjust the reaction to pH 4.8 by adding 20% acetic acid.
10. Deproteinize by shaking for 16 hr. with a mixture of 40 ml. chloroform and 8 ml. butyl alcohol.
11. The resulting solution should give negative tests for protein with 20% trichloracetic acid, 5% sulfosalicylic acid, and saturation with picric acid.
12. Recover the fraction containing the A substance by precipitating with 2.5 vol. 95% alcohol.
13. Dialyze a solution of this substance in water through cellophane against successive changes of distilled water. Keep refrigerated during dialysis.
14. Precipitate the active fraction in 10 vol. acetone.
15. The substance tends to remain in colloidal suspension but forms a flocculent precipitate quite readily after the addition of a few crystals of sodium chloride. Collect the precipitate on a hardened filter paper, wash with acetone, and dry over sulfuric acid.

Group-specific substances are now available commercially from several sources.

PROFESSIONAL DONORS

Professional donors should carry a book in which are inscribed the name, residence, age, result of serologic tests, and the blood group. Each withdrawal of blood should be entered in this book, together with the date.

The question of just when blood can safely be taken from the same person the second time has been much discussed. The rate of hemoglobin regeneration in blood donors has been studied. Apparently donations of 500 ml. blood at intervals of 4-5 wk. are not harmful to male donors, but in female donors anemia often develops under similar conditions. Blood should not be taken more frequently than once every 8 wk. (N.I.H. requirements). Hemoglobin regeneration is slower in female donors than in male donors. The average drop in blood hemoglobin after the removal of 555 ml. blood is 2.3 gm., and the average time required to replace this amount is 49.6 days. With a smaller donation and a smaller drop in the blood hemoglobin, the recovery period is shorter. Subsequent donations may be given with safety as soon as the blood hemoglobin has returned to its original level. A minimum interval of 8 wk. should be allowed between blood donations, provided that at that time the hemoglobin of the donor has returned to normal. Administration of 1 gm. iron and ammonium citrates per day increases the daily hemoglobin regeneration by 49% and shortens the recovery period from 49.6 days to 35.2 days during the first period of its administration. It has progressively less effect after subsequent blood donations.

DISEASES THAT MAY BE TRANSMITTED BY TRANSFUSION

Syphilis: The donor must be free from acute or chronic disease; more especially must it be proved as accurately as possible that he does not have syphilis. A physical examination should be made by a physician, and serologic tests including preferably the VDRL and a standard complement fixation test such as the Kolmer must be made. It must be remembered that although a negative serologic reaction for syphilis is not complete proof that the donor is free of the disease, a positive reaction is sufficient reason to reject a candidate for donor.

There are many cases on record in which syphilis has been communicated to the recipient because of the use of a syphilitic donor's blood. In the case cited by Wildegans,[273] the patient showed widespread syphilitic skin eruption 10 wk. after the transfusion. The case of Moritsch and Wittman[274] details transmission of syphilis from a donor who had a negative complement fixation reaction but who later was proved to have had a primary syphilitic lesion at the time of the transfusion, which further points up the importance of the physical examination.

The syphilitic infection is transmitted directly into the blood stream without development of any primary manifestation. As a rule, the incubation period is 4-10 wk. and is usually followed by a vigorous and typical roseola (syphilis d'emblée).

Professional and voluntary blood donors, who may be exposed to infection with syphilis during intervals between transfusions, should have serologic tests made for syphilis prior to every blood transfusion regardless of the frequency of the donations and relation to the recipient. As pointed out by Rein et al.,[275] blood donors' assertions of noninfection cannot be depended upon and should not be taken seriously.

With the advent of blood banks, the problem of transmission of syphilis through blood transfusions became somewhat simplified because (1) ample time is available for carrying out tests for syphilis prior to using the donor blood and (2) blood stored at refrigerator temperature for 72 hr. is possibly incapable of transmitting syphilis even though obtained from a donor whose freshly drawn blood is infectious.

Turner and Diseker[276] conducted experiments on the duration of infectivity of *Treponema pallidum* in citrated blood stored under conditions obtaining in blood banks. They added *T. pallidum* to citrated blood from both human beings and rabbits and determined the infectivity of the mixture for rabbits after various periods of refrigeration. Blood from syphilitic rabbits, known to be in an infectious stage, was likewise tested. Blood from human beings with early syphilis was not tested because even under the most favorable conditions rabbits are infected with difficulty with such material. The strain of *T. pallidum* used in the experiments was well adapted to the rabbit. The experiments showed that under the conditions obtaining in blood banks, syphilitic treponemas probably undergo progressive deterioration during the storage period. Even when large numbers of virulent treponemas were added to citrated whole blood, the mixtures were not infectious for normal rabbits after storage for 3 or more days. After storage for 1 and 2 days, although viable organisms were still present, they were evidently considerably reduced in numbers or in virulence since the incubation period of the lesions resulting from the inoculation of the same amounts of the stored mixture was significantly prolonged, and in some instances the inoculated animals escaped infection. Turner and Diseker concluded that the infectivity of syphilis treponemas in citrated whole blood rarely persisted for longer than 3 days at refrigerator temperature.

Bloch[277] obtained infection with material stored for 72 hr. but did not demonstrate survival for 96 hr. He concluded that there is definite risk of transmitting syphilis when using blood from patients with early syphilis if the blood has been preserved for 72 hr. or less in a blood bank.

Although the risk of transmitting syphilis through the use of stored syphilitic blood diminishes rapidly after 96 hr., it is still unwise to use blood from persons with known early syphilis.

As Gradwohl[278] stated, "these experimental observations confirm the statements made above and should cause one to pause in listening to speculative platitudes from those uninformed in experimental data that syphilitic blood when stored is safe and can be given with impunity. The axiom that no syphilitic blood should ever be given in transfusion, whether fresh or stored, still obtains."*

Viral hepatitis: Hepatitis, apparently of viral origin, may be transmitted by blood transfusion. The incidence of supposedly healthy but nevertheless infectious donors is approximately 0.2-0.5%. The incubation period varies from 2 wk. to 6 mo. Cases with short incubation periods are thought to be due to virus A, infectious hepatitis, whereas those with incubation periods of 6 wk. or longer are thought to be due to virus B, serum hepatitis. In practice it is difficult to classify individual cases. The incidence of hepatitis is reduced by careful history and by exclusion from future blood donations of all donors whose blood might have induced hepatitis. It is difficult to distinguish between hepatitis due to the blood or blood fraction previously administered, natural infection, and use of inadequately sterilized syringes and needles. The necessity for careful sterilization of syringes and needles or any skin or mucous membrane-penetrating device should be constantly emphasized to reduce the incidence of hepatitis. Use of expendable apparatus and needles will obviate this.

On the subject of hepatitis carriers, Unger[279] suggested that donors be asked the following questions, and that if the answer to any of them is "yes," the donor should be rejected: (1) Have you ever been jaundiced? (2) Have you ever had a prolonged, febrile, undiagnosed illness? (3) Have you recently received an injection of whole blood or blood products? Unger also stated that since **blood contaminated by the hepatitis virus cannot be detected,** the blood bank at New York University Medical Center places the following notice on each bottle of blood issued: "Despite careful selection of donors, this blood may contain the virus of homologous serum hepatitis."

Malaria: Refer to p. 1585.

Other diseases: Diseases such as rubella and brucellosis may rarely be transmitted by blood transfusion.

UNTOWARD REACTIONS FOLLOWING BLOOD TRANSFUSIONS[280, 281]

Up to the time of the appearance of the publications of Landsteiner[282, 283] there had been repeated grave manifestations of agglutination and hemolysis from the mixture of incompatible bloods. His work showing the blood groups of human beings laid the foundation upon which has been built the relatively safe and secure methods of blood transfusion as practiced today. Reactions sometimes occur because of errors in blood grouping and the consequent transfusion of blood of an incompatible group. Wiener et al.[284] discussed their experience with reactions in more than 3000 transfusions, dividing transfusion reactions into 2 main groups: (1) those due to some specific incompatibility between the blood of the patient and that of the donor and (2) those due to nonspecific agents, the latter constituting the vast majority.

---

*From Gradwohl, R. B. H.: Clinical laboratory methods and diagnosis, ed. 3, St. Louis, 1943, The C. V. Mosby Co.

Attention has been called to the danger of using group O blood indiscriminately as a universal donor. Levine and Mabee[285] pointed out that in group O donors with high isoagglutinin titers the dilution of donor's serum in the patient's circulation might not be sufficient to prevent hemolytic reaction; in fact, cases have been reported of hemolytic reactions following use of such dangerous universal donors. It is reasonable to believe that such instances of reactions are certainly high when universal donors are used routinely.

Transfusions of blood containing the Rh agglutinogen to patients lacking the agglutinogen, with subsequent anti-Rh agglutinin development, is definitely a factor in many blood transfusion reactions. This has been fully explained on pp. 1507ff.

All transfusion reactions should be investigated to determine avoidable causes, and this is particularly true when the patient may require additional transfusions.

Hemolytic reactions

Hemolysis in vivo follows when incompatible blood antigens and antibodies are present in the circulation. There is a relative decrease in red cells and release of free hemoglobin, which colors the plasma or serum and may appear in the urine. Free hemoglobin is converted to bilirubin, as shown by increased serum bilirubin levels, and jaundice may develop. Kidney disease with lower nephron nephrosis is a possible complication and is characterized by oliguria, hematuria, anuria, and an increased blood urea. In extreme instances death follows.

Hemolytic reactions may occur after administration of a small amount of blood, but they occur usually after introduction of 50 ml. or more of blood. The patients complain of tingling sensation or a sense of great discomfort and anxiety, fullness in the head, precordial oppression or a constricting feeling in the chest and difficulty in getting their breath, and severe pain in the back of the neck, chest, and especially in the lumbar region. Signs of collapse follow, with rapid feeble pulse, cold clammy skin, marked flushing of the face, dyspnea, cyanosis, drop in blood pressure, dilatation of the pupils, and nausea and vomiting.

In less severe instances there may be very little complaint on the part of the patient. When a hemolytic reaction is suspected, the red count, test for free hemoglobin in the blood, serum bilirubin, and urine volume and free hemoglobin tests prove or disprove the suspicion. Rise in bilirubin values and a positive direct Coombs (antiglobulin) test during the first 24 hr. after transfusion are important in diagnosis.

The cause of a hemolytic reaction should be ascertained when possible. The pretransfusion blood specimens of the donors and recipient and fresh specimens from the donors and recipient should be retested for blood group and Rh-Hr types and antibodies and for antibodies of other systems when other tests prove negative. Cross-matching tests should also be repeated, including antiglobulin tests.

One possible cause of a hemolytic transfusion reaction may be an error in identification, which could occur at the time of withdrawal of the blood specimen. Such errors are avoided if the test tubes are carefully marked with full identification with a clearly inscribed and firmly attached label. Identification of such specimens by casual wax pencil marking on glass should be prohibited. Blood banks and laboratories must insist upon properly identified material. To avoid this error, careful identification should be made of the blood in pilot tubes, and such tubes should be firmly attached to containers to receive the blood before the phlebotomy takes place. It is also imperative that blood be administered only after careful inspection of the statement of compatibility to be sure that the blood is given to the correct patient. Awareness of possibility of error of identification lessens the incidence of such reactions.

Nonspecific reactions

Allergic reactions: Allergic reactions produce hives, edema (angioneurotic edema), or a tendency to asthma. Donors with active extreme allergic manifestations should be avoided. The cause of most allergic reactions is not well understood. They may be associated with fever and even with chills, but more commonly there is little increase in temperature. Adrenalin or antihistaminics are often used in treatment. If a recipient has had an allergic reaction from a blood transfusion, use of antihistaminics administered orally or by injection beforehand may possibly be helpful in preventing a subsequent similar reaction.

Pyrogenic reactions: Pyrogenic reactions are associated with a sharp temperature rise and often with chills and are usually transient. They were much more common in the past. The use of expendable equipment has greatly reduced the incidence of these reactions. Careful cleansing of all equipment with which blood comes in contact and prompt sterilization of such equipment after cleansing have also greatly reduced pyrogenic reactions due to contaminating chemicals or bacterial toxins. An occasional reaction may be due to the use of intravenous administration needles that have received only casual cleansing. Recent evidence points to the presence of leukoagglutinins in recipients as the cause of some pyrogenic reactions. Such reactions follow multiple transfusions. In such cases administer packed red cells prepared free of white cells.

Cardiopulmonary reactions (volume, circulatory overload): Occasional patients, particularly those with cardiac or pulmonary disease, display intolerance to rapid infusion of such materials as blood which persist in the patient's circulation. The symptoms commonly seen are those of pulmonary edema together with a rapid feeble pulse and a shocklike state. Blood transfusion should be given slowly or in lesser volume per infusion, or packed red blood cells should be used when cardiac or pulmonary disease is present.

Bacterial contamination: With the use of sterile equipment, careful disinfection of the skin of the donor and patient, and storage in a refrigerator at 2°-10° C., preferably 4°-6°, the chances that multiplication of any bacteria present will take place is minimized. Entry into the bottle during storage is strictly prohibited. Nevertheless, at times bacteria gain access to the blood and may multiply. The most dangerous are gram-negative bacteria which can grow at low temperatures and produce highly toxic endotoxins. Contamination of the blood is suspected if it changes color (bluish black), if a zone of hemolysis is observed in the lowermost portion of supernatant plasma, or if the plasma seems to have unusually large quantities of free hemoglobin when the blood is shaken and the cells are allowed to resettle. Some bacteria metabolize citrate, and clots will develop in the blood. The appearance of clots in blood previously thought satisfactory should arouse suspicion.

In some instances administration of contaminated blood is followed by a persistent shocklike state, with moderate fever and occasionally death. Evidence of hemolysis may be seen. If the remainder of the blood can be saved, with precautions taken to prevent contamination from handling, cultures and smears of the remaining blood may clarify the problem. Strict aseptic technic is important.

Coagulation defects: Hemorrhagic disorders frequently follow use of massive transfusions of **over-age** blood, for example, administration of 10-15 or more units in a 24 hr. period. This has been named "oozing disease" because blood oozes from all cut surfaces. Bleeding may also occur from mucous membranes, sites of needle punctures, and sites of injury; petechiae are sometimes noted.

Thrombocytopenia is a common finding in such patients and is probably due to a loss of platelets at initial bleeding sites, failure of stored blood to replace the lost platelets, and perhaps destruction or removal of platelets by administered blood. The platelet deficiency, however, does not always seem severe enough to cause the bleeding. Deficiencies of other clotting factors and the appearance of a fibrinolysin have been observed in some patients.

The complication is most likely to occur in patients who already have a hemorrhagic diathesis or in those who have liver disease. Treatment is difficult and should include vigorous effort to stop bleeding at local sites together with transfusion of fresh blood that comes in contact only with nonwettable surfaces.

Since transfusion of incompatible blood may also lead to coagulation defects, this cause is often suspected. Keeping this in mind should encourage those responsible to take care that blood used in massive transfusions is, as always, carefully cross matched.

Cardiac arrest: Massive transfusions are sometimes followed by hypotension and cardiac arrest. It is generally believed that this is due to free potassium in stored blood or to depression of **ionized** calcium in the recipient which is bound in nonionized form by excess citrate in transfused blood. The heart's normal pumping function depends on a minimal level of circulating ionized calcium. The disorder is often called "citrate intoxication." The liver ordinarily rapidly detoxifies citrate as it enters the circulation; therefore, the disorder is most likely to occur in patients with poorly functioning livers or in circumstances when transfused blood is unable to reach the liver in adequate amounts.

Treatment is somewhat empirical and depends on the intravenous administration of ionized calcium, e.g., $CaCl_2$, in periodic injections. The disorder may be avoided by use of uncitrated blood, e.g., blood collected in heparin or over a cation-exchange resin. The use of uncitrated blood, however, introduces other complications so that citrate remains the anticoagulant of choice for the vast majority of transfusions.

Overheating of blood: Blood should not be warmed to 37° C. before administration, because if the temperature of even a small portion of the blood is raised above 37°, toxic changes ensue. Overheated blood induces pyrogenic and even hemolytic reactions.

Outdated blood: Administration in a short time of large quantities of blood approaching expiration date may introduce into the recipient appreciable quantities of at least partially degenerated red cells that are rapidly hemolyzed. This may result in release of free hemoglobin in quantities in excess of the bilirubin-clearing mechanisms of the recipient, and a temporary, usually mild degree of jaundice may be observed.

Pharmaceutical incompatibilty: No drugs or solutions should be mixed into blood or injected through the walls of intravenous administration sets while blood is being infused unless it is certain that no pharmaceutical incompatibility exists; e.g., calcium-containing preparations induce clotting. Low pH vitamin preparations may cause denaturation. Tincture of iodine used wastefully in preparing the donor's skin or sterilizing a stopper may be introduced into the blood and denature it.

Other reactions: Bank blood, particularly with ACD solution as anticoagulant, has a tendency to form minute masses of fibrin on standing. Such blood is perfectly safe if administered through a filter to avoid entrance of such particles into the recipient. The finer mesh filters, 75-200 holes/sq.in. are preferable. On occasion, bloods of different groups may be administered to a single recipient, e g., A and B bloods to an AB recipient. In these instances such bloods may react with each other within the intravenous administration set. The problem is avoided by changing the intravenous administration equipment when the donor blood group is changed.

TECHNIC OF WHOLE BLOOD TRANSFUSION

Direct method of blood transfusion

There are various methods of direct blood transfusions dependent upon the type of apparatus used. The first modern method for blood transfusion using an apparatus was that described by Unger.[258-288] This apparatus permitted withdrawal of blood from the donor and simultaneous injection of saline into the patient. A stopcock was then turned and the reverse situation resulted; blood could be injected into the patient and saline simultaneously injected into the donor. It was this immediate flushing with saline of that part of the instrument not used for the aspiration or injection of blood that ensured freedom from clotting.

Another method is that using multiple glass syringes. This method employs a battery of about twenty 20 ml. glass syringes, sterilized and placed on a sterile table close to the donor. An assistant inserts a needle into the donor's vein, and the operator inserts a needle into the recipient's vein. The first 20 ml. syringe is half filled with warm saline, i.e., about 10 ml., and 10 ml. blood are withdrawn from the donor. The syringe is quickly disconnected and connected to the needle in the recipient's vein, and the first syringe material is injected. While this is being injected, the assistant takes the next 20 ml. syringe, fills it with blood, passes it to the operator, who in turn injects it. In this way the operator, by counting the number of syringes alongside his table, sees at all times just how many ml. blood he has injected.

Indirect method of blood transfusion

The best method of indirect blood transfusion is one that makes use of vacuum bottles, a closed circuit to prevent bacterial contamination, and expendable tubing, needles, and other equipment.*

The use of rubber tubing in blood transfusion is now obsolete. We have therefore eliminated all reference to directions for cleaning and sterilizing such tubing.

The blood equipment consists of Transfuso Vac units, Plasma Vac units, Plastic Cube-Pac units, and plasma separation units, in addition to Plexi-

---

*Such equipment is manufactured by Baxter Laboratories, Inc., Morton Grove, Ill.; by Abbott Laboratories, Chicago, Ill., and by Cutter Laboratories, San Francisco, Calif. The Baxter equipment is described here. See Figs. 497-505.

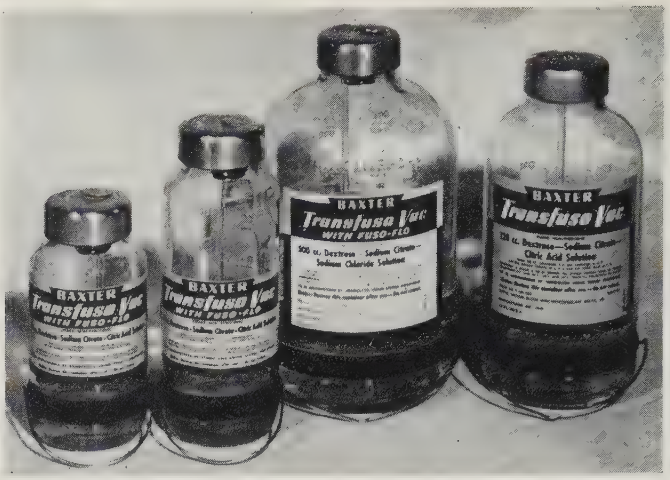

Fig. 497. Transfuso Vac containers. Blood collected in these containers may be stored up to 21 days and administered as whole blood, or plasma may be prepared from the stored blood. The remaining cells may be used for red cell infusion. Capacities of containers are, from left to right, 150, 250, 1000, and 500 ml. (Courtesy Baxter Laboratories, Inc., Morton Grove, Ill.)

tron blood collection sets, aspirating sets, blood and plasma administration sets, and accessories designed for blood banking procedures.

The Transfuso Vac container (Fig. 497) is a vacuum unit for collecting, storing, and administering blood and for collecting blood for eventual preparation of plasma. Blood can be administered from the same unit into which it was originally collected by plugging a Plexitron blood administration set through the closed hole outlet of the stopper. If collected blood is not used for whole blood transfusion, the supernatant plasma can be recovered in a Plasma Vac unit. Transfuso Vac units are available with anticoagulants in varying amounts for the collection of 150, 250, 480, and 500 ml. blood, with or without the Fuso-Flo stoppers for preliminary straining and with or without internal silicone coating to provide a nonwettable surface.

The Fuso-Flo stopper provides preliminary straining of blood or plasma prior to filtration in the administration set and helps to promote smooth, uninterrupted flow and full utilization of blood. See Fig. 504.

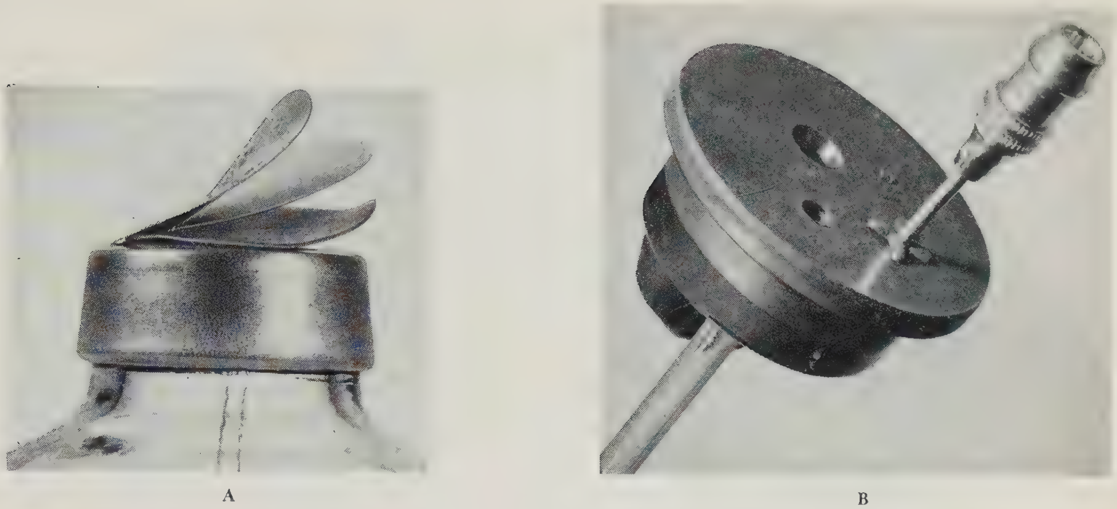
Collection of blood, using expendable units

Preparation of donor's arm: The operator must wash his hands thoroughly before venesection.

1. Place a blood pressure cuff on the donor's arm, setting the pressure at slightly below diastolic level; then prepare the donor's arm.
2. Select the vein most suitable for puncture and prepare the site as follows:
   - (a) Use an acceptable soap or detergent to cleanse the skin, rubbing the skin vigorously in a circular fashion. Allow 1 min. for this step.
   - (b) Remove the dirt and fat with a solution of 10% acetone in 70% alcohol.
   - (c) Treat the skin with 3.5% alcoholic solution of iodine. Prepare the puncture site from the center outward so as to avoid contamination. As soon as the iodine is dry, remove it with a solution of 10% acetone in 70% alcohol or a saturated solution of sodium thiosulfate in 70% alcohol.
   - (d) Anesthetize the site for insertion by injecting 1 or 2% procaine intradermally. Take care that donors are checked for possible sensitivity to the drug before administering it.
   - (e) Leave a sterile alcohol or dry sponge over the proposed puncture site and do not remove until the needle is ready to be inserted into the vein.
   - (f) Do not touch the skin again once it has been prepared. Additional exploration of the area may be made after the needle has been inserted beneath the skin.

Collection of blood: The needles must be either heat-sterilized or, preferably, should be expendable, and no needle must be used on more than one donor. These precautions are necessary to prevent possible transmission of homologous serum hepatitis.

1. Tear the metal seal from the Transfuso Vac, lift off the metal disk, and remove the top plastic diaphragm aseptically (Fig. 498, *A*). Clamp the Plexitron tubing of the donor set.
2. Insert the needle of the donor set perpendicularly through the sealing diaphragm and stopper at the point marked "X" on the top of the Transfuso Vac. Immediately after insertion, recheck the clamp on the tubing to make certain it is still closed.
3. Insert the needle in the donor's vein through the anesthetized skin with the bevel of the needle up.
4. Loosen the clamp. If the blood does not flow immediately, close the clamp and improve the position of the needle. Improper placement of the needle may cause collapse of the tubing. It will be expanded again by flowing blood when the needle is properly placed in the vein. This is a good check on the needle position. When the blood is flowing freely, slowly open the clamp further. The flow of



A B

Fig. 498. A, Closure of Transfuso Vac and Plasma Vac containers. Note the metal identification disk under which is a plastic disk which protects sterility and a thin rubber disk to protect the surface of the stopper. **B,** Baxter blood and plasma container stopper. The puncture position is marked with an "X." This thicker portion of the stopper will reseal after use so that the vacuum is retained after the blood unit is filled. (Courtesy Baxter Laboratories, Inc., Morton Grove, Ill.)

blood gradually increases until the desired rate is established. The average rate is between 75 and 125 ml./min. The usual causes of insufficient flow of blood are (a) the needle is not in a good position in the vein and (b) the pressure in the blood pressure cuff is too high or too low. Occasionally, a better flow can be maintained if the donor slowly opens and clenches the hand.

Note: If it becomes necessary to remove the needle from the vein, always close the clamp before removing the needle. After the needle has been removed from the vein, hold it as high as possible above the clamp and very slowly open the clamp, allowing the blood remaining in the tubing to be drawn into the bottle. Instantly close the clamp when the blood is entirely out of the tubing. Reinsert the donor needle and slowly reopen the clamp so as not to collapse the vein.

5. When the desired amount of blood has been drawn, clamp the tubing. Remove the blood pressure cuff and withdraw the needle from the vein. Remove the needle from the Transfuso Vac and salvage the blood from the tubing for serologic study by opening the clamp and allowing the blood to run into the sterile pilot tubes, one with and one without anticoagulant. Shake the tube containing the anticoagulant. **Note:** Some blood banks do not use the pilot tubes with anticoagulant.
6. Agitate the Transfuso Vac a minimum of 3 min., assuring adequate mixing of the anticoagulant and blood, thus safeguarding against clotting.

To administer whole blood

1. Invert the Transfuso Vac several times to resuspend the blood cells.
2. With a pair of sharp scissors cut the rubber diaphragm at the extreme edge, farthest from the air tube.

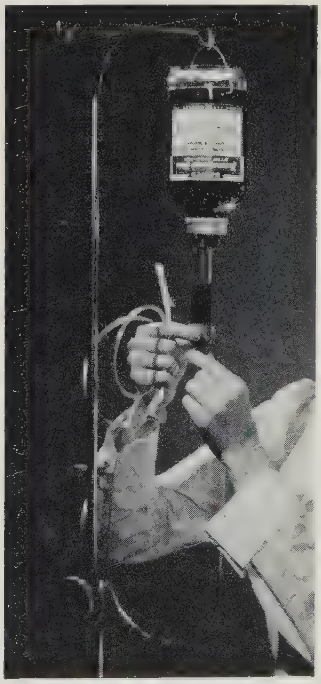


Fig. 499. Drip device of Plexitron administration set is filled with enough blood to cover the filter. (Courtesy Baxter Laboratories, Inc., Morton Grove, Ill.)

3. Tear the diaphragm straight across, exposing both holes in the rubber stopper.
4. Close the clamp on the Plexitron tubing.
5. Insert the drip device of Plexitron administration set into the bottle of blood, suspend the bottle by its bail, and fill the drip device with blood as shown in Figs. 499 and 500 *A.*
6. Establish the blood level in the drip device;

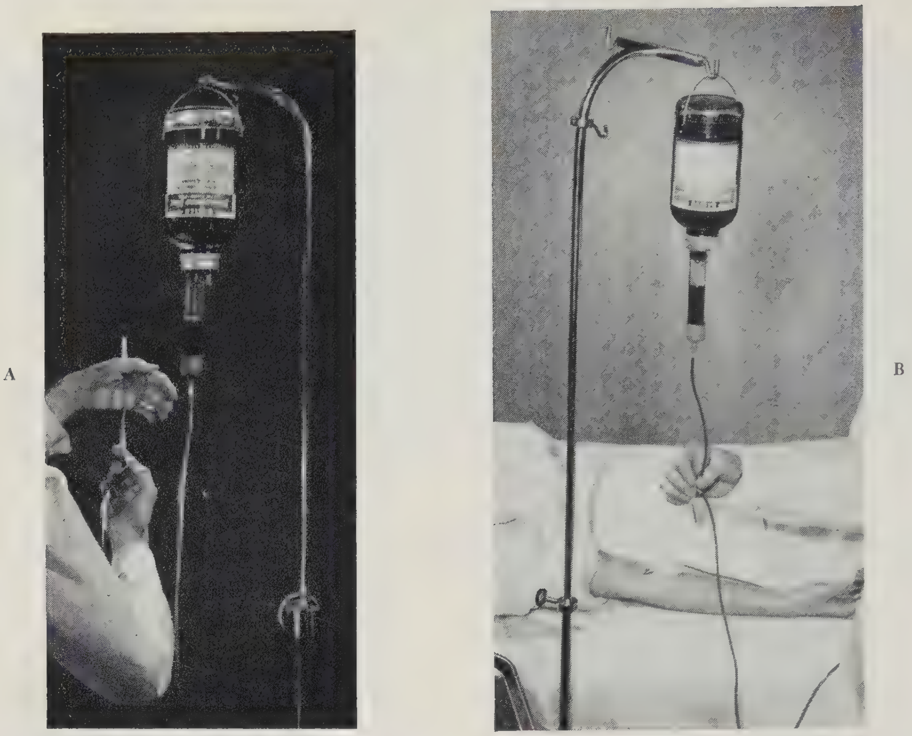

Fig. 500. A, Opening clamp to fill remainder of set before attaching vein needle to nylon needle adapter. This is done after the blood level in the drip device of Plexitron administration set has been established. **B,** Adjusting clamp to control rate of blood administration. (Courtesy Baxter Laboratories, Inc., Morton Grove, Ill.)

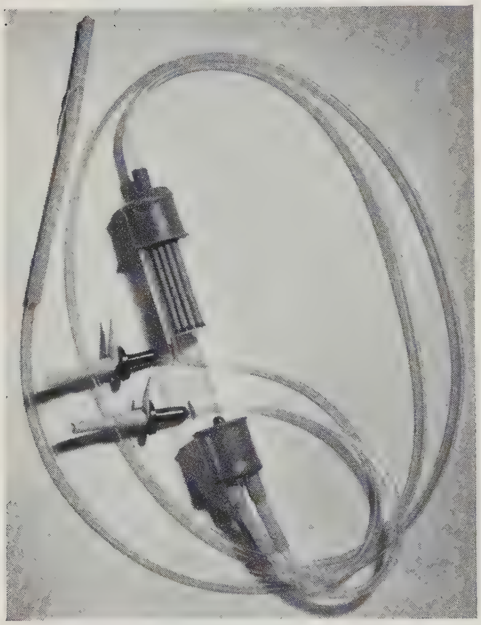

Fig. 501. Sterile expendable Plexitron Y-type set for administering blood, plasma, or serum with solutions, alternately or simultaneously. (Courtesy Baxter Laboratories, Inc., Morton Grove, Ill.)

then open the clamp to fill the remainder of the set and to remove all air from the tubing.

7. Attach the vein needle to the nylon needle adapter and again be sure that there is no air in the needle or the tubing.
8. Make puncture of the patient's vein in the usual manner, after disinfecting the skin, and proceed with the transfusion.
9. Adjust the clamp to control the rate of blood administration (Fig. 500, *B*).

If one desires to start the transfusion with saline or to mix saline with the blood or to follow the transfusion with an injection of saline, connect the Transfuso Vac to the bottle of sterile saline, connecting them with a Y outfit leading into a filter drip. This Y outfit is also expendable. See Figs. 501-503.

Plastic bags for transfusions

A method of collecting blood for whole blood, plasma, platelet, and other blood constituents transfusions, by the use of plastic bags, has been devised. The Fenwal system* consists of standard Blood-Pak units and recipient sets. It provides for collection, storage, and administration of whole blood taken in ACD solution, as well as blood components. The units are available for collection of 500,

450, or 250 ml. blood. One advantage in using plastic bags is that they preserve the blood platelets, which are quickly disintegrated in glass containers.

Collection of blood:

1. Place donor in the position preferred and suspend the unit on a spring donor scale or stand. If the spring donor scale is used, adjust it for tare weight of the unit. Place a loose overhand knot in the donor tube approximately 4 in. from the needle (Fig. 506, *A*).
2. If the automatic donor scale is used, preposition the weight for collection of the desired amount of blood, suspend the unit, and thread the donor tube through notches in the studs in the lever arm and support block (Fig. 506, *B*).
3. Place a blood pressure cuff with tubes pointed toward the shoulder, with the lower edge of the cuff well above the intended site for venipuncture; then inflate the cuff to 60 mm. Hg and locate the vein.
4. Prepare the skin area.
5. Grasp the needle hub firmly and pull off the Interlock cover.
6. Insert the needle with the bevel side up well into the vein. If desired, the needle may be secured in position with adhesive tape.
7. Release the bead in the juncture of the donor tube and the bag to permit the blood to flow. Squeeze the tubing above the bead between the thumb and forefinger. This moves the bead completely into the unit (Fig. 506, *C*).
8. Mix the blood and anticoagulant, beginning as soon as blood flow has been established, elevating the bottom of the unit gently several times during collection. Do not put any tension on the tubing which might disturb the needle.
9. If the spring donor scale is used, collect the blood to the desired volume. If the automatic donor scale is used, the weight of the unit depresses a lever arm which closes the donor tube and stops the flow of blood.
10. Close the donor tube near its attachment to the unit, using a clamp (Fig. 506, *D*), release the pressure in the cuff, and remove the cuff. Apply a sterile dressing and withdraw the needle from the vein. It is customary to have the donor elevate the arm without flexing the elbow and continue digital pressure to prevent oozing.
11. Insert the needle through the stopper of the evacuated pilot tube to obtain blood without

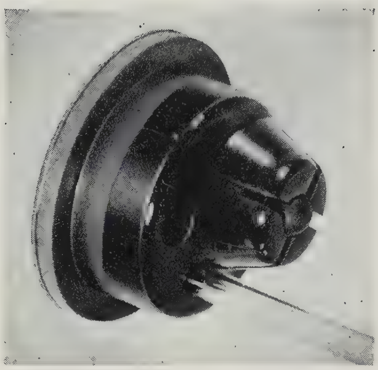

Fig. 504

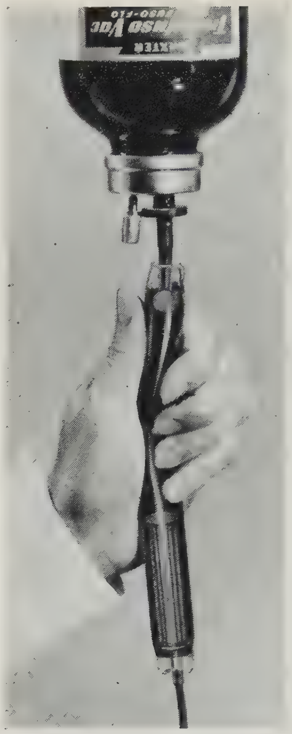

Fig. 505

Fig. 504. Fuso-Flo stopper available for Transfuso Vac containers. Although it does not replace the blood filter, it acts as a preliminary strainer for blood or plasma during administration and prevents the fibrin of stored blood from retarding the flow. (Courtesy Baxter Laboratories, Inc., Morton Grove, Ill.)

Fig. 505. Baxter Plexitron combination administration set and pressure pump, which enables administration of blood at the normal rate or rapidly under pressure. The rate of administration is determined by pumping action. This pump **cannot pump air,** since it operates with fluids. It contains a filter that permits rapid administration through mesh fine enough to remove particulate matter. (Courtesy Baxter Laboratories, Inc., Morton Grove, Ill.)

anticoagulant for serologic testing and blood grouping (Fig. 506, *E*). All the blood in the donor tube must be evacuated. Pull the knot until it is "white tight"; then cut the donor tube between the knot and the needle, withdraw the needle from the evacuated pilot tube, and discard the cut portion and the needle. A seal may be applied, according to the manufacturer's direction. Seal at mark X nearest the needle and sever in the mid-portion of the seal. Crimp the tubing with mechanical pressure and sever on the needle side of the clip.

12. Mix the blood thoroughly, lay the bag flat, and release the clamp. Permit citrated blood to reflux into the donor tube, strip, and refill the donor tube once.
13. Seal off all segments at the X points. Insert through slits on either side of the bag. Always start the seals at the distal end of the tube and work toward the bag. If the seals are started proximal to the bag and then made in the opposite direction, the segments might rupture due to pressure buildup.
14. The unit may be placed in an upright position in a plastic holder, and it must be refrigerated at once.

Other equipment is available, such as Hemolator,* and special anticoagulants are also supplied by the manufacturer.

Transfusion procedure:

1. Remove the recipient set and prepare for assembly.
2. Mix plasma and cells thoroughly by inverting the plastic unit at least 12 times.
3. Close the control clamp tightly on the lower end of the plastic tubing.
4. Grasp the end of the coupler cover, push toward the flange, and then twist to loosen (Fig. 507, *A*). Do not remove.
5. Grasp the tabs closest to the side of the bag and pull them apart. Fold back to expose sterile outlet tube (Fig. 507, *B*).
6. Hold the plastic unit between the thumb and forefinger over the folded tabs, remove the cover from the coupler, insert the coupler into the outlet tube, and twist until it is all the way in (Fig. 507, *C*).
7. Remove the needle adapter cover.
8. Hold the unit in an inverted position, open the control clamp, and squeeze the bag to fill the filter chamber with blood.

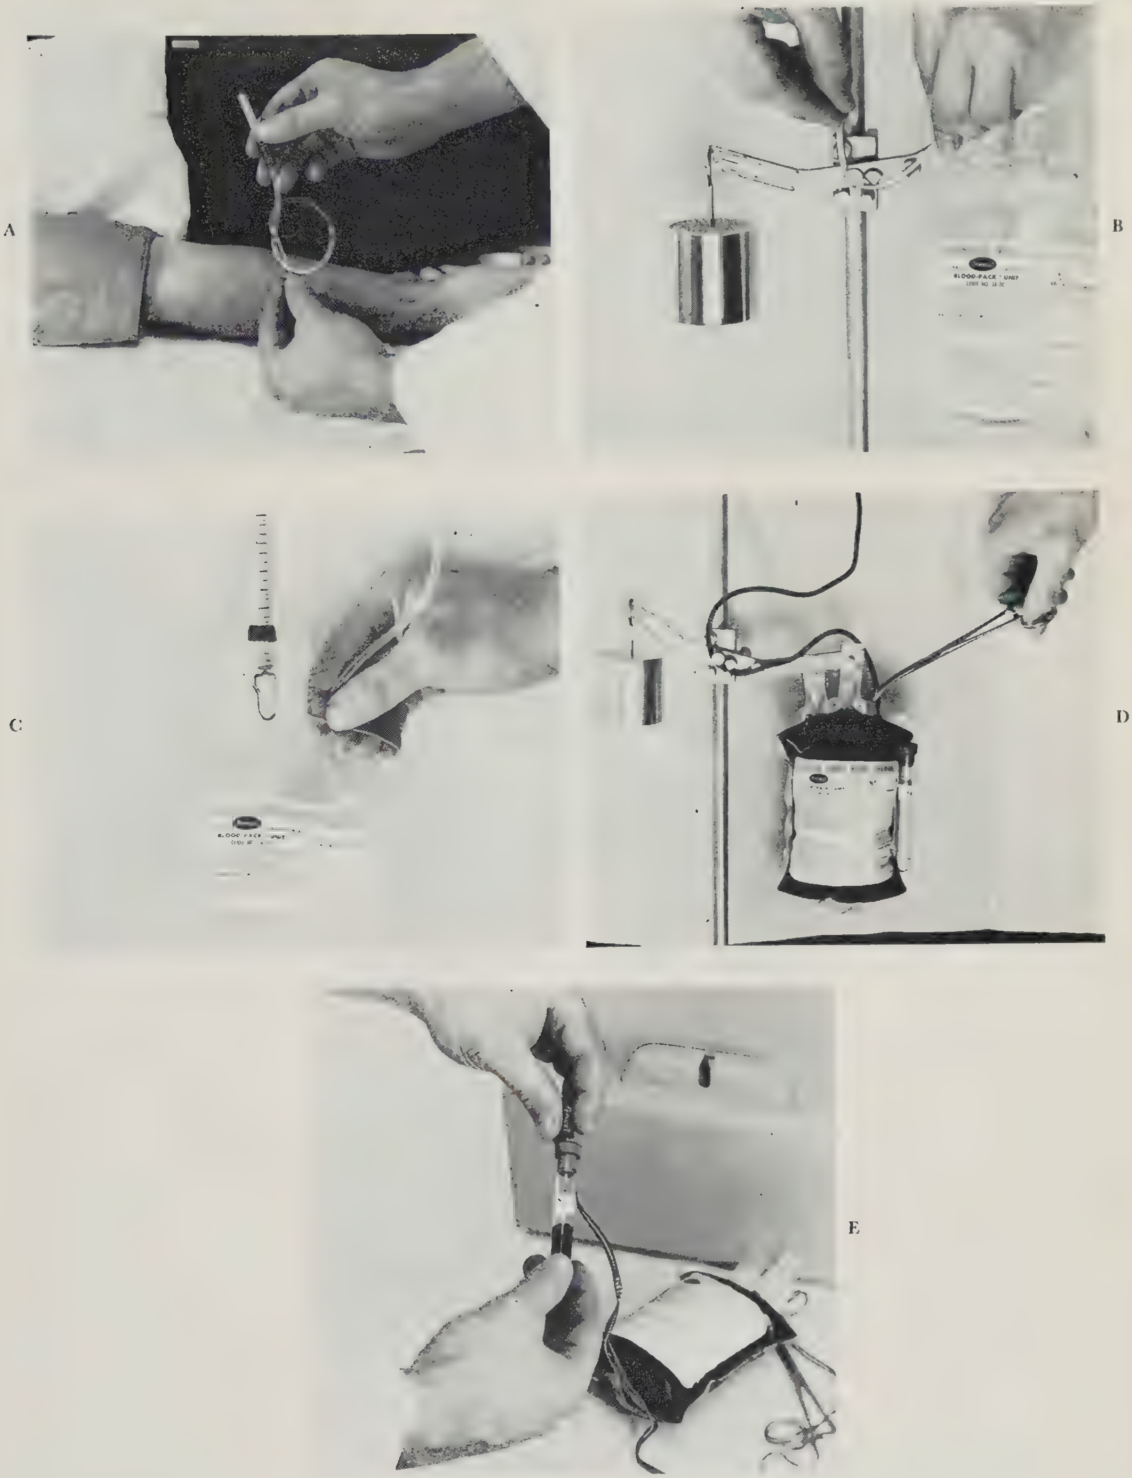

Fig. 506. Collecting blood by use of plastic bags. **A,** Placing loose overhand knot in donor tube. **B,** Pre-positioning weight for desired quantity of blood. **C,** Moving bead into Blood-Pak unit. **D,** Clamping off donor tube. **E,** Collecting clotted blood for serology and blood grouping. (From Technical Manual, Morton Grove, Ill., 1962, Fenwal Laboratories.)

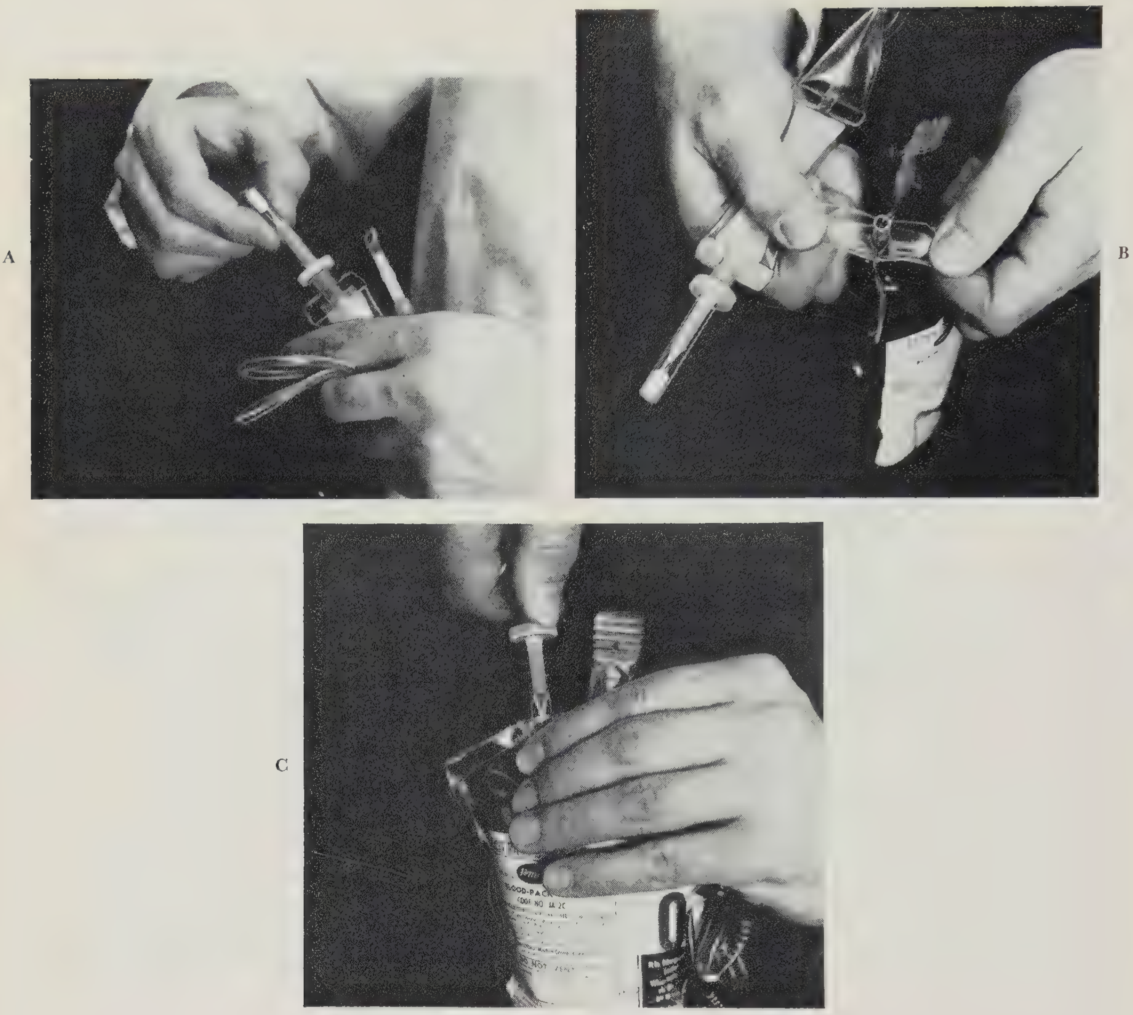

Fig. 507. Transfusion procedure, using blood collected in plastic bags. **A,** Loosening coupler cover. **B,** Exposing sterile outlet tube. **C,** Inserting coupler into outlet tube. (From Technical Manual, Morton Grove, Ill., 1962, Fenwal Laboratories.)

9. Close the control clamp and suspend the unit.
10. Squeeze the drip chamber slightly; then release it. This fills it about ¼ full.
11. Attach the sterile needle. Release the clamp to fill the tubing with blood to the needle point; then close the clamp tightly.
12. Insert the needle into the recipient's vein in the usual fashion after disinfecting the skin, adjust the control clamp for desired flow rate, and continue with the transfusion.

Blood component separation: Standard centrifuge cups for 650 ml. bottles may be used for all Fenwal blood pack units of 300, 500, or 600 ml. A table of r.p.m. and recommended g's is supplied with the units. Full directions for preparing blood platelets, packed red cells, plasma, etc. are included with the apparatus.

PRESERVATION OF WHOLE BLOOD IN THE FROZEN STATE

Whole blood modified with addition of dextrose and lactose, alone or in combination, to obtain a 0.2M concentration of lactose, a 0.7-1.2M concentration of glucose, or an additive molarity of 0.6 with both sugars may be frozen in about 10 sec. or less by immersion in CO_2-ethanol mixtures at –60° to –78° C.[289] It is then thawed equally rapidly at +37° to +40° C., and 95% of the erythrocytes are recovered intact. Without the sugars recovery of human erythrocytes frozen and thawed under similar conditions averages 29.3%. Recovery and posttransfusion survival of erythrocytes depend on the temperature of storage. At –58° C. recovery and survival deteriorate rapidly, at –70° C. recovery rate is fairly well maintained for about 40 days, but the post-transfusion survival is unsatisfactory after 3 weeks of storage, and at −93° C. ± 2° C. satisfactory recovery and survival are maintained for at least 6 mo.

BLOOD FROM CADAVERS FOR TRANSFUSION—HISTORICAL

Considerable interest was evoked by the announcement of Judin, chief surgeon of Sklifasovski Emergency Hospital in Moscow, who within 3 yr. had performed more than 300 blood transfusions, taking the blood from dead individuals, storing it, and then injecting it into living patients. Judin's work has been referred to by Gosset, chief surgeon of Salpetriere Hospital in Paris, in a publication entitled "La transfusion du sang de cadavre a l'homme."

In Moscow, whenever an acute accidental death occurred from suicide, homicide, or in an industrial accidental way, the dead subjects were immediately brought to one hospital where their entire venous blood was removed and stored. The cadaver was strapped on his back on the operating table, covered with sheets and sterile drapings, just as would be done in the case of a major operation on the living. The neck was left exposed and prepared with iodine and alcohol, etc. The jugular vein was exposed and 2 slits made into the vein, one for a cannula to receive blood from the head, the other to receive blood from below. These cannulas were connected with glass sections and rubber tubing, terminating in sterile glass jars stoppered with cotton. No citrate was added. The blood clotted, was placed in a refrigerator, and within 2 hr. the blood was fluid. The clots had autolyzed. The operating table was tipped forward at a sharp angle and blood permitted to flow by gravity into the jars. The filled jars were kept at refrigerator temperature just 1° or 2° above freezing point and warmed in a water bath at 40° C. just before use. Judin kept this blood as long as a month and used it without reaction. Kahn and complement fixation tests were made on the specimens before use.

According to this account of Judin's work, the blood of many cadavers has been tested and found sterile. Of course, the subjects used are persons who have died suddenly, from accidents, suicide, or heart attack. It is claimed that all fresh blood from this type of death is free from bacteria. This raises a question, for in 1904 Gradwohl[290] reported an account of a research upon this very question; namely, does the blood of cadavers meeting death from acute accident or from a sudden illness contain bacteria? This was in reply to a publication of Simmonds,[291] who claimed that in a bacteriologic examination of the cardiac blood of 1200 subjects, he found a streptococcus in 95% of all cases, autopsy being performed from 12-36 hr. after death. Canon[292] later claimed that Simmonds' work was in error in that cardiac blood alone was examined and that if at the same time venous blood had been examined, it would have been found that venous blood was sterile, even with streptococci in the heart blood. Grahwohl's work was undertaken in an attempt to settle this point, and so 50 cases were selected from his service at the Coroner's office, in the main, gunshot wounds of the chest, fractures of the skull, 10 cases of valvular leak, 3 cases of rupture of aortic aneurysm, 6 cases of nephritis, a few cases of purulent peritonitis from abortions, etc. The time elapsing from death to the moment of autopsy performance varied from as little as 2 hr. to as long as 10 hr. In 78% of these cases bacteria of various kinds were found in the cardiac blood; in only 3 cases were bacteria found in blood from the median basilic vein. The bacteria found were streptococci, staphylococci, *Proteus vulgaris, Escherichia coli,* pneumococci, and pyocyaneus. Gradwohl concluded that there is a rapid invasion of the cardiac blood soon after death, from neighboring organs, and that bacteriologic results therefore from cardiac blood in the cadaver must be weighed in the balance before being accepted as causative factors in deaths of such cases.

These findings give us pause in accepting the Russian announcement, which, although emphasizing that the blood from the jugular veins is free from bacteria, still does not take into account that blood drainage in Judin's technic, coming from the region of the heart as well as from other parts, makes it possible to introduce these postmortem invaders into the recipient end of the transfusion. The modern blood bank supplants this Russian procedure.

DIFFERENTIAL AGGLUTINATION[293] —THE FATE OF TRANSFUSED CELLS

The principle of the differential agglutination test is to take a sample of the patient's blood after a transfusion with universal donor blood and test it with serum capable of agglutinating the patient's cells. Since the donor belongs to group O, his cells will not be agglutinated by the specific antiserum. For example, if an individual of group A is given group O blood, a count may be made of those cells not agglutinated by anti-**A** serum after the transfusion. Group O cells are not agglutinable by anti-**A** serum, but the patient's group A cells are, and thus it may be assumed that any cells not agglutinated are the transfused cells. It must be remembered, however, that in normal blood approximately 50,000 cells/cu.mm. are not agglutinable by specific antisera, and this must be considered when the test is performed. The method of tracing the fate of transfused red blood cells was first used by Todd and White[294] in cattle. Ashby[295] used the method for the first time in man.

When the patient receives blood of his own group, the differential agglutination test may be made only provided the M-N types of the donor and recipient differ. The results with anti-**M** serum are more striking than when group O blood is used for patients of groups A, B, and AB, for, if tests are made using anti-**M** serum on blood containing the M agglutinogen, very few cells remain unagglutinated as contrasted with the 50,000/cu.mm. not agglutinable by anti-**A** or anti-**B** sera. For example, if OMN blood is transfused to an ON patient, when tests are made using anti-**M** serum on the patient's blood after the transfusion, only the donor's MN cells are agglutinated; any unagglutinated cells are the patient's. If the donor is ON and the patient is OMN, the unagglutinated cells in tests with anti-**M** serum are the donor's.

Landsteiner et al.,[296] Wiener,[276] and Dekkers[298] established that the blood cells of the donor survive in the patient's circulation for periods up to 3-4 mo. in the usual case where the patient is transfused with fresh compatible blood either from a universal donor or from a donor of the homologous group. Wiener and Schaefer[299] showed that the survival time of erythrocytes in bank blood is roughly in inverse proportion to the period of storage.

If incompatible blood is transfused, it remains in the circulation usually for only a short time,[300, 301] so that even if the transfusion is tolerated, at best it is of only transient benefit because of the rapid destruction of blood cells. However, Jervell[302] found incompatible cells in an infant for more than 6 wk. after a transfusion, and Wiener found group AB cells present in a group O infant 50 days after a transfusion.

Procedure: The method of making the test is to dilute the patient's blood taken before the transfusion with potent specific antiserum, in the usual manner for making a red blood count. Count the number of inagglutinable cells/cu.mm. in the patient's blood.

Repeat this test after the transfusion.

To determine the number of donor cells/cu.mm., subtract the number of unagglutinated cells before the transfusion from the number after the transfusion and record the number/cu.mm. Use formula for figuring red counts on pp. 1103 and 1106.

If the count after the transfusion exceeds the count before the transfusion, it is assumed that the transfused erythrocytes are still present in the patient's blood.

Wiener and Peters[303] applied differential agglutination tests to the study of posttransfusion hemolytic reactions and found that even when patient and donor are of the same blood group, if the bloods are incompatible due to factors other than **A** or **B**, the donor's cells are eliminated rapidly from the patient's circulation, within a period of a few hours or days, rather than in 3 or 4 mo. The diagnosis of hemolytic transfusion reactions using this method rests on the assumption that the donor's blood has been eliminated from the patient's circulation.

PREVENTION OF HEMOLYTIC REACTIONS

No matter how carefully one groups bloods and performs all the tests for compatibility, certain reactions at times seem bound to occur. This is possibly due to the fact that there are as yet certain facts about the problem of intragroup reactions that have not been solved. Accordingly, Wiener et al.[304] suggested the use of a biologic test to supplement those in vitro tests commonly used. The use of a biologic test was suggested first by Oehlecker,[305] who advised the injection of 10 ml. blood, waiting 10 min., and then proceeding with the remainder of the blood if no reaction occurs. This method was not too successful because the reaction is often delayed beyond the 10 min. period of Oehlecker. Wiener[304] therefore recommended the following procedure.

Biologic test

Transfuse 50 ml. of donor's citrated blood. After 2 hr. have elapsed, if no reaction has occurred administer the balance of 100 ml. blood. If a reaction occurs, withdraw 10 ml. blood from the patient and treat it in the same manner as the pretransfusion citrated sample used for the cross-matching test. Centrifuge the citrated blood samples and compare the color of the plasma in the 2 tubes. The syringe and needles **must be dry.**

If there is no change in the appearance of the patient's plasma, proceed with the transfusion of larger amounts of donor's blood. If the supernatant plasma of the posttransfusion specimen is distinctly redder than that of the pretransfusion sample, give no more of this donor's blood.

After 100 ml. of donor's blood have been injected, it is possible to demonstrate the survival of the donor's cells by the method of differential agglutination (p. 1579) when the biologic test is negative, in patients having a red cell count of 2½ million cells/c.mm. or less.

In positive reactions, 2 hr. after the test injection of 50 ml. blood, patient may have a severe chill and rise in temperature, but clinical symptoms may be mild or absent. Place more reliance on the appearance of the patient's plasma which will show a distinct rise in icteric index as compared with the pretransfusion sample.

Stored blood

ADDINE G. ERSKINE

BLOOD BANKS

The so-called "blood bank"[306-308] was first established in Russia, but the first in America was at the Cook County Hospital, Chicago, Ill. It was eminently successful and has been adopted throughout the world. It is essentially a method of keeping on hand quantities of blood so that the hospital is always prepared to give blood transfusions. Like all banks, it is operated on the principle that withdrawal of blood means substitution of other blood, so that the supply on hand is fairly constant. A blood bank is a useful adjunct for an institution, provided it can afford the equipment and personnel.

Unless a blood bank is properly equipped and under control of responsible personnel and is continuously checked, it is obviously a dangerous addition to any hospital program.

Blood is obtained from relatives and friends of patients who are transfused. There must be direct contact with the donors. Donors should be between the ages of 21 and 59 yr. and in good health; they should be free from syphilis as proved by serology and physical examination; and there should be no history of recent illness, mild or severe; chronic alcoholics should be rejected. Donors who meet these requirements must certify in writing that they release the hospital from all liability, and they must give permission to use their blood as the hospital authorities may elect. The rules governing a donor clinic are as follows:

1. Those in charge must be well trained and well supervised.
2. Simple, uniform technic must be used.
3. Unusual care must be taken in technic to preserve the product.
4. Discomfort of the donor must be reduced to a minimum.
5. Adequate room must be provided and unnecessary delay avoided.

The practice is to draw blood from all donors without preliminary typing or testing. This blood is deposited in favor of the patient for whom it was given. That means that each transfused patient has an account and he may receive blood until his account has been exhausted. If any patient has more than is needed, this may be transferred to the account of some patient who lacked donors. Withdrawing blood from all donors who volunteer prevents the necessity of taking large amounts from any one person. All samples must be thoroughly tested before being used.

Storage of blood in a refrigerator is carried out immediately since undue exposure to room temperature and unnecessary handling may result in hemolysis. The optimum storage temperature is 4° C. with a permissible range of temperature from 2° to 6° C. Citrated blood will freeze between 0 and –1° C. Attachment of the refrigerator to an electric circuit separate from that of all other electric appliances is advisable so that current failure will not so quickly occur.

If failure of refrigeration allows the temperature to rise, an alarm system and recording device alert the staff.

The blood is checked daily by the banker for evidence of hemolysis.

The equipment for procuring blood is essentially the same as that described for blood transfusion. Blood is dispensed daily during the regular banking hours except for emergency transfusions. Request is made to the lab-

Fig. 508. In a Red Cross Blood Center a nurse replaces her equipment after taking a pint of blood from a donor. A Red Cross volunteer nurse's aide lends assistance.

oratory to determine the patient's blood group, and the request, with the patient's blood, is sent to the bank, where cross-matching tests are made. All blood in the blood bank should have been previously grouped and subgrouped, including the Rh type.

Blood that has been removed from storage should be transfused immediately. It should be handled no more than necessary. An intern should remain with the transfused patient for at least the first 15 min. All reactions should be reported to the director of the blood bank service. All reports of transfusions should be returned to the blood bank within 12 hr. after transfusion.

It must be repeated here that all blood in the blood bank should be proved to have come from nonsyphilitic, nonmalarial, and nonhepatitis patients. Routine culture tests should be made to detect bacterial contamination.

No blood should be used that has been kept longer than 3 wk. Outdated bloods may be used to procure plasma, following the practice of removing plasma from the whole blood as outlined on p. 1589. In addition, the red cells may be saved for use in special medical and surgical conditions.

The American Red Cross program was instituted in this country to provide blood transfusion service for the smaller hospitals which cannot afford to conduct a blood bank of their own. There are now 45 Regional Centers.

AMERICAN RED CROSS BLOOD PROGRAM*

The American Red Cross had its first experience in blood procurement during World War II, when it collected approximately 14 million pints of blood which were turned over to commercial laboratories for processing for the Armed Forces. The Red Cross served only as a collection agency; all other processes were carried out either by the Army or Navy or by laboratories under contract to them. Following World War II, the Red Cross expected to leave the field of blood collecting and did. However, technical advances made during the war increased the demand for blood, particularly by physicians who had had available both blood and plasma and occasionally serum albumin. Because of this demand some Red Cross chapters were permitted to operate so-called "walking blood banks" on a community basis; others operated collection centers. Although these permissive programs served a need in limited areas, the need for blood was critical in many others. Upon the request of the Army and Navy, Veterans Administration, American Hospital Association, American Medical Association, United States Public Health Service, and other allied organiza-

---

*This section has been prepared by the St. Louis Regional Blood Program, American Red Cross, St. Louis, Mo.

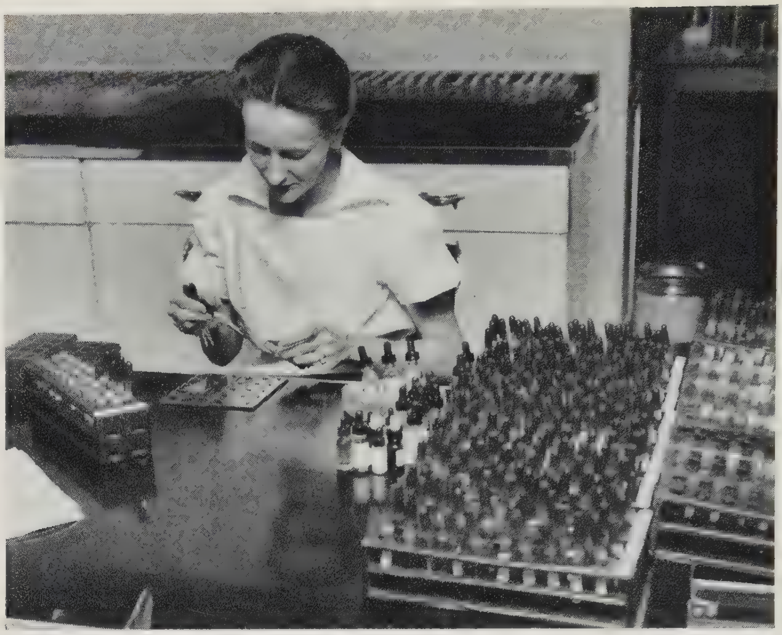

Fig. 509. Technician in the laboratory of the St. Louis Regional Blood Center making blood grouping tests, including the Rh factor. This is a mass operation. There were 410 blood specimens on the day the photograph was taken; each 2 represent a blood donor. In the background can be seen tubes lined up for the confirmatory tests using serum against known A and B cells.

tions, the Red Cross investigated the possibility of a national blood program.

With the endorsement in principle of its program, the Red Cross opened its first Regional Blood Center in Rochester, N. Y., in January, 1948. The St. Louis Center was the twelfth to open. Its opening date was August, 1948. There are now 55 Regional Centers. Fifteen Defense Centers came into being for the collection of plasma after the Korean conflict began.

A Regional Center opens in a particular metropolitan area after receiving approval of the American Hospital Association, Catholic Hospital Association, any hospitals not belonging to either, Medical Society, Public Health Service, and the Red Cross Chapter in that city and those in the surrounding areas expecting to be served by mobile units. Defense Centers opened with the same approvals plus an understanding that blood collected by these centers would not be distributed to hospitals in the area but would either be used as whole blood in Korea or processed by commercial laboratories as plasma, serum albumin, or immune globulin for the Armed Forces. Blood quotas of approximately 5% of the population per year were set for Regional Centers and about half that for Defense Centers.

The original aim of the Red Cross Program was to make blood and blood derivatives available to all whenever and wherever needed. It was realized by those outlining the program that this ambitious aim could be reached only through complete cooperation of the American public, which really is the American Red Cross. Cooperation had to come through many channels: (1) people must be donors so that the product would be available, (2) hospitals and doctors must be willing to use blood in a highly intelligent and conservative manner, and (3) technical personnel must be willing to learn enough about blood to be able to administer it with the least amount of hazard. Hospital administrative persons, technicians, nurses, and Red Cross personnel had to be able to explain the simple operating details of the program to recipients. These details are primarily concerned with why the administration charge is made and what it covers, why some hospitals continue to operate their own blood banks and receive little Red Cross blood, and why some hospitals receive their total supply from Red Cross, and other such questions.

The technical problems have been well handled by physicians and laboratory technicians. Those not previously accustomed to having blood available have sought and obtained the necessary information for safe administration. In explaining the technical aspects of the program, we must pay tribute to the outstanding experts in American medicine who outlined the technical operation of the program and who continue to give it direction. The official Medical Advisory Committee of the Red Cross Blood Program is the same as the Blood and Blood Derivatives Committee of the National Research Council. This committee participated in the writing of and approved the technical manual used by the various centers. The technical operation of each center has the approval of the National Institutes of Health and has a yearly inspection. The technical aspects of the program may be divided into 4 units for the sake of discussion: donor requirements and acceptance, collection technic, laboratory work, and distribution.

Donor requirements may be divided into those requirements set up for the protection of the donor and those requirements set up for the protection of the recipient.

Requirements protecting the donor

Age: Persons between the ages of 18 and 59 yr. are acceptable; persons from 18 through 21 yr. must have written parental permission unless married; persons on active duty in the Armed Forces are acceptable without parental consent.

Temperature and pulse: Temperature and pulse are checked, and any abnormalities are reported to the attending physician.

Weight: Donors must weigh at least 110 lbs.

Blood pressure: In general, persons with systolic pressure between 100 and 200 are acceptable. The physician checks on the medical history of some in this group and may reject them on his findings.

Hemoglobin: 12.5 gm./100 ml. for women and 13.5 gm. for men is considered the lowest level for acceptance. Those falling below this level are rejected by the physician. The hemoglobin test is made by the Phillips and Van Slyke copper sulfate specific gravity technic. A disposable lancet is used in pricking the finger. All lancets and needles used are of the disposable type in order to eliminate the danger of transmitting homologous serum jaundice from one donor to another.

History: In order that no one ill of some acute disease or chronic illness be taken as a donor, each donor is asked questions concerned with the following conditions: illness in past month, surgical operations in past 6 mo., tuberculosis, diabetes, rheumatic fever, cardiovascular disease, kidney disease, persistent cough, pain in chest, shortness of breath, fainting spells, and convulsions. Any person giving a positive answer to any of these questions is automatically referred to the attending physician who accepts or rejects him on an individual basis. Extreme apprehension is occasionally the cause for rejection. The physician makes an attempt to give the prospective donor a good understanding of why he is rejected, whether or not he may give blood at another time, and what course to follow.

Requirements protecting the recipient

Blood or plasma transfusion: No donor is accepted who has had a blood or plasma transfusion in the past 6 mo.

Malaria or antimalarial therapy: Donors who have had a history of malaria or who have received intensive suppressive therapy but who have had neither a clinical attack nor suppressive therapy in the preceding 2 yr. may be accepted for donations to be used as whole blood. Donors who have had neither a clinical attack of malaria nor intensive suppressive therapy in the past 6 mo. may be accepted for donations to be used as plasma or plasma fractions only.

Brucellosis: Persons having had undulant fever within the past 2 yr. are rejected. If the disease occurred more than 2 yr. ago, the donor is acceptable.

Jaundice: Persons having had infectious hepatitis or homologous serum jaundice within the past 2 yr. may not be donors. Persons having had contact with either disease in the past 6 mo. may not be donors. This blood shall be clearly marked for derivatives only.

The problem of contact with homologous serum jaundice and infectious hepatitis presents a real problem when considering laboratory technicians, nurses, physicians, and other hospital personnel as donors. There have been many reports of "needle jaundice" in persons performing venipunctures and examining the blood of patients. All laboratory personnel must exercise the greatest care to protect themselves from infection by the blood of any patient. Any break in the skin should be carefully protected.

Allergy, asthma, and hay fever: The transmission of nonspecific antibodies by stored blood does not present the great problem that it does in fresh blood; nevertheless, a person who feels well but gives a history of recent allergic manifestations is accepted for plasma or derivatives only.

Immunizations: In general, a person may give blood 24 hr. after receiving immunizations. There are exceptions, however.

Rabies: Donors may not be accepted until 1 yr. after the last immunization.

Smallpox: Donors may be accepted 2 wk. after an immune reaction or after the scab comes off.

Yellow fever: Donors may be accepted 2 wk. after the last injection.

Poliomyelitis: Donors may be accepted 24 hr. after the last injection, with the exception of oral immunization for poliomyelitis, in which case the donor would be accepted 6 wk. after the last immunization.

Typhoid, typhus, Rocky Mountain spotted fever, influenza, cholera, diphtheria, and tetanus: Donors may be accepted 24 hr. after the last injection.

Vitamin, hormone, liver, and other injections: Donors must be evaluated by the physician on an individual basis.

Cortisone therapy: Donors must be evaluated on an individual basis.

Collection methods

The actual collection technic depends to a degree on the type of equipment used. At the present time all venipuncture sets and bottles used are of the expendable type made by commercial houses. Whole blood collections are taken in bottles containing 110 ml. acid-citrate-dextrose (ACD) solutions.

The rubber stopper is prepared with 2% aqueous iodine and 70% alcohol before insertion of the needle. The arm preparation is made with 50% aqueous green soap and 2% aqueous iodine removed with 70% alcohol. Bleedings for ACD collections are performed in 5-7 min. Blood collected in ACD is carefully agitated approximately 5 times during withdrawal and is thoroughly shaken after withdrawal is completed. Immediate refrigeration is instituted.

We shall outline the procedures as carried out by the St. Louis Regional Blood Program. Blood collected in ACD solution is distributed only after the following laboratory work has been done:

1. Determinations of A-B-O groups by known antisera and known cells.
2. Determinations of the Rh factor, **Rh**$_0$ (D), **rh′** (C), **rh″** (E), and $\mathfrak{R}\mathbf{h}_0$ (D^u).
3. Serologic test for syphilis is the VDRL.
4. Titrations have been discontinued on all group O donors. Group O, ACD bottles are labeled "Isoagglutinin titer not determined." We discourage the use of group O blood as universal donor blood but realize that in cases of extreme emergency it must be used. Titrations should be carried out in hospital laboratories if group O blood is to be used as universal donor.

The A-B-O groupings and Rh typings are made by the slide method from clotted samples collected at the time of venipuncture. A Clay-Adams viewer is used for the Rh tests. Commercial sera of a potency meeting National Institutes of Health standards are used.

Although the standard 3-tube Kahn is used for the serologic test for syphilis in some Red Cross Blood Centers, many others are converting to the VDRL syphilis test. Donors with positive tests are followed up as recommended by the State Health Department.

The laboratory procedures are of the simplest type commensurate with the greatest accuracy possible. Perhaps the greatest problem for new personnel and a continuously troublesome problem for the experienced technician in mass typing is that of keeping all determinations related to one unit of blood carefully identified. The elimination of the human error in mixing samples and numbers relating to samples must be accomplished. In American Red Cross Blood Centers we have found the use of one number to identify a given sample and the use of one laboratory worksheet with no copying to be most helpful in preventing the most common errors in transcribing. "Reverse grouping" using unknown sera plus known A and B cells (2%) is made as a check against the original grouping tests. The value of 2 technicians reading the same test cannot be overemphasized.

Labeling, storage, and distribution of blood is the final unit for consideration. Every bottle is properly identified as to contents, including the formula of the anticoagulant, date of expiration (21 days from collection for ACD), name and address of collecting agency, and results of laboratory tests, i.e., serology, grouping, and typing. A whole blood number corresponding to that on the donor's medical history card appears on the bottle label and can be used to trace any unit of blood to the donor. Each ACD bottle has a pilot tube of clotted blood taken at time of venipuncture securely taped to it. This tube is taped to the bottle prior to the venipuncture and is not removed at any time in the Center.

Blood is stored at a temperature of 4°-6° C. in a refrigerator used for this purpose only and which has a constant recording device and alarm system.

The blood is distributed by the American Red Cross in precooled iced cases.

Chapter 81

Blood plasma

ADDINE G. ERSKINE

An enormous amount of literature has accumulated regarding the use of blood plasma as a substitute for whole blood for transfusion in certain indicated cases. The advantages of plasma are that it can be used without typing and can be stored in liquid, frozen, or dried states for months or years and then administered safely without significant deterioration of its component qualities. It is readily available for immediate use, and when injected, it does not increase the concentration of red blood cells in cases of shock and burns where hemoconcentration is already present. Manifestly, the use of whole blood where hemoconcentration is already present is contraindicated.

HISTORICAL DATA UPON THE USE OF LIQUID PLASMA*

Blood plasma as a substitute for whole blood was suggested as early as March, 1918, by Gordon R. Ward[309] in England. He pointed out that one of the chief troubles with whole blood is that the recipient's plasma might hemolyze the corpuscles of the donor. He made the observation that death from hemorrhage was not due to lack of hemoglobin but from loss of fluid, and thus the great need in these patients is for replacement of the depleted fluid. He suggested that this could be done by the administration of citrated plasma which could be preserved easily and injected safely.

Rous and Wilson[310] in 1918, while working on hemorrhage in animals, used plasma to replace the blood loss and pointed out that replacement of red blood cells is not essential because even in severe hemorrhage a sufficient number of cells remains to support life but that loss of blood volume is the important factor. They were able to restore the blood pressure to normal following gross hemorrhage and to maintain it by replacing the removed blood with an equal quantity of plasma. Where hemorrhage is too great, loss of red blood cells is important also.

Mann[311] in 1918 discussed the use of serum for treating surgical shock produced experimentally in dogs. He noted that parenteral injection of homologous serum produced results that were as good as or even better than any of the methods employed in the treatment of experimental shock. It is worthy of mention that his best results were obtained with relatively large doses of serum. He asserted that homologous serum might be of value under conditions in which serum could be kept and whole blood could not be obtained.

Strumia[312] began using human serum intravenously in 1927 for the treatment of severe infections. Later in 1927 he began using plasma because of the simplicity of preparation and its greater yield. It was noted then that even heterologous plasma given intravenously caused no reactions, whereas homologous sera commonly caused severe reactions. This difference in behavior of plasma and serum had previously been observed and commented on by Brodie[313] in 1900. Untoward reactions from serum were thought by him to be due to the process of fibrin precipitation when serum is separated from the clotting blood. This hypothesis continues to be conjectural.

Gradwohl[314] recommended plasma in the treatment of a severe burn case.

Weech et al.[315] in 1933, while performing plasmapheresis experiments in dogs, were able to produce a normal state in their animals by administering transfusions of normal dog serum.

The use of plasma intravenously in man as a hemostatic agent was reported by Filatov and Kartasevskij[316] in 1935. The same year Heinatz and Sokolow[317] used plasma in the treatment of hemolytic shock.

Elliott[318] in 1936 suggested the use of untyped serum and plasma for treatment of surgical, obstetric, or traumatic shock in which transfusions were indicated. He rationalized that the need for replacing the lost blood volume was more important than the red blood cells, since the maintenance of osmotic pressure is a function of the plasma proteins. Elliott also propounded the idea that liquid plasma could be stored for long periods without deterioration. The findings of other investigators have supported his contentions.

---

*Many of these historical facts were found in the publication by Lt. Comdr. L. R. Newhouser, United States Navy, and Captain D. B. Kendrick, Jr., United States Army, Medical Corps, entitled "Human plasma" prepared April, 1941.

Fantus[319] in 1937 advocated the use of normal human serum because of its therapeutic and natural immunizing properties. He stated that in shock without hemorrhage and in burns intravenous injection of blood serum is much more rational than that of blood because these patients usually have an excess of red blood cells/c.mm.

Alovski and Burceva[320] published a favorable report in 1937 on the use of plasma as a substitute for whole blood in gynecologic conditions. Mahoney[321] in 1938 recorded encouraging results with preserved plasma in the treatment of experimental and clinical shock. Elkinton[322] and McClure[323] in 1939, working separately, obtained good results with plasma in burn cases. Tatum et al.[324] in 1939 suggested a technic for the preparation of whole blood substitutes in war conditions. Plasma was recommended as "an ideal substitute for whole blood in the emergency treatment of shock and hemorrhage from war wounds." They outlined the technic of collecting blood in a vacuum bottle, centrifuging the blood, and then aspirating the supernatant plasma into a second vacuum bottle for storage. In 1940 Elliott et al.[325] recommended the use of dilute, preserved, liquid plasma. The same year Strumia[312] advocated citrated blood plasma without cross matching for the treatment of burns and shock. Thalhimer[326] reported favorably on the use of convalescent serum for administering antibodies. Best and Solandt,[327] discussing their work on experimental shock, reported encouraging evidence in favor of using plasma and serum in preventing shock. Levinson et al.[328] have shown the value of serum in the treatment of posthemorrhagic shock in experimental animals. Kendrick[329] in 1941 advocated the use for military purposes of concentrated and normal dilutions of plasma for the prevention and treatment of shock in the combat zone. Kekwick and Whitby[330] in 1941, after using plasma for the treatment of shock and hemorrhage in air raid casualties in England, concluded that plasma and blood are equally effective in restoring blood volume in injuries of this type.

PREPARATION AND USE OF PLASMA

Plasma is the liquid portion of blood. In addition to fibrinogen, antihemophilic globulin, and prothrombin, all of which are involved in the clotting mechanism, plasma also contains antibodies present in the globulin fraction, crystalloids, electrolytes, and blood colloids, largely albumin, which exert osmotic forces for maintaining a normal blood volume. A supply of plasma ready for injection should be kept in blood banks for emergency use.

In order to obtain a maximum yield of plasma, whole blood is preferably taken in 4% sodium citrate. Fibrinogen is more stable when plasma is collected in sodium citrate than when ACD solution is used as the anticoagulant. Immediately after withdrawal, the blood should be placed in a refrigerator. When blood has been taken in sodium citrate, the plasma must be separated from the cells within 4 days of collection. When ACD solution is used, the plasma may be removed at any time within 26 days after storage in a refrigerator. See p. 1574 for plastic bags.

The blood may be centrifuged at 2000 r.p.m. for 1 hr. to separate the plasma from the cellular elements. If it is not centrifuged and the cells settle by gravity, the yield of plasma is reduced by approximately 15%. Centrifuged blood should be placed in a refrigerator overnight before the plasma is removed so that any cells that have been stirred up may resettle.

The plasma should be aspirated in a special room with no air currents, and all sterile precautions must be observed throughout its preparation.

Technic of preparation of plasma

This technic requires the use of equipment by which blood may be obtained and the plasma prepared under sterile conditions.*

It is necessary to have a supply of Transfuso Vacs of 500 ml. capacity. The bottle is a sterile vacuum unit designed to fit centrifuge cups. Sterile vacuum containers are available for removal of the supernatant plasma after centrifugation. These are known as Plasma Vacs, for the preparation of plasma. A Plexitron expendable set for the control of the blood flow into the sterile vacuum container is also necessary.

1. Prepare the blood donor in the usual manner. Cleanse the skin at the site of the needle insertion with alcohol-iodine. Constrict the upper arm with a short piece of rubber tubing or preferably with a blood pressure cuff.
2. Withdraw blood in the manner outlined on pp. 1572 and 1575. Before placing it in a refrigerator, break the vacuum by inserting a sterile air filter.
3. When the Transfuso Vacs are to be centrifuged, remove the air filter, place the bottles in centrifuge cups, and balance accurately. When centrifuging such large quantities, it is imperative that the bottles opposite one another be in perfect balance. If they are not, it is not possible to prepare clear plasma, and the centrifuge is likely to be damaged. For balancing, place rubber bands around the neck of the lighter Transfuso Vacs until they are in balance with the heavier ones.
4. Centrifuge for 45 min. to 1 hr. at 2000 r.p.m. to separate the plasma from the cells. Any jarring of the centrifuge or the Transfuso Vacs will disturb the cell layer, and poor plasma will result.

---

*The equipment described here is manufactured by the Baxter Laboratories, Inc., Morton Grove, Ill.

5. For the removal of the supernatant plasma use an expendable aspirating set. Cut away the thin rubber disk.
6. Disinfect the stopper of the Transfuso Vac with alcohol-iodine and insert an air filter.
7. Remove the aspirating needle from its sterile wrappings and thrust it through the thin depression in the stopper into the plasma; then, resting both elbows on the bench, one on either side of the bottle, gently lower the aspirating needle into the plasma, controlling the action of the needle by holding the point against the glass wall of the bottle. Keep a bright light directly behind the blood bottle for ease in watching the needle and the plasma level. It is important that the needle of the air filter be above the surface of the plasma. After inserting the long aspirating needle, open the clamp gently without disturbing the bottle and allow the plasma to flow into the Plasma Vac. Take care that no air is sucked into the plasma bottle. See Fig. 510.
8. The cellular elements in the blood bottle must not be disturbed. If cells are inadvertently drawn over with the plasma, the plasma bottle must be recentrifuged and the supernatant plasma removed from the cells through a closed system.
9. After all the plasma has been removed, close the clamp and allow the small amount of plasma remaining in the tubing to run into sterile test tubes by holding the tubing vertically and opening the valve slightly. Then test the plasma samples for sterility by anaerobic and aerobic cultures. If the plasma is found to be sterile after sufficient time has elapsed, it is then ready for use or dilution. Do not use plasma containing undue amounts of fats or any that show signs of high bilirubin content.

The completed pooled plasma or serum in accordance with the regulations of the National Institutes of Health relating to plasma shall contain not more than 25 mg. of hemoglobin/100 ml.

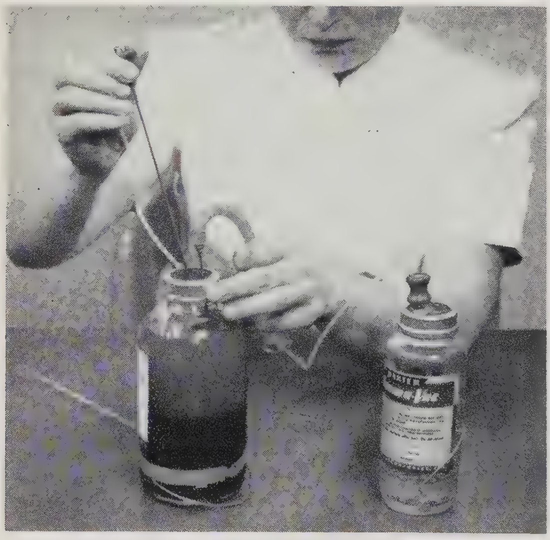

Fig. 510. Aspirating plasma. The plasma will be drawn off into a vacuum container. (Courtesy Baxter Laboratories, Inc., Morton Grove, Ill.)

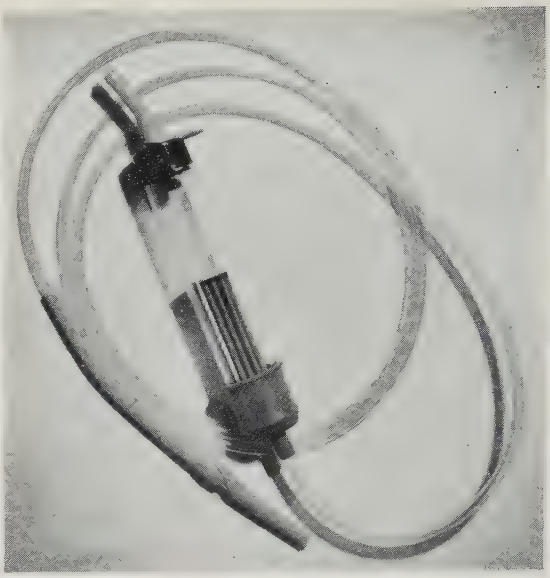

Fig. 511. Sterile expendable Plexitron set for administering blood, plasma, or serum. (Courtesy Baxter Laboratories, Inc., Morton Grove, Ill.)

If the cells remaining in the blood bottle after removal of the plasma are to be kept for cell suspension transfusion, close the hole in the blood bottle stopper aseptically by encasing the top of the bottle with a tight-fitting sterile hood. A different aspirating needle must be used in each blood bottle when the cells are to be used for transfusion.

When all the plasma has been aspirated from one bottle of blood, close the clamp and withdraw the aspirating needle from the blood bottle. Using all sterile precautions, enter another blood bottle first with the airway and then with the aspirating needle; then release the clamp. The needle in the pooling bottle remains in place. Continue until the desired amount of pooled plasma is obtained.

The isoagglutinin titer of pooled plasma is less than that of separate plasma, not only because the dilution lowers the titers but also because groups A and AB plasma contain some group A-specific substance and groups B and AB plasma contain some group B-specific substance, which will partially neutralize their respective isoagglutinins. A 2 L. pool of plasma should contain not more than 3 units of group O plasma, 2-4 units of group A, and 1-3 units of group B or AB plasma. When plasma is stored at room temperature after pooling, the isoagglutinin titer decreases further.

Withdraw 10 ml. for each 1000 ml. plasma from the pooled plasma, using a glycerinated Luer-Lok syringe and needle, and eject into fluid thiogly-

collate medium. Incubate the culture at 30°-32° C. for 2 wk. as a sterility control. When sterility has been proved, divide the pooled plasma into several smaller containers, each of approximately 300 ml. size, using the same technic as in the pooling process. Make cultures from the pilot sample taken at the time of division.

Label each bottle clearly, indicating the expiration date. Liquid plasma has an expiration date of 2 yr. from the time of withdrawal of the oldest blood in the pool. It should be stored at slightly higher than room temperature.

Homologous serum hepatitis may be transmitted by whole blood, plasma, serum, thrombin, or fibrinogen. The greater the size of the pool of plasma, the greater the number of cases of hepatitis in the event the pool contains virus. Limiting the pool size to less than 10 blood donations and storage of liquid plasma at 30°-32° C. for 6 mo. or longer greatly reduces the risk of hepatitis. Evidence indicates that shorter time at higher temperature or longer time at lower temperature and the use of ultraviolet irradiation with a shorter storage period in the liquid state may be equally satisfactory.

Plasma from the blood of a single donor may be aspirated into another container and administered to a patient from this container. This is called "single donor plasma." If it is not intended for the treatment of coagulation defects, it may be stored at room temperature.

Fresh frozen plasma

Factors that correct the clotting defect in hemophilia are thermolabile and disappear quite rapidly from plasma stored at room temperature, but they are retained in fresh plasma and in plasma frozen shortly after collection. Fresh frozen plasma is usually prepared from a single donation and not from a pool.

Special attention must be taken to maintain a low temperature during processing and storage of the plasma. The plasma must be frozen within 4 hr. of bleeding the donor and at −18° C. or colder. It must be thawed rapidly just prior to administration. When stored at this temperature, the antihemophilic activity remains relatively unchanged for months, perhaps years.

1. To prepare fresh frozen plasma, centrifuge the blood at 2800 r.p.m. for 10 min. as soon as possible after collection (the total centrifuge time is approximately 40 min. from beginning to end since it requires some time to reach the proper centrifuge speed and to permit the centrifuge head to coast to a stop). Pre-chill the centrifuge cups in a refrigerator.
2. Use ice water to balance the centrifuge cups.
3. Pre-chill the flasks that are to receive the plasma.
4. Take a sample for culture at the time the plasma is aspirated.
5. Attach a pilot sample of plasma securely to the bottle for cross matching and to check on a possible reaction. If a group AB donor is used, no pilot sample is considered necessary in some banks, but this is not recommended. Some blood banks use only group AB blood for preparing fresh frozen plasma.

The quantity of plasma in each container may be varied: 50 ml. for an infant, 125 ml. for a child, and 250 ml. for an adult.

6. As soon as the bottle is filled and labeled, place in a freezer in a slanting position next to the wall containing the coils. After freezing, place the bottle in an upright position. If the plasma thaws during storage, it must be discarded.
7. Transport the bottle in dry ice outside the blood bank.
8. To prepare the plasma for injection, thaw in a 37° C. water bath or a pan of tepid water and administer **immediately** after thawing. **Discard if not used.**

Plastic bags may be used for this process. When using plastic bags, a heavy object should be placed on the bag during the freezing process to make a dimple, which will disappear if the plasma thaws without the knowledge of the bank personnel.

Plastics that have been subjected to low temperatures become brittle and may crack or break easily, so that plastic bags containing frozen plasma should be handled with care. Upon removal from a freezer, a plastic bag should remain at room temperature for 5-10 min. before being placed in a 37° C. water bath.

PLASMA AND SERUM FRACTIONS*

Normal human serum albumin: Normal serum albumin, human, is usually distributed in a 25% salt-poor solution in three sizes: 20, 50, and 100 ml. The 100 ml. unit is osmotically equivalent to 500 ml. citrated plasma.

Albumin is used in the treatment of shock, burns, and hypoproteinemia. It is free of the homologous serum hepatitis virus and for this reason is preferred to plasma. However, for the preparation of one 100 ml. unit of normal serum albumin, 3.6 donations of blood are required, which makes the cost relatively high and therefore limits its use.

When whole blood and plasma are judiciously administered, they are usually as effective as or more effective than albumin in diseases in which albumin may be used.

Fibrinogen: Fibrinogen is now commercially available. It is used in any condition associated with a fibrinogen deficiency. Such a deficiency is suspected if blood does not clot or if clotted blood reassumes the liquid state. Fibrinogen deficiency is rare. When present it may result in extensive hemorrhage. It is an infrequent complication of childbirth and chest or abdominal surgery. There is also a congenital form of fibrinogen deficiency. Refer to p. 1227.

Fibrinogen is available in dried form in 1 gm. quantities. It is dissolved in water and administered intravenously. The purified product is more useful than fresh blood in controlling hemorrhage, especially in obstetric hemorrhage due to afibrinogenemia or fibrinolysis. There is great risk of transmitting hepatitis by the use of purified fibrinogen and therefore it should be used only in emergency. A pint of fresh blood may contain 0.5-1.5 gm. fibrinogen.

Antihemophilic globulin: Antihemophilic globulin is not commercially available as yet (1963), but it has been prepared in dried form. It must be reconstituted with water for intravenous administration. It is prepared from fresh blood during the fractionating process. The quantity to be injected into a hemophiliac depends on the ability of the given lot to correct the clotting defect of the individual patient.

Specific antibody immune serum (human convalescent serum)—measles, mumps, pertussis, poliomyelitis, and scarlet fever immune sera: Immune sera from convalescent donors or immune globulins are used for passive immunization against certain infections. These sera have high antibody content and confer a short passive immunity, from 3-5 wk. The immunity is short lived because the antibody proteins are metabolized and excreted. Such therapy is more useful for prophylaxis than for treatment of established disease. No standard of potency has been established for most of these sera except in the case of poliomyelitis serum. Pertussis immune serum can be standardized, but this is not required. There is danger of transmitting homologous serum hepatitis by the use of immune sera. Effective antibiotics and sufficient quantities of immune globulin are used more often than the immune sera.

Human convalescent sera for the above diseases are prepared by pooling the serum from adult donors not more than 6 mo. after convalescence from the specific infectious disease. In poliomyelitis, donors may be accepted from 2-5 yr. after recovery from an attack of paralytic poliomyelitis. Pertussis serum comes from donors who have had whooping cough, and they are given pertussis vaccine prior to blood donation. Manifestly, donors must be selected with great care. The pooled serum is filtered through a Berkefeld N filter and radiated with ultraviolet light.

Merthiolate is used as a preservative in the liquid sera. Sterility and toxicity tests are performed. The expiration date of liquid sera is 1 yr. from the date of issue. The date of issue may be preceded by a 2 yr. storage period at a temperature not exceeding 5° C.

Immune sera are usually administered intramuscularly, but they may be given intravenously if the product has aged for 1 mo. Dosage schedules are recommended by the manufacturer.

Immune globulin for measles and poliomyelitis: The gamma globulin fraction of plasma usually contains the highest antibody concentration. The gamma globulins comprise about 16% of the total plasma proteins.

---

*The section on plasma fractions has been abstracted from Chapter VI of Technical methods and procedures, revised edition, 1960, by permission of the American Association of Blood Banks, Chicago, Ill.

Citrated plasma, plasma salvaged from blood taken in ACD solution, reconstituted lyophilized plasma, and blood collected from placental sources may all be used for fractionation. Each lot of finished product represents a plasma pool from more than 1000 donors. The final product is a 16.5% ± 1.5% solution of globulin in a 2.25% solution of glycine.

Immune serum globulin is effective in prophylaxis of measles, poliomyelitis, and infectious hepatitis but not of homologous serum hepatitis.

It has also been used advantageously in maintaining general resistance against infections in patients with agammaglobulinemia, hereditary or acquired. It is administered only intramuscularly.

PLATELET TRANSFUSIONS

At times it is necessary to transfuse blood platelets to correct a platelet deficiency. This may be accomplished by the use of platelet-rich whole blood, platelet-rich plasma, or platelet suspensions. As many intact platelets as possible should be retained.

The blood must be exposed only to nonwetting surfaces during collection, storage, and administration. Plastic apparatus or apparatus coated with silicone or other similar agents may be used. The transfusion must take place as soon after blood donation as possible, preferably within 4 hr. Platelets that have been stored for 24-48 hr. have a shorter survival time than do fresh platelets, but they are still effective in the treatment of platelet deficiencies. The blood should be taken from donors whose blood is rich in platelets, and although blood from normal donors does not have as high a platelet count as blood from, for example, a polycythemia patient, it often will help correct a platelet deficiency.

Platelet-rich plasma is prepared by aspirating plasma from several units of blood that have been centrifuged slowly, collecting the plasma in a pooling bottle. The platelet suspensions are prepared from this plasma pool by centrifuging it hard and then removing the clear plasma, retaining the platelets. A more or less direct transfusion from donor to recipient, using siliconed needles and syringes, may also be used to transfer platelets from one person to another.

A method of separation and storage of platelets and at the same time obtaining plasma rich in antihemophilic globulin and packed red cells has been described by Strumia.[331] The whole blood is taken from normal, healthy, fasting donors or from polycythemia patients who are bled for therapeutic reasons. These individuals are preferably group O. Collect the blood in 500 ml. plastic bags containing the standard amount of ACD solution. All tubing and collection receptacles should be plastic and the needles must be carefully siliconized.

1. Mix the blood rapidly and with minimal agitation, and carry out the same precautions in subsequent handling. Cool the plastic bags containing the blood promptly; then centrifuge in a cold room or pack the bags in ice and centrifuge at less than 500 g for 20 min., which will sediment the red cells.
2. Transfer the supernatant platelet-rich plasma through a closed system, using plastic tubing and siliconized needles, to an empty 300 ml. plastic bag without disturbing the erythrocyte layer. In making the transfer gently press the bag containing the centrifuged blood, beginning at the lower part of the bag and proceeding gradually to the upper part.
3. Centrifuge the separated platelet-rich plasma in the cold for 1 hr. at 2000 r.p.m. with a centrifugal force of 1800 g or more. The platelets and leukocytes will be entirely sedimented in the form of a white, viscid material.
4. Remove the supernatant platelet-free plasma and transfer to a sterile plastic bag or glass bottle, leaving 25-40 ml. plasma remaining in the bag.

The platelet-free plasma is rich in antihemophilic globulin. It should be shell-frozen immediately and freeze-dried as soon as possible for optimal preservation. Plasma properly prepared and freeze-dried maintains its essential properties for approximately 5 yr.

Stir up the platelet concentrate by gentle agitation in the bag. Remove a small sample and test for sterility and also make a count of the platelets. Freeze the bags with the concentrated platelets by using ethanol-dry ice mixture and maintain in a frozen state at −20° C. or lower. The platelets should also be tested for thromboplastic activity by means of the thromboplastin generation test.

Transfusion of concentrated platelet suspensions may cause vasospasm if carried out too rapidly, but the platelets that correspond to the content of 500 ml. blood may be safely transfused over a period of about 15 min.

Strumia has stated that whole blood collected in plastic apparatus and immediately cooled and stored at 1°-2° C. retains active platelets for at least 74 hr.

PYROGENS

In the preparation of accessories all distilled water should be pyrogen-free, sterile, and otherwise suitable. What is meant by **pyrogen-free** distilled water? In 1911 Hort and Penfold[332] showed that the intravenous injection of freshly distilled water caused no symptoms in animals and in man, whereas the intravenous injection of the same water, after it had been incubated in unsterile vessels, caused a febrile reaction. These writers decided that this principle, provisionally called **pyrogen**, was a product associated with bacteria but was not a part of the bacterial bodies themselves. The fever-producing principle was still present after the water had been passed through a Berkefeld filter. These facts were confirmed by Siebert[333] in 1923 by injecting distilled water intravenously into rabbits. In 1934 Banks[334] reported that *Pseudomonas urea* and *scissa,* which he isolated from surface waters, were pyrogenic. Most of the work on pyrogenic substance has been confined to the bacteria found in waters. Co Tui and Schrift[335] showed that pyrogen production is much more widespread than was first embraced in the concepts of Siebert and Banks. They investigated 18 strains of microorganisms of different genera, tribes, and families, making tests (1) with bacterial strains grown in initially pyrogen-free broths; (2) using bacteria that were most convenient to grow on slants or in Kolle flasks, washing out the colonies with pyrogen-free physiologic saline containing 0.4% phenol, inactivating for 45 min. by heat, then filtering and testing the sterile filtrate; (3) testing 9 organisms in the form of vaccine made with pyrogen-free water. All the vaccines were passed through a Berkefeld filter.

Their estimate of a pyrogenic reaction in a dog was (1) a leukopenia 30-45 min. after the intravenous injection of the pyrogenic material and (2) a rise in temperature 30 min. after injection, reaching a peak in 2-4 hr. and returning to normal in 4-5 hr. In mildly severe reactions there were prostration and gastrointestinal symptoms, such as vomiting and diarrhea. The vomitus and stool may contain blood. These symptoms are comparable to those in man.

Pyrogenicity of bacterial contaminants found in biologic products

Probey and Pittman[336] investigated the pyrogenic properties of those microorganisms isolated from blood or plasma during the various stages of processing dried normal human plasma, to determine the quantitative and qualitative nature of the thermal response of rabbits (1) to living bacteria, (2) to heat-killed bacteria, and (3) to whole cultures grown in serum.

The materials used were 49 cultures from 8 processing laboratories widely distributed throughout the United States. Twenty-eight representative cultures were selected for study including staphylococci, micrococci, streptococci, gram-negative bacilli, and spore-forming and nonspore-forming gram-positive bacilli. The sodium chloride solution, which was used as the diluent, was prepared with one lot of sodium chloride proved by animal test to be pyrogen-free and with water freshly redistilled in a glass still. Each lot was tested and accepted for use only if the rabbit thermal response induced was characteristic of pyrogen-free saline.

Methods

The thermogenic properties of the test material were determined by the pyrogen test as described in the *U. S. Pharmacopoeia* XII, with a few changes.

The pyrexial response induced by the bacterial suspensions was computed by 3 procedures: (1) **high above normal,** the U.S.P. method, bases the computation on the temperature deviation from the pretreatment normal temperature; (2) **high above control** records the difference between the maximum temperature deviation induced by the test material and that of the pyrogen-free control; and (3) **peak above control** computes the pyrexia as the difference between the temperature induced by the test solution at the time of maximum temperature rise and the temperature of the pyrogen-free controls at the corresponding hour.

Since the pyrogen-free saline control in practically every instance induced a depression from the preinjection normal temperature, the normal physiologic reaction of the rabbit to injection of pyrogen-free saline is depression of the normal temperature. For this reason Hort and Penfold believed that the evaluation of the pyrogen test should be predicated upon the normal physiologic response of the rabbit to injection with a pyrogen-free control and not upon the pretreatment normal temperature as is now recommended by the *U. S. Pharmacopoeia.* Another observation is that the quantitative characteristic of pyrogens, as reported for the bacteria studied, indicates that a slight febrile response in rabbits, of less than the 0.6° C. temperature elevation permitted by the U.S.P. XII test, is in fact due to pyrogen contamination. This marginal amount of pyrogen may be sufficient to cause clinical reactions in human beings, since Co Tui and Schrift have observed that the rabbit is only ⅓ as sensitive to pyrogens as is man. Co Tui[337] later recommended that the official test be more quantitative and suggested the use of several test doses to ensure freedom from marginal pyrogen contamination. Until the characteristics of pyrogens are more fully elucidated, the observation period of the animal thermal test should be continued until the maximum response has been reached or until the temperature curve has definitely entered the downward phase. Work on contaminated blood or blood plasma during the processing of dried normal human plasma indicates that the contaminating bacteria are all capable of inducing fever in rabbits and that the count of bacteria in a contaminated blood product does not furnish an index of pyrogenicity.

The dog has a much more stable thermoregulatory mechanism but is less sensitive to pyrogen than is the rabbit. A positive test in the dog is so characteristic, however, with the additional symptoms of leukopenia, vomiting, and diarrhea, that it is unmistakable. For this reason a positive test in the dog is much more significant than a negative one. To summarize, the rabbit is the better animal to test for the absence of pyrogen, whereas the dog is the better animal to establish the presence of pyrogen. Both animals must be used to complete the picture. Both dogs and rabbits have been used for several positive pyrogen tests without developing manifest immunity or tolerance.

The rabbit is approximately 3 times, and the dog at least 6 times, less sensitive than man to purified pyrogen from typhoid vaccine.

Test dosages: Assuming that the above figures hold for pyrogen from sources other than the typhoid bacillus, the rabbit should receive as much as 3 times the maximum per kg. dose in man and the dog 6 times. In order to approximate the dose in man, the rabbit test dose must therefore be not less than 50-100 ml./kg. body weight. Although this amount of fluid almost approximates the total blood volume of the animal, if the dose is injected in 10-30 min., the rabbit can easily take care of the plethora. But, in any event, the symptoms of plethora are different from those of a pyrogenic reaction. Since the dog is to be used as a **positive** test animal, any dose that elicits the reaction shows the degree of pyrogenicity of the solution. This can be arrived at by trial and error, starting from a minimum dose of 250 ml.

Procedure of the test: The test is run in 2 parts, the preliminary part on rabbits, the confirmatory part on dogs.

Preliminary test: Use albino rabbits of 2½-3 kg. These rabbits should previously have been conditioned for several days to handling and taking of rectal temperatures until these procedures provoke no struggling and their rectal temperature readings are constant within 0.25° C. in 3 readings taken 15 min. apart. Before injection, temperature readings taken at 15 min. intervals must not be over 39° C. The thermometers must be inserted the same distance beyond the internal sphincter of the rectum and allowed to remain there for 2 min.

Warm the test solution to nearly the temperature of the animals; inject 50 ml./kg. body weight into one animal and 100 ml./kg. body weight into the second animal no faster than 10 ml./min. Take the temperature readings every half hour for 4 hr. after the injection. A rise of over 5° C. in 1-3 hr. after injection is taken as presumptive evidence of the presence of pyrogen. A pyrogenic sample ought to give a more severe response with 100 ml. than with 50 ml.

Confirmatory test: This is not necessary where a positive presumptive test is enough to lead to the condemnation of a product as unfit for human use. When more positive evidence may be required in many legal or medicolegal complications, the clear-cut result of a positive dog test is not easy to controvert. Perform the test as follows: One healthy dog of 15 kg. body weight, conditioned to the taking of rectal temperature, with an initial rectal temperature of not over 39° C. and blood count not exceeding 20,000 white blood cells/cu.mm., is used. Depending upon the response of the rabbits, give 250-1500 ml. of the fluid intravenously through one of the external jugular veins, not faster than 30 ml./min. Take the blood count again 45 min. and the temperature every 30 min. after the injection. Leukopenia, a fall of 5000 cells/cu.mm. or over and temperature rise of 5° C. from 1-3 hr. after the injection are evidences of the presence of pyrogen. The occurrence of emesis, prostration, and diarrhea are added checks.

Pyrogen production is more common than is generally believed. It is not confined to any one group but occurs in a number of different groups of bacteria. Nor is it associated with nucleic acid, with pathogenicity, chromogenicity, or with the property of taking the Gram stain. The production of pyrogen by a member of the yeast group suggests that even higher forms than bacteria may possess this property of pyrogen production. Chemically and immunologically, pyrogen is still an unknown entity.

The importance of pyrogenic substances resides in the fact that they cause reactions from the use of improperly cleaned infusion equipment and intravenous solutions, such as Ringer's solution, glucose solution, citrated solutions of defibrinated blood, etc.

DRIED PLASMA*

In order to provide plasma in a compact form, resort has been made to the use of the lyophil technic, such as was worked out by Flosdorf and Mudd.[338] These two workers determined that the content of antibodies and complement in serum rapidly frozen and then dehydrated in the frozen state under high vacuum shows no detectable decrease in the processing and, furthermore, that the rate of the subsequent deterioration is reduced to a small fraction of that which takes place in the liquid state. Scudder[339] stated that whole blood deteriorates rapidly, whereas lyophilized plasma may show no appreciable change even after years. By the electrophoretic method of analysis the protein patterns for the lyophilized plasma differ little from that of the fresh control, whereas protein patterns dried at 37° C. show wide variation.

---

*Liquid plasma is preferred. Drying plasma preserves the hepatitis virus. Liquid plasma kept at room temperature for 6 mo. or longer loses its capacity to cause homologous serum jaundice.

A number of methods have been described, but the recommendation is made that if one desires to use dried plasma, it should be purchased from a reliable firm.

One finished lyophilized product is known as Lyovac* Normal Human Plasma. When desiccated, it retains its therapeutic value and remains stable for at least 5 yr. and is available for use by the addition of pyrogen-free distilled water. It is stated that the content of specific and nonspecific antibodies, complement, and coagulating elements, together with ⅗ of the platelets, is essentially the same as that of the original fresh plasma.

Precautions regarding the use of lyophilized plasma:

1. Remove the needle before all the water runs in.
2. Do not warm.
3. Dissolve in 5 min., shaking at room temperature, to obtain a clear solution.

---

Chapter 82

Medicolegal aspects of blood grouping

ADDINE G. ERSKINE

It must be accepted that once the blood group of an individual is established it remains unchanged throughout life. This basic fact constitutes the principle upon which forensic examinations of blood are made. Today the evidence of blood tests is routinely accepted in many courts, and many states have passed statutes empowering their courts to order such tests whenever parentage is disputed. New York, in 1935, was the first state to adopt a blood test law. From March 22, 1935, until November 17, 1949, almost 15 yr., the Court of Special Sessions in New York City had never adjudged as a father of a child a man excluded by blood tests. This record was broken, however, on November 17, 1949, by the court's decision in a case in which the accused was declared the father of a child despite the fact that 2 independently performed blood tests excluded him as a possible parent.[340] As Wiener[341] has observed, the reliability of the blood grouping test is still so great that no other type of evidence can approach it. The Institute of Forensic Medicine of Copenhagen and the Danish Medicolegal Council have submitted to the Danish courts written instructions regarding the reliability and judicial acceptance of blood test exclusions, concluding as follows[342]:

1. Paternity incompatible with the A-B-O system can be excluded with just as great a certainty as may be given by any biologic method.
2. Paternity incompatible with the M-N system can be excluded with just as great a certainty as may be given by any biologic methods.

It is emphasized that no deviation from the inheritance of the M-N system has ever been seen. (Refer to factor **M**^{e}, p. 1551.)

Likewise, the possibility of an erroneous exclusion of paternity after the A-B-O system may also be disregarded in practice.

The Danish courts are thus advised by their Medicolegal Institute that the blood test exclusions are entirely reliable and should be accorded decisive effect. It must be noted that these tests must be performed by experts especially trained for this examination.

Blood tests are also used to solve other legal problems, notably in assisting to determine whether blood stains have come from one person or another, particularly in cases of murder, rape, and hit-and-run driving. There are certain limitations to the use of blood grouping in determining innocence or guilt when examining blood stains. Since the majority of persons belong to either group O or group A and only a smaller percentage to groups B and AB, the tendency of the tests might more frequently suggest innocence rather than guilt. For example, the blood composing a stain on a suspect's clothing and that of the true criminal may be of the same group. A defense could be raised that the stains upon the clothing of the accused were produced by his own blood. The value of the test is of course apparent when the blood stains under examination are of the same group as the blood of the victim but of a different group from that of the suspect. Blood grouping reactions reduce the given number of individuals from whom a given sample of blood may have been derived.

BLOOD GROUPS AND HEREDITY

With the present knowledge of genetics it has become evident that problems of disputed parentage can be clarified by the application of the mendelian laws of heredity to the problem of blood groups. Fortunately, the blood groups are inherited precisely by a relatively simple mechanism. It must be emphasized that blood tests can be used only as negative proof of parentage, i.e., they can **disprove** paternity or maternity but they cannot **prove** them.

The serologic differences in the blood cells have been proved to be determined by heredity and are not influenced by environment. Ottenberg and Epstein[343] and von Dungern and Hirszfeld[344] proved that the 4 Landsteiner blood groups are inherited. Bernstein[345] in 1925 established the exact mechanism of heredity. These inherited factors follow Mendel's laws. With respect to what is meant by mendelian dominants, one must turn to the painstaking research of Johann Mendel, born in 1822 of German parentage in the village of Heinzendorf in Silesia. At the age of 21, in 1843, he entered the Augustinian Monastery at Brünn, Austria, there spending the remainder of his life except for a short period of study at Vienna. His name upon entrance to the Monastery became Gregor, and now he is known as Gregor Johann Mendel. In a little strip of garden behind the monastery building, Mendel conducted his experiments upon hybridization. In his rooms he hybridized mice, along the edge of the garden he experimented with bees, and in the garden itself, he crossed many kinds of plants. His famous experimental work was performed with garden peas, columbine, snapdragons, slipperworts, pumpkins, four-o'clocks, beans, etc. His work with garden peas is the most notable. Seven pairs of peas with contrasting characteristics were used by him, including smooth seeds and wrinkled seeds, yellow cotyledons and green cotyledons, inflated pods and constricted pods, yellow pods when unripe and green pods when unripe, flowers in the axils of the leaves and flowers at the ends of the stems, white seed coats and brown seed coats, tall plants and dwarf plants.

Mendel crossed tall plants with dwarf plants and produced the first filial generation, known as F_1, all of which were tall. When these tall plants were selfed, they produced both tall and dwarf plants, there being 3 times as many tall plants as dwarf plants. In the second generation ⅔ of the tall plants when selfed produced tall and dwarf plants in the ratio of 3:1, just like the F_1 plants. All the F_1 plants were tall, because, according to Mendel, the factor determining tallness was **dominant** to the factor for dwarfness. When hybrid tall plants were selfed, tallness showed up in the proportion of 3:1. The factor that did not produce its effect in the presence of the contrasting factor he called **recessive.** Thus, **tallness** was the dominant factor and **dwarfness** was the recessive.

Mendel's work was published in 1866, but very little attention was paid to it until the botanists deVries, Correns, and von Tschermak reached conclusions similar to his but independent of each other. His paper was then rediscovered and credit given to him after 30 yr. Thus in 1900 his work was made known to the scientific world.

Classifications based upon genetic formulas are known as **genotypes,** whereas the final observable results are known as the **phenotype** (refer to pp. 1492 and 1493). Thus for phenotype A the possible genotypes are *AA* and *AO*, whereas in group B (phenotype B), *BB* and *BO* are the possible genotypes corresponding to phenotype B; in group O the genotype is *OO*, the phenotype O; whereas in group AB the genotype is *AB*, and the phenotype is likewise AB. The various genotypes have been worked out by experts, using serologic methods and family studies, and these form the basis of study in heredity of blood groups.

The units of heredity occur in pairs, one member of each pair being contributed by the father and the other by the mother. When the egg or sperm cells are produced, the members of each gene pair separate so that each cell contains only a single gene of each kind. When the sperm fertilizes the egg, the **zygote** is formed, and the genes are paired again in the offspring.

Agglutinogen M is determined by the gene *M* and agglutinogen N by the gene *N*, so that only 3 combinations of the genes in the M-N system are possible: *MM*, *NN*, and *MN*, corresponding to 3 blood types, M, N, and MN. When an individual of type MN is

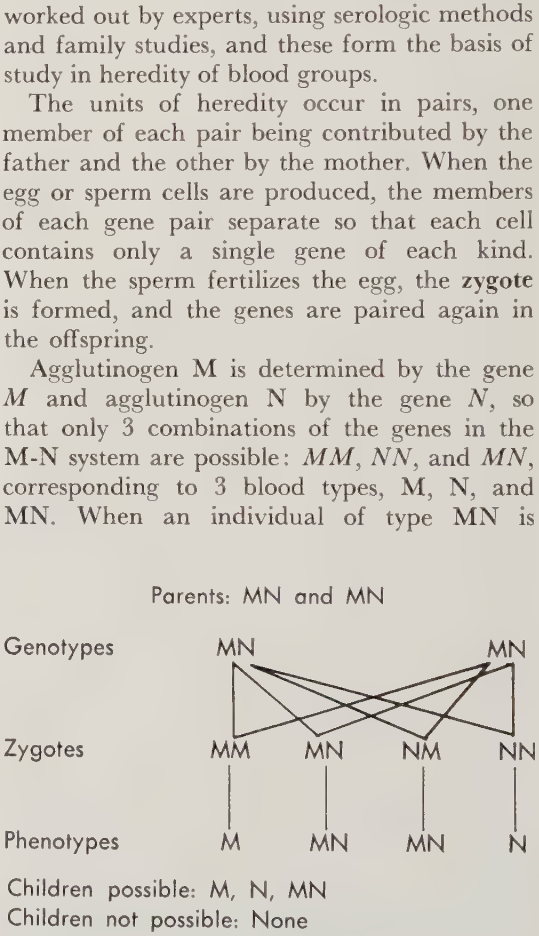

Fig. 514. Mating MN × MN.

	Father		Mother
Parents' phenotypes	Rh_1rh		Rh_2rh
Possible genotypes	R^1r	×	R^2r
	R^1R°	×	R^2R°
	$R^{\circ}r'$	×	$R^{\circ}r''$

		Sperm			
		R^1	R°	r'	r
Ova	R^2	R^1R^2	R^2R°	R^2r'	R^2r
	R°	R^1R°	$R^{\circ}R^{\circ}$	$R^{\circ}r'$	$R^{\circ}r$
	r''	R^1r''	$R^{\circ}r''$	$r'r''$	$r''r$
	r	R^1r	$R^{\circ}r$	$r'r$	rr

Possible genotype in children, rearranged:

rr; $r'r$; $r''r$; $r'r''$; $R^{\circ}R^{\circ}$ and $R^{\circ}r$; R^1r, R^1R°, and $R^{\circ}r'$; R^2r, R^2R°, and $R^{\circ}r''$; R^1R^2, R^1r'', and R^2r'.

Possible phenotypes in children—all others excluded:

rh, rh′rh, rh″rh, rh_yrh, Rh_o, Rh_1rh, Rh_2rh, and Rh_zRh_o.

Fig. 515. Method of working out a sample mating to determine possible phenotypes of children in the Rh-Hr system. (Courtesy Dr. A. S. Wiener.)

mated to another individual of type MN, the children possible to this mating are shown in Fig. 514.

Because of the large number of blood factors and hence the various possible phenotypes in the Rh-Hr system, the determination of children possible to certain matings is more complex. Fig. 515 is an example of a method of determining the possible phenotypes of children in matings in the Rh-Hr system. Wiener has selected as an example a father of type Rh_1, phenotype Rh_1rh, and a mother of type Rh_2, phenotype Rh_2rh. (The determination of the phenotypes and the possible genotypes is given in full in Table 314.) The children possible to such a mating are given in Fig. 515. See also pp. 1607-1612.

BLOOD GROUPING TESTS IN THE EXCLUSION OF PATERNITY

In order to gain a complete understanding of this subject, the monograph by Wiener and Wexler, *Heredity of the blood groups,*[346] should be thoroughly studied. Because the human blood group factors have been shown to be inherited, blood grouping tests can be applied to the problem of paternity. Wiener has outlined types of cases in which such tests are applied. Unger has also reported important cases and observations on this subject.[347]

1. A man accused of the paternity of a child born out of wedlock denies the charge. This is the most common type of case for which blood grouping tests are ordered.
2. A man accused of assault or rape tries to prove innocence by showing that he is not the father of the child born to the complainant.
3. A child is born in lawful wedlock, but the husband denies paternity.
4. It is suspected that 2 newborn infants have been interchanged in a hospital.
5. A woman may simulate pregnancy and childbirth and may claim that a certain child is hers, to compel a man to marry her or to obtain dower in a dead husband's estate.
6. An individual who wishes to migrate to the United States asserts that his parents are American citizens living in the States, but it is suspected that the claim is fraudulent.

Blood tests are used only to exclude, not to prove, paternity. Examinations should be restricted to such tests that have been proved reliable and in which an adequate number of studies on heredity have been carried out. The Committee on Medicolegal Problems of the American Medical Association has recommended that the routine tests for court cases be limited to the **A** and **B** factors of the A-B-O system, the **M** and **N** factors of the M-N-S-U system, and the $\mathbf{Rh_o}$, **rh′**, **rh″**, **hr′**, and **hr″** factors of the Rh-Hr system. In private cases or under special circumstances, qualified medicolegal experts may carry out more complete examinations.

With respect to the blood groups, certain fundamental facts are apparent:

1. Blood factors cannot appear in the blood of a child unless present in the blood of one or both parents. This is true in all the blood group systems. If both parents have a definite blood structure, it is usually but not always present in all the children.
2. A person belonging to group AB cannot be the parent of a group O child.
3. A person belonging to group O cannot be the parent of a group AB child.
4. If a child is type M, the **M** factor must have been present in the blood of both the mother and father; similarly, if the child is group N, the **N** factor must have been present in the blood of both mother and father.
5. A person of type MN has derived the **M** factor from one parent and the **N** factor from the other.
6. The **M** factor cannot appear in a child unless it is present in a parent; similarly, the

N factor must be present in one or both parents in order to appear in a child.

7. If either or both parents are type M, the offspring cannot be type N. If either or both parents are type N, the offspring cannot be type M.

8. If both parents are Rh negative, there can be no Rh factor in the agglutinogens of any of the children.

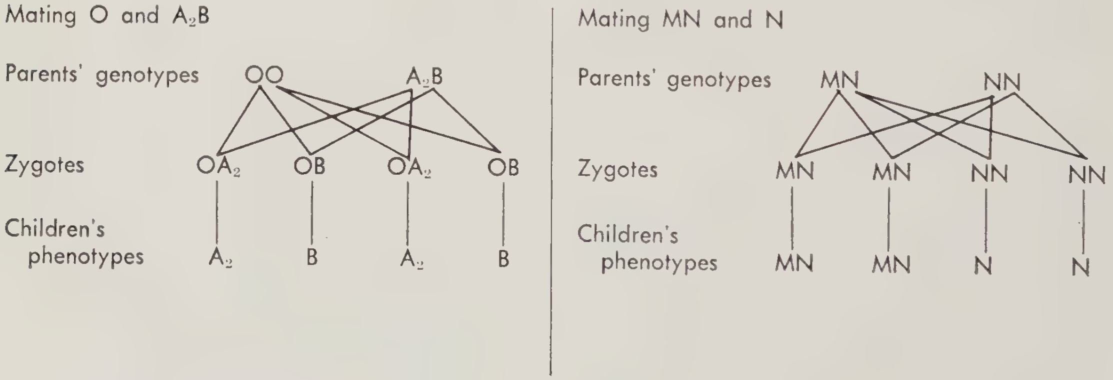
None of the Rh factors can appear in the blood of a child unless present in the blood of at least one of the parents. Since the factors of any Rh agglutinogen are inherited as a block, as Wiener has pointed out, a knowledge of the genotype possibilities in any given case is essential. A complete list of the possible matings in the Rh-Hr system and phenotypes of children is found in Table 349.

The following case has been described by Gradwohl[348] to illustrate the manner of using blood group systems A-B-O and M-N in cases of disputed paternity.

> This was a case in which the husband feared that he was not the father of his 4 yr. old child, although he stated that he had no reason to doubt the faithfulness of his wife. The father wanted this test carried out because one of his friends, evidently a trouble maker, had suggested to him in a bantering manner that he might not be the father of his child. This caused him such mental unrest that he determined to have the tests made to ease his mind. Fortunately, we were able to accomplish this purpose.
>
> The mother, child, and husband were tested in the usual manner for blood groups A-B and types M-N. The results of the tests were as follows:
>
> Mother was OMN
> Child was A_2N
> Father was A_2BN
>
> With this rather unusual combination of blood groups it was very easy to state that this man could have been the father of the child, although, as stated above, actual paternity cannot be definitely proved by these tests. Since the child possessed the agglutinogen N, which was present also in the mother's blood, the father must necessarily have had agglutinogen N in his erythrocytes. With a group O mother and a group A_2B father, the children will be either A_2 or B but not O or A_2B. (Tables 347 and 348.)
>
> Genetics for this case would be expressed as shown in Fig. 516.

With the rapid advances and discoveries in the field of blood grouping, we may look forward to a time, predicted by Landsteiner, when blood groups will be as specifically identifying as fingerprints, but that time has not yet arrived. Unger states that in approximately 50% of cases it may be impossible to establish the innocence of a man falsely accused of paternity. For example, if both the mother and the infant are group O MN and the accused man is group O MN, and all Rh phenotypes and genotypes are compatible, resort to the other factors must be made. No conclusions can be drawn on the basis of the A-B-O, M-N, and Rh-Hr tests in such a case except that the accused cannot be excluded as a possible father of the child. If, however, the accused is group AB, he is at once exonerated in this case, since no AB individual can be the parent of a group O child.

One fact must be emphasized, as Wiener has repeatedly shown, and that is that the factors of each Rh-Hr blood group agglutinogen are inherited as a block; for example, if one of the parents is type Rh_1Rh_1 and the other parent is type rh, the children possible must be ascertained by figuring the genotype of the first parent as R^1R^1, or R^1r' (Table



Children possible: A_2, B, MN, N

Children not possible: O, A_1, A_1B, A_2B, M

Fig. 516. Mating OMN × A_2BN.

314) and the genotype of the second parent as rr. The children possible to this union could be only R^1r or $r'r$; i.e., phenotype Rh$_1$rh or rh′rh but not any other phenotype. But if the Rh$_1$ parent is phenotype Rh$_1$rh, the genotypes could be R^1r, R^1R^0, or R^0r', in which case the children possible (with the other parent type rh) would be R^1r, R^0r, $r'r$, or rr. The phenotypes of the children in this mating could be Rh$_1$rh, Rh$_0$rh, rh′rh, or rh. An example of a mating of an Rh$_1$rh individual with an Rh$_2$rh person is given in Fig. 515.

In making tests to determine paternity, in which the Rh-Hr system of blood groups is used, it is vitally important that the phenotype of the parents be established. In such cases tests of the cells are made using at least all the standard anti-Rh and anti-Hr testing sera: anti-**Rh**$_0$, anti-**rh′**, anti-**rh″**, anti-**hr′**, and anti-**hr″**. It is also suggested that anti-**rh**^{w} testing serum be used as an additional aid in determining the phenotypes and possible genotypes of the parents.

Wiener[349] cited an unusual case which had been reported in detail by Franceschetti et al.[350]

> The blood specimens were submitted to Wiener and others for examination because the results of the A-B-O and M-N tests were inconclusive. The father of a pair of 5 yr. old twins, who did not look alike, while at a party noticed a boy who looked like one of his twins. Inquiry revealed that this boy had been born in the same hospital as the twins, and on the same day, and the possibility presented itself that there might have been an interchange.
>
> The boy in question and the twin he resembled both belonged to type A$_1$ MN Rh$_1$Rh$_2$ whereas the dissimilar "twin" belonged to type rh. The mother of the twins was Rh$_1$Rh$_1$. Since the genotypes of the mother were either R^1R^1 or R^1r', she could not have had an Rh-negative baby, since one of its r genes must be derived from the mother and the other from the father. Wiener states that he has been informed that the 2 boys who had been interchanged in the hospital have now been restored to their rightful parents by order of the court.
>
> Another case cited by Wiener in the same article was of a problem presented by 2 men, one married and the father of 2 children. His wife was pregnant for the third time. The problem was whether the husband or the other man was the father of the baby soon to be born. The bloods of the 2 men and the expectant mother were typed, and as soon as the baby was born her blood was tested. The results are given in Table 344.
>
> No decision in this case was possible on the basis of the A-B-O types, since the husband could be of the genotype A_2O and the other man could be BO. Nor could any decision be made on the basis of the M-N or P types. With regard to the Rh-Hr tests, the mother and baby were both type rh, genotype rr. One of the baby's r genes is obviously derived from the mother, the other from the father. If the husband were really the father, one would have to assume that he belonged to the rare genotype R^zr. On the other hand, the other man belonged to type Rh$_0$, and most Caucasoids of this type belong to genotype R^0r. The plausible conclusion was, therefore, that the other man and not the husband was the father of the baby. To solve the problem more definitely, the older 2 children were typed and both proved to be A$_2$ MN Rh$_2$rh. Accordingly, the father had to possess an R^2 gene and therefore did not belong to genotype R^zr. This definitely excluded him as the father of the third child.
>
> An interesting sidelight of the case is that the relationship between the 2 men was very amicable, and they shared all expenses equally. It was agreed that since the other man was the father of the child, he would adopt it without informing his own wife of the circumstances. In order to avoid comment from the mother's relatives, the baby was to have been sent to an institution because supposedly it was ill, and presumably the relatives were led to believe that the baby failed to recover.

Table 344

Blood of	*Group and subgroup*	*M-N type*	*Rh-Hr type*	*P factor*
Husband	A$_2$	M	Rh$_z$Rh$_0$	Negative
Wife	A$_2$	MN	rh	Negative
Baby girl	O	M	rh	Negative
Other man	B	M	Rh$_0$	Negative

Qualifications of experts

The Committee on Medicolegal Problems of the American Medical Association published 2 reports dealing with the medicolegal application of blood grouping tests[351-353] in which the importance of permitting only fully qualified experts to carry out blood tests in medicolegal cases has been stressed. This is to avoid the possibility of errors and miscarriages of justice. Serious errors have been made in the hands of unqualified laboratory personnel in performing these delicate tests.

Blood groups and disputed maternity

Blood tests may also be used in excluding disputed maternity in kidnapping cases, in cases in which newborn babies have been inadvertently interchanged in hospitals, and in immigration cases in which an individual seeking admission to the United States falsely claims certain American citizens as his parents. Wiener[354] reported 2 kidnapping cases in New York City where blood grouping tests were applied successfully.

When Anti-Rh_0 tube serum gives a negative result, wash contents of tube 4 (Anti-Rh_0 slide serum) three times with saline, remove saline, shake, replace in water bath 5 minutes, add 1 drop of Coombs serum, shake, centrifuge 2 minutes at 500 to 1000 r.p.m., and read. If positive, $\mathfrak{R}h_0$ is present.

Fig. 517. Setup for blood grouping tests in cases of disputed paternity.

TECHNIC OF BLOOD GROUPING TESTS FOR THE EXCLUSION OF PATERNITY*

All tests should be made at least in duplicate, using 2 sets of antisera from 2 different manufacturing sources. If these are not available, use 2 sets of antisera from the same manufacturer but from batches with different lot numbers. All tests should be read by 2 different persons without knowledge of the results obtained by one another, or the "blind" test of Wiener should be used. Refer to Fig. 517.

It is necessary to have blood specimens from (1) the mother, (2) the baby, and (3) the putative father.

Use clotted blood to obtain serum. Loosen the clot, centrifuge, and remove the supernatant serum, placing it in a properly labeled tube.

Obtain liquid whole blood by taking the specimens in dry anticoagulant (pp. 1461 and 1462) and invert 10-12 times to prevent clotting. The supernatant plasma may be used in place of serum.

If only clotted blood is submitted, make the cell suspensions (both in their own serum and in saline) by dipping a wooden applicator stick in the clot, stirring, and transferring the cells clinging to the applicator stick to the serum or the saline. In the case of serum-suspended cells, the concentration of the cells should be 50%. Centrifuge the suspension and remove enough serum to leave half cells and half serum. With saline-suspended cells the final concentration after washing should be a 2-3% or in some special tests, 5%. If the blood has been taken in an anticoagulant, transfer sufficient whole blood to saline to make the proper suspension.

---

*The author wishes to acknowledge the kindness of Dr. L. J. Unger in demonstrating these tests to me in his laboratory.

Wash the saline-suspended cells once with saline and resuspend to a 2-4% concentration.

The following antisera will be needed: standard anti-**A**, anti-**B**, anti-**A**$_1$ (absorbed group B serum) for A-B-O tests and subgroups; anti-**M**, anti-**N**, for the M-N system; and anti-**rh**′, and anti-**rh**″, and anti-**Rh**$_0$ saline agglutinating serum, and anti-**Rh**$_0$ conglutinating or slide test serum, for Rh factors; anti-**hr**′ and anti-**hr**″ to determine Rh phenotypes.

Prepare saline-suspended cells of the mother's, the baby's, and the putative father's bloods. Wash the cells once with saline and resuspend to a 2-4% concentration in saline. In testing for the Hr factors, use ficinated cells (p. 1463).

1. Test the cells for A-B-O groups by mixing the cells with anti-A and anti-**B** sera of high titer. At the same time make controls on the antisera. Carry out the technic given on pp. 1467ff.
2. Check the results in step 1 by testing the serum or plasma of the mother, baby, and putative father against known A and B cells suspended in saline (p. 1469). If results in step 2 are different from results in step 1, repeat the tests, using different antisera in step 1. When isohemolysis occurs, the results cannot be determined readily; inactivate the serum, cool to room temperature, and repeat the test.
3. Subgroup all A and AB bloods using cell suspensions against absorbed anti-**A** serum or anti-**A**$_1$ Lectin on which proper controls have been made. See p. 1471.
4. Test the cells against anti-**M** and anti-**N** sera on which proper controls have been run. This will give the M-N types. See p. 1554.
5. Prepare 3 sets of tubes in racks having 4 rows of holes and use small Kahn tubes in each case (7-8 mm. inside diameter). Each set of 4 tubes must be prepared for tests of (1) the blood of the mother, (2) the baby, and (3) the putative father. See Table 345. Saline-suspended cells washed once and resuspended in saline are used, except that ficinated cells are best for Hr testing.

Test for **rh**^{w} only when the unknown cells are shown to have **rh**′, as in types Rh_1, Rh_z, rh′, and rh_y. Do not add the anti-**rh**^{w} serum, which is in short supply, until tests for **rh**′ have been proved positive. If these tests are negative, it is not necessary to make the test for **rh**^{w}. Use 1 drop of unknown cells + 1 drop of anti-**rh**^{w} serum.

6. While these racks are standing at their respective temperatures (see specific procedures for each factor), prepare a set of tubes for Hr testing:
   (a) Prepare the cells of the mother, baby, and putative father as follows: Place 2 drops of saline-suspended cells to be tested (after washing twice in saline and resuspending to a 3-5% concentration) in each of 2 small Kahn tubes labeled, respectively, hr′ and hr″ and identified as containing the mother's blood, that of the baby, or that of the putative father.
   (b) Add to each tube 1 drop of 1% ficin diluted 1:5 with saline (p. 1463).
   (c) Shake well.
   (d) Place in a water bath at 37° C. for 15 min. for completion of the enzyme treatment of the cells.
   (e) Wash once with saline and remove the supernatant fluid.
   (f) Add 1 drop of anti-**hr**′ serum to the tubes labeled hr′ and 1 drop of anti-**hr**″ serum to the tubes labeled hr″.
   (g) Do not add the Hr antisera until tests for **rh**′ and **rh**″ have been shown to be positive. If the test for **rh**′ is positive, proceed with the test for **hr**′. If the test for **rh**″ is positive, proceed with the test for **hr**″. (It is generally thought that it is not necessary to test for **hr**′ if tests for **rh**′ are negative or to test for **hr**″ when tests for **rh**″ are negative, and that Rh-negative bloods with rare exception are **hr**′ and **hr**″ positive, but all $\overline{Rh}_0$ and $\overline{\overline{Rh}}_0$ bloods would be missed by following this procedure.)
   (h) Shake well and place in a water bath at 37° C. for 40 min.-1 hr.
7. Read the results of the Rh tests in the usual manner, as directed on p. 1517. If tests for **Rh**$_0$ are negative in tube 3, wash the cells in **tube 4** three times with saline; then, after removing all the saline proceed with the antiglobulin (Coombs) test. Refer to p. 1517. This is the test for $\mathfrak{Rh}_0$.
8. Gently dislodge the sediment in the test for **rh**^{w} and read the results macroscopically and under a scanning lens of a microscope. If the results are negative, as they are in many cases because of the nature of the **rh**^{w} antisera, proceed as follows:
   (a) Wash the contents of the tube showing negative results 3 times with saline; after

Father	–	+		–	+	+	+	+	Not necessary	+	+	B N Rh$_z$Rh$_0$ (see Table 314)
Baby	+	–	–	+	+	–	+	+	Not necessary	+	+	A$_2$ MN Rh$_2$rh (see Table 314)

Confirmation of A-B-O grouping

	Serum + A$_1$ cells	*Serum + B cells*
Mother	–	+
Father	+	–
Baby	–	+

The following combinations of genotypes are possible in this case:
Mother: A_2A_2 *or* A_2O, MM, rr
Father: BB or BO (if this man is the father of this child, he must be BO), NN, R^zR^0 or R^1R^z, or R^zr, R^1r'', R^zr', R^0r^y
Baby: A_2A_2 or A_2O (if this man is the father of the child), MN, R^2R^0 or R^2r or R^0r''.

---

*Except for the rare types containing $\overline{\mathbf{Rh}}_0$ or $\overline{\overline{\mathbf{Rh}}}_0$, Rh-negative bloods are invariably **hr**′ and **hr**″ positive.

the last washing and centrifugation turn the tubes upside down and strike hard against a gauze pad to remove all trace of saline, but do not remove the cells.

(b) Add 1 drop of antiglobulin (Coombs) serum to each tube and shake.

(c) Centrifuge for 1 min. at 1000 r.p.m. without further incubation.

(d) Read the results of the tests after centrifugation both macroscopically over a lighted viewing box and under a scanning lens of a microscope. Report whether the results are positive or negative and the degree of agglutination if positive.

(e) In reporting results of tests for Rh-Hr factors, always report in terms of phenotypes, not genotypes, by referring to Table 314.

9. As a confirmation of the results of Hr testing, make slide tests on whole blood using anti-**hr**′ and anti-**hr**″ conglutinating (slide test) serum. These tests may be omitted if desired.

Table 346 shows results in a test made of mother, father, and baby and conclusions drawn with respect to A-B-O, M-N, and Rh-Hr types. See also Tables 347-349.

The discovery of the blood factor **hr**^{S} by Maurice Shapiro will aid in solving some of the baffling cases in the study of blood group genetics. Many commercial anti-**hr**″ sera contain unknown quantities of anti-**hr**^{S}.

For further information concerning the use of blood grouping tests in disputed paternity, refer to Wiener and Wexler,[346] Wiener,[372, 374, 374h] and Schatkin.[374a]

A summary of the various matings and possible children is shown in Tables 347-349.

SUMMARY AND CONCLUSIONS OF THE REPORT OF THE COMMITTEE ON MEDICOLEGAL PROBLEMS OF THE AMERICAN MEDICAL ASSOCIATION[355]

"Because the use of two systems of nomenclature for the Rh-Hr system leads to confusion and misunderstanding, the Committee on Medicolegal Problems of the American Medical Association recommends the adoption of a single uniform system for medicolegal reports. It is recommended that, unless and until some other convention can be agreed upon, the original Rh-Hr notations be kept as the standard and sole nomenclature for preparing approved medicolegal reports on Rh types.

"It is recommended that routine medicolegal applications of blood grouping be restricted at present to tests for the four blood groups, O, A, B, and AB of the A-B-O system; the three types M, N, and MN of the M-N-S system; and factors **Rh**$_{0}$, **rh′**, **rh″**, and **hr′** of the Rh system. Tests for additional factors and systems are considered insufficiently established for routine use at present, although they may provide evidence in particular selected cases. Such evidence should be submitted in a separate letter not part of the standard report and should be presented with proper caution. Similarly, the value of rare combinations of groups providing indication of paternity, in contrast to the conventional use of the tests to establish only nonpaternity, should be recognized in unusual cases but should be treated with caution in a separate communication not part of the definitive report."*

It must be stressed that only those especially trained in making medicolegal blood grouping tests should be permitted to make such examinations and that ability to group and match blood for transfusions does not qualify one for medicolegal work. Since the Committee on Medicolegal Problems of the American Medical Association has recommended the use of Rh-Hr nomenclature and not the C-D-E notations, one of the qualifications of the expert necessarily is that such a person must be thoroughly versed in the recommended nomenclature.

IDENTIFICATION OF BLOOD STAINS

Identification of blood stains is made in cases of alleged hit-and-run driving, rape,

murder, or wherever stains suspected of being blood are found. The specimens are received in the laboratory on a variety of objects. These must all be carefully labeled in indelible ink, and the specimens must be kept for possible later presentation in court. This work must be done only by those properly qualified to perform the tests. It is much more difficult to perform these tests than is ordinary blood grouping. It requires much practice to develop the accuracy required in medicolegal examinations. At least 50 known blood stains should be correctly identified before a person is qualified to perform this work in medicolegal cases.

Gradwohl[356] pointed out the importance of maintaining the integrity of the chain of evidence. All evidence should be collected by members of the laboratory staff and by no one else, and the laboratory staff must work in close harmony with the homicide squad. Material should be brought to the director's office, routinely entered in the laboratory book of entry, with time, names, and other pertinent data all written, and receipts properly given by those who receive the specimen. Full written data must be compiled covering the name of the person who brought in the specimen, the time brought in, and the date. A receipt should be given to the individual who brings in the material, and that person should also make a written statement that he has brought in the material. One must be prepared to submit all this written evidence during the trial of the case.

Identifying a blood stain presents 3 problems: (1) Is the stain produced by blood? (2) If so, is this human blood? (3) To what blood group does it belong?

Tests to prove that stains are blood

Chemical tests and spectroscopic examination

Chemical tests and spectroscopic examination will definitely establish the identity of a stain as blood or not blood.

Benzidine test

The benzidine test may be made directly on the stained area or on an extract of or scrapings from the stain. In any case control tests must be made of the unstained area at the same time that tests are made of the stain. All glassware used in the test must be new or thoroughly cleaned and dried in a hot-air oven.

1. Prepare an extract in saline of the material suspected of being blood. If this is in the form of scrapings, use a very small amount of the scrapings without dissolving, or, if preferred, dissolve in a **minimum** quantity of physiologic saline.
2. If the stain is on cloth, cut out the stained portion, place it in a small (7 mm. inside diameter), tube, and add 1 or 2 drops of saline. Mark the area from which the stain has been removed, using indelible ink.
3. Prepare the control specimens from the unstained material in a similar manner. If the control specimens show a positive reaction, no further work may be done, as the test in such cases would be unreliable.
4. Prepare a saturated solution of benzidine, special for blood, in glacial acetic acid* by placing a small amount of benzidine in a clean small tube, free from blood, and adding about 0.5-1 ml. glacial acetic acid to it. Shake vigorously. If all the crystals dissolve, add more benzidine until the acetic acid will not take up more of the benzidine. This solution must be prepared fresh for each test.
5. Add an equal volume of 3% hydrogen peroxide and mix thoroughly. If this solution turns green or blue, discard and prepare a fresh solution, using different glassware, because the green or blue color in the reagent may have been caused by blood either in the glassware or in the chemicals used to prepare the solution.
6. Place a drop of the extract or the scrapings on a **new** clean glass slide and add a drop of the benzidine reagent. This reagent may be added with a wooden applicator stick or with a small glass rod. Or add the reagent directly to the stained area without any preliminary preparation.

---

*The benzidine dihydrochloride test, p. 1835, may be used instead.

A green or blue color indicates the presence of blood. If this color fails to appear, repeat the test. If no color appears, the stain was not derived from blood and the test is terminated at this point. If the specimen from the unstained portion of the material shows a blue or green color with this test, the results of the test on the stained area are valueless and no further work may be done.

Phenolphthalein test (reduced phenolphthalein test)

Refer to p. 1834 for details of this test.

Spectroscopic examination of blood stains

Although the spectroscopic examination of blood is not routine practice, it is used at times in testing denatured blood.

The spectroscopic examination is based upon the fact that when a solution of blood is examined in a spectroscope, certain black bands, called absorption bands, will be formed in the solar spectrum. Especially constructed spectroscopes are used. These instruments are so made that the absorption properties of translucent color fluids can be observed on the solar spectrum. There are many varieties of spectroscopes—a large laboratory spectroscope, a smaller direct vision spectroscope, and a microspectroscope that can be attached to an ordinary microscope. The last instrument is used only when a minute quantity of specimen is available.

1. Dissolve the stain in distilled water. The solution must be quite dilute.
2. Place the solution in a small glass chamber with parallel sides so arranged that rays of light will pass directly through it; then place the chamber containing the dissolved stain in the spectroscope and adjust the instrument so that the spectrum is clearly visible. The blood will absorb some of the light rays from the spectrum, producing characteristic absorption bands, which vary with the type of blood pigment present.

Oxyhemoglobin: 2 bands in the yellow between the Fraunhofer lines D and E.

Hemoglobin: A broad band between D and E, with a small rim over D on the red side of the spectrum.

Carboxyhemoglobin: Similar to oxyhemoglobin. Addition of ammonium sulfide reduces oxyhemoglobin to hemoglobin but leaves carboxyhemoglobin unchanged.

Methemoglobin: A dark band in the red between C and D but nearer C. If the solution is diluted properly, it splits into bands resembling bands of acid hematin.

Acid hematin: A sharp band between C and D, nearer to C, and a broad band, not clearly defined, between D and F.

Alkaline hematin: A band between C and D. It also absorbs the violet end of the spectrum.

Hemochromogen: A sharp, dark band between D and E and a pale, broader band over E.

Hematoporphyrin in alkaline solutions: A faint line between C and D, a broader band at D and extending toward E, a band between D and E but nearly at E, and a broad band between E and F.

Old stains, when diluted, give hemoglobin and oxyhemoglobin bands. If a weak alkali is added, alkaline hematin is formed. If a weak acid is added, acid hematin is formed. Old and decomposed stains yield positive tests for hematoporphyrin. Add strong alkali to a portion of the blood solution to obtain alkaline hematoporphyrin bands.

Fresh blood shows oxyhemoglobin bands. Add a weak solution of ammonium sulfide to obtain the spectrum of hemoglobin. Add a dilute sodium hydroxide solution for hemochromogen bands. These 2 tests prove the presence of blood and also eliminate substances of vegetable and animal origin with spectra similar to that of oxyhemoglobin.

Tests to determine whether the stains are human blood

Precipitin test

The principle of the precipitin test is based upon the work of Kraus who showed that by immunizing a rabbit with injections of a culture of a bacterium one could obtain a serum which, when added to a filtered culture of that bacterium, produces a precipitate in it. Bordet[357] and Gengou[358] went further in carrying out this immunization experiment.

Uhlenhuth worked out the same principle in relation to the precipitin test and its value as a medicolegal procedure. He injected rabbits with human blood and tested the antiserum on 19 different bloods, finding a positive reaction only with human blood. Uhlenhuth[359] published his tests on blood-stained articles such as sticks, sand, cotton, trousers, hatchet, etc. He showed that the antiserum made by injecting rabbits with human blood acted only with suspected human blood and that antiserum injected with pig's blood reacted only with pig's blood, etc. In other words, a precipitation occurs in the blood when in contact with homologous blood. Perhaps the most exhaustive of all these works was done by Nuttall,[360] who examined sera of all animals of any importance on the face of the globe.

Nuttall[360] in 1904 gave a classical account of blood relationships by means of the precipitin test. His work was done primarily to show that a common property exists in the blood of certain groups of animals, a property that has persisted throughout the ages which elapsed during our possible evolution from a common ancestor. He placed Man and Apes in one order, based on this work, the Anthropoidea. Since the publication of Nuttall's book in 1904 and the present time, there have been occasional references in the literature on the specificity of the precipitin test.[361] Gradwohl[362] found that chimpanzee blood gave a ring reaction identical to that given by human blood, with antihuman precipitin serum, and that human blood gave an identical ring reaction with antichimpanzee precipitin serum. He further showed[363] the same results using blood from the gorilla and the olive baboon *(Papio anubis)*.

In a personal communication from Lloyd M. Shupe, Columbus, Ohio, it was pointed out that some antihuman precipitin sera also give positive reactions with raccoon blood. This has been confirmed in our own laboratories.

In other words, using the "ring" precipitin test, it is impossible to differentiate the bloods of these 3 primates and man. Duncan-Taylor and Gordon,[364] by special alum absorption methods, thought it was possible to produce a precipitin serum which would exclude the blood of primates when the "ring" test is made. Their method is given on p. 1616. Gordon also examined blood stain extracts against an ox serum-absorbed antihuman precipitin serum to establish that it is primate blood, but this absorbed serum is of very poor potency.

There is no simple, practicable method available at present to distinguish between the blood stains of man and the other primates (apes, monkeys including baboons, lemurs, or nachtaapje.

Two principal methods of carrying out the precipitin test are available: the ring test technic and the flocculation test. The precipitins which are formed in animals by the injection of human blood are precipitins not for blood only but also for human protein. It is for this reason that this test can be used not only for the identification of blood but also for seminal stains, bone fragments, and meat adulteration; e.g., addition of chopped horse meat to chopped beef.

It is necessary that the antiserum used in the test be made properly and that it be tested on sufficient numbers of known positive speci-

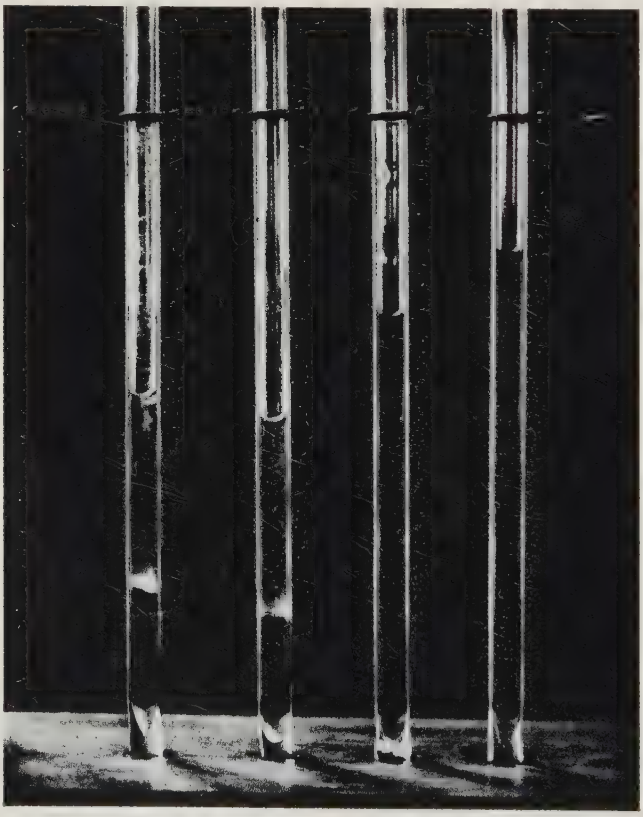

Fig. 518. Precipitin ring test. **A,** Antichimpanzee serum vs. chimpanzee blood. **B,** Antichimpanzee serum vs. human blood. **C,** Antichimpanzee serum vs. guinea pig blood. **D,** Antichimpanzee blood vs. rabbit blood. (From Gradwohl, R. B. H.: Lab. Digest 15:4, May, 1952.)

mens to warrant its use in medicolegal procedures. These antisera react with groups of mammalian bloods, and therefore in order to single out an individual of the mammalian group one must resort to high dilutions. By high dilutions is meant that the antiserum must be very potent and the material under investigation extremely well diluted for the actual test.

The use of a reliable antiserum is of course one of the most important considerations in making this test. Either prepare these antisera in the laboratory or purchase them from reliable biological houses. The latter is probably better for those who do only an occasional precipitin test. These antisera are quite stable.

In preparing the antisera it is best to employ a number of animals for the immunizations, at least 6. Animals may be immunized by injecting human blood daily over a period of 6 weeks. After this time a quantity of blood is taken from the ear and tested with a known positive human blood. If it is effective in a high dilution, the animals are bled to the point of exsanguination under aseptic precautions and the blood is collected in a sterile manner. Blood from these animals should be taken preferably several hours after the rabbits have eaten or during a period of fasting. If blood is taken from the animal immediately after a meal, the serum is likely to be opalescent.

An antiserum to be efficient should so act that 0.1 ml. when added to its respective serum-antigen in a dilution of 1:1000 produces a turbidity either at once or in 1-5 min. at the latest, with the formation of a distinct precipitate in 30-60 min.

Preparation of antihuman precipitin serum: Following is the method used by Gradwohl. It gives excellent results.

Select 6 healthy rabbits. Make 50 ml. of a 1:10 dilution of sterile human serum or plasma in saline by adding 45 ml. sterile physiologic saline to 5 ml. human serum or plasma obtained under sterile conditions.

Mark each rabbit with a tag or with indelible ink for identification, and keep complete records of each rabbit and each injection. Inject 2 ml. of 1:10 dilution of human serum or plasma into the marginal ear vein of each rabbit. Beginning on Monday and continuing through Saturday make daily injections so that a total of 6 injections is given to each rabbit.

Allow 1 wk. to elapse; then inject each rabbit with 2 ml. of 1:10 dilution of human serum or plasma **intramuscularly** (to prevent anaphylaxis), followed by daily injections for the next 5 days, giving these 5 injections intravenously as in the first week.

Allow 1 wk. rest interval. Repeat the 6 injections of 2 ml. of 1:10 dilution of human serum or plasma, giving the first injection intramuscularly and the next 5 intravenously.

Wait 1 wk. Then withdraw a small quantity of blood from each rabbit, allow to clot, loosen the clot, centrifuge, remove the supernatant serum, and test the serum to determine whether any antihuman precipitin has developed. In other words, carry out an actual precipitin test as described below to determine whether the rabbit's serum will detect the presence of human blood. Usually 1 or more of the 6 rabbits will show this antihuman precipitating antibody. Estimate by dilutions the potency of the antibody. Reject all rabbits' sera not reacting in at least a 1:1000 dilution. Carry out controls with both positive and negative specimens.

If 1 or more of these rabbits has developed an antihuman precipitin of high titer, procure the entire content of blood from the selected rabbit or rabbits by dissecting the carotid artery and bleeding into sterile 50 ml. Rockefeller centrifuge tubes, using all sterile precautions. (See p. 808 for method of bleeding rabbit from the carotid artery.)

Label the Rockefeller tubes carefully and allow the blood to clot in a slanting position. Loosen the clots by striking the tubes against the palm of the hand, refrigerate 24 hr.; then centrifuge at high speed for at least 20-30 min. to separate the serum. With all sterile precautions carefully decant the supernatant serum and place it in sterile corked tubes. Inactivate at 56° C. to destroy the natural complement and to kill air bacteria which may have entered the blood during the procuring process. Add enough Merthiolate as a preservative to give a 1:10,000 concentration (0.1 ml. of 10% solution to 100 ml. serum).

Ampule in 1 ml. quantities in sterile glass ampules, using sterile precautions. Seal in a flame, label with the number of the rabbit, the date, and titer, and store in a refrigerator.

Technic of precipitin "ring" test:

Use 5 mm. tubing with a 2 mm. bore. This is very heavy-walled narrow glass tubing. Cut it into 12 cm. lengths and seal one end in the flame. These very small caliber test tubes are used in the precipitin test. They must be clean and dry.

Soak the material to be examined in saline for some time. When stains have been exposed to high temperatures, it is necessary to soak as long as 72 hr. This extraction should be carried out in a refrigerator to avoid bacterial action and turbidity. No chemical solvents except saline should be used, regardless of how difficult it may be to obtain an extract. If the extract contains debris or is cloudy, centrifuge and use the supernatant liquid for the test or filter through a Berkefeld filter. Use a minimal quantity of saline for the extraction.

Prepare a similar extract of the **unstained portion** of the material under examination. Make the dilution about the same as that of the stained area.

Various dilutions of the extract should be used, preferably a 1:100 and 1:1000, although higher dilutions may be made and tested if desired. Dilutions of the stain of 1:1000 or higher will show only a scanty foam upon shaking.

Prepare a dilution of **known human serum** of approximately 1:100 strength by adding 1 small drop of human serum to 5 ml. saline.

Prepare a **negative control serum** by adding 1 drop of bovine or canine blood serum to 5 ml. saline (1:100).

Place antihuman precipitin serum in each of 5 small caliber tubes described above. Add this to a depth of several cm. Label the tubes (1) blood stain, (2) unstained portion, (3) known human serum, (4) bovine or canine serum, and (5) saline.

Stratify an **equal volume** of solution from the suspected stain on the serum in the first tube; use the extract from the unstained portion in the second tube, diluted human serum in the third tube, diluted canine or bovine serum in the fourth tube, and saline in the fifth tube. This is accomplished by placing the solution above the serum so that it stands about 1 mm. above it and then giving it a quick flick with the finger so that the 2 fluids come in contact with each other but do not mix.

Allow all tubes to stand at room temperature for 5 min. and read at the end of this time.

If the stain contains human blood, a white line will appear at the point of contact between the 2 liquids. This will be definite within 5 min.

This result cannot be relied upon unless the control tests are as follows: negative reaction in tube 2, positive in tube 3, and negative in tubes 4 and 5. Positive reactions occur from human perspiration, urine, etc.

In carrying out the test the numerous controls must be used, all carefully marked. If the object of the test is merely to identify the suspected stain as coming from a human source, the procedure can be rapidly carried out. But if the blood is not of human origin and an opinion is desired regarding its source, it then becomes necessary to test the blood serum in turn with antisera of different specificities until a positive result is obtained. It is helpful in such cases if the circumstances give some clue as to what species blood is likely to be present.

It has been found that human blood stains dried for 10-15 yr. may still show a positive reaction. Hansemann,[365] Meyer[366] and Friedenthal have given accounts of their examinations of mummy tissue with the use of precipitating antisera. The first obtained a positive reaction with such material 4000 yr. old, the second with tissue 5000 yr. old, whereas the last named failed to get a positive reaction with mummy tissue 500 yr. old. Nuttall[367] has shown that if there is a mixture of several different bloods in solution, this does not prevent a reaction from taking place between an antiserum and its homologous blood in this test. This has been confirmed by Ziemke[368] and Smith and Glaister.[369]

Human blood stains that have been washed in water leaving only a faint color of the blood on the garment will still show the reaction.

Smith and Glaister[369] first steeped 24 hr. old and 9 wk. old human blood stains, on white cotton fabric, in cold water for as long as 5 hr. and these still yielded a precipitin reaction. In addition, an appreciable quantity of serum was also found in the steepings. They then subjected 12 wk. old stains to the action of boiling water for from 5 min. up to 1 hr. These stains still yielded a precipitin reaction following extraction with saline for a period of 24 hr. Stains 14 wk. old, however, similarly treated, failed to give a positive reaction on the application of a related antiserum. They concluded, therefore, that in case of fresh stains, boiling quickly extracts the unfixed portion of the blood serum, but in older stains the degree of fixation does not readily permit the serum to pass into solution with the water, although **prolonged** steeping in saline thereafter successfully extracts a sufficient quantity to yield a positive reaction.

If the stains have been soaked in soap powder, this contraindicates the use of this test for medicolegal purposes. Experiments on blood stains with various woods and leathers soaked with blood indicate that the test is always reliable, provided the proper dilution is made.

Alum-precipitated precipitin serum—Duncan-Taylor and Gordon:

Alum antigen:

1. Dilute 25 ml. normal serum with 80 ml. distilled water.
2. Add 90 ml. 10% potassium alum in distilled water.
3. Adjust the reaction to pH 6.5 with 5N sodium hydroxide solution and centrifuge.
4. Wash the sediment twice with 200 ml. 1:10,000 Merthiolate-saline.
5. After centrifugation dilute the final precipitate to 100 ml. with 1:10,000 Merthiolate-saline.

Ten ml. of the antigen are equivalent to 2.5 ml. serum.

Preparation of antiserum: Animals should weigh more than 4 kg. each and be in good condition.

1. Give 5 ml. amounts intramuscularly into both hind legs of the rabbit.
2. Make experimental bleedings by a single puncture of the marginal ear vein on the twentieth day after injection. If sufficiently high titer is obtained, keep the animals without food for 24 hr. and then bleed them from the carotid artery (p. 808), collecting the blood in sterile 50 ml. Rockefeller tubes.
3. Allow the blood to clot in a slanting position, loosen the clot by striking the tube against the palm of the hand, centrifuge for about 30 min., and remove the serum, observing sterile precautions. Place in a sterile graduate

Ox-blood absorption:
1. Measure the serum.
2. Add 7% by volume ox serum to the antiserum.
3. Mix and maintain at room temperature for 2 hr.; then place in a refrigerator at 5° C. overnight.
4. Centrifuge and remove the supernatant fluid.
5. Sterilize by filtration through a Seitz filter.
6. Ampule.

This alum-precipitated ox serum-absorbed antihuman precipitin serum will establish whether or not the blood stain is derived from primates, according to Gordon. **When positive with ox-absorbed serum, the stain is derived from primates.**

If any of the primates is to be excluded by a precipitin test, the antihuman precipitin serum must be prepared in an animal the species of which is to be excluded. Gradwohl[361] has reported results different from those of Taylor and Gordon in that he obtained very little difference in the reaction of chimpanzee blood with absorbed or nonabsorbed antihuman precipitin serum. The reactions were almost indistinguishable.

Reliability of "ring" test:
1. A positive reaction means the presence of human blood.
2. Primate blood (chimpanzee, gorilla, olive baboon, lemur, etc.) will give an identical reaction.
3. Absorption of antihuman precipitin serum with ox blood does not necessarily remove the quality which gives a positive reaction with the antiserum and anthropoid blood.

Flocculation test for identification of mammalian bloods—Libby photronreflectometer (Photron'er)[370]

Gemeroy et al.[370] believe that by the use of a photronreflectometer to determine exact turbidities produced by mixing an antiserum with its corresponding antigen (antihuman precipitin serum with various dilutions of human sera), a serologic correspondence curve for that antiserum can be established, and if the serum is diluted sufficiently, it no longer reacts to a significant degree with any heterologous antigen tested against it in the native state; a different correspondence curve is established for this heterologous antigen. In other words, if an antihuman precipitin serum gives positive "ring" tests with both human and rhesus monkey bloods when the serum is not diluted, the probabilities are that it will not give powerful reactions with rhesus blood when the antiserum is diluted, although it will react strongly with human serum. In the preparation of an antiserum it should therefore be possible to establish turbidity curves showing the type obtained with the antiserum in question and human serum, and the antiserum and other mammalian bloods. Gemeroy et al. have conducted numerous experiments and have produced normal titration curves of antihuman sera titrated with human, chimpanzee, and rhesus antigens. They report the serologic correspondence of the various antigens in percentage relationships with the curve produced by human serum (antigen).

To carry out this work, they use the Libby Photron'er,[370] which makes use of, or measures the amount of, scattered or reflected light that passes through a liquid. It is a delicate means of detecting finely suspended particles. A relatively small number of suspended particles reflects sufficient light to produce a significant reading on the galvanometer, and the greater the number of particles in suspension, the greater the amount of turbidity. A quantitative relationship can be established between the turbidity of a solution and the nitrogen content of a precipitate in protein antigen-antibody systems.

They use alum-precipitated serum for injection of rabbits. In the test the antiserum is serially diluted with buffered saline.

Reagents:
1. Buffered saline.
2. Sodium phosphate solution.
   Dissolve 11.876 gm. Na_2HPO_4 in distilled water and dilute to 1000 ml. with distilled water.
3. Potassium phosphate solution.
   Dissolve 9.078 gm. KH_2PO_4 in distilled water and dilute to 1000 ml. with distilled water.

Procedure:
1. Add 6 ml. of sodium phosphate solution and 4 ml. potassium phosphate solution to 50 ml. 0.85% sodium chloride solution.
2. Dilute to 100 ml. with 0.85% sodium chloride.

Serial dilutions of the serum, 1:250, 1:500, 1:1000, 1:2000, 1:4000, 1:8000, 1:16,000, 1:32,000, 1:64,000, 1:128,000, 1:256,000, and 1:512,000, are made with buffered saline. Each dilution is mixed with the antigen (serum being tested against the antiserum) and tested in the Photron'er. The sum of the turbidities noted from the complete reaction range of the antigen-antibody mixtures represents the precipitation capacity of the antiserum. Comparisons of total turbidities resulting from these summations represent the serologic correspondence of all the antigens tested with a single antiserum.

By making turbidity curves at various dilutions, using the antiserum against different

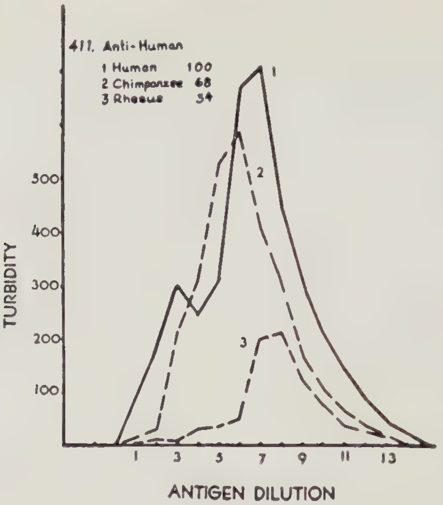

Fig. 519. Normal titration curves when an antihuman serum is titrated with human, chimpanzee, and rhesus antigens. The serologic correspondence of these antigens is recorded in percentage relationships at the top of the figure. (From Gradwohl, R. B. H.: Legal medicine, St. Louis, 1954, The C. V. Mosby Co.)

bloods, one can determine the exact dilution of the antiserum where further dilution would practically "wipe out" any reaction with certain bloods, thereby making this reaction almost species specific. It is possible that this flocculation test may find wider use in identifying specific blood when more facts have been established. For complete details, refer to Gradwohl.[361]

Tests to identify the blood group of stains

The third problem to be solved is the determination of the group of blood to which this human blood stain belongs. For practical purposes the investigation must be limited to a search for the A, B, O, and AB groups and at times for the **M** factor. Results of attempted identification of blood stains for the Rh types are disappointing. The **N** factor disappears rapidly in dried blood, but the **M** factor can be found at times, so that tests for the M-N types are likewise disappointing.

Identification of the various blood factors in a dried stain is often used in forensic medicine to prove that a certain stain did **not** come from a certain individual. If in a given case the blood group of the suspect and that of the victim are the same, no deductions can be drawn, for the stain might have come from the suspect. One must remember that a stain on clothing may be due to group receptors coming from the individual himself. Underclothing worn for several days is almost certain to contain A and B receptors if these are present in the blood and sweat.

But if the investigator obtains different results with the stain found on the suspect and the suspect's own blood, then evidently the stain was derived from a different individual. And if the stain has the same blood factors as the blood of the victim, it might or might not have been derived from the victim.

If liquid blood (unhemolyzed) is submitted, tests are run in the same manner as those used in blood grouping for transfusions. If the blood is submitted in the form of a "crust," and this blood is fairly fresh (not more than 48 hr. old) and sufficient material is submitted, the crust test may be run. Usually, however, one resorts to the agglutinin absorption test to identify blood stains.

Examination of blood crusts

A few sq.mm. of a thin crust, weighing 0.1-1 mg., are sufficient for the crust test. Thick crusts are not satisfactory since they cause the cover slip that is placed over the preparation to be raised too high.

Use a scalpel or razor blade to dislodge the crust from smooth surfaces such as glass, stone, shoe leather, etc. or to cut it from a fabric in which it is embedded.

The test cells used in the crust method should be highly sensitive, the cover glass must be manipulated to break up rouleaux in order to distinguish pseudoagglutination from true isoagglutination, and cells of group O must be used as a control against aggregation produced by other nonspecific causes.

The crust test detects isoagglutinins in the dried blood and is therefore tested against known A_1, B, and O cells.

Procedure:

1. Place 2 small, thin crusts of blood on opposite ends of a glass slide, properly labeled.

2. Near the crust on the left side place 1 or 2 drops of 2% suspension of sensitive A_1 cells, and near the crust on the right side place 1 or 2 drops of 2% suspension, in saline, of sensitive B cells.
3. Place a cover glass over each preparation so that the liquid comes in contact with the edge of the crust and no air bubbles separate the crust from the liquid.
4. Prepare another slide with another portion of the crust and add a 2% suspension of group O cells, placing a cover glass over the preparation.
5. The cover slips must be placed on the mixtures immediately, before the stain has a chance to dissolve. Avoid pressure as much as possible.
6. Wait a few minutes; then examine the preparations microscopically for signs of agglutination. While making these observations, the cover slips may be momentarily subjected to gentle pressure in order to break up any pseudoagglutination present.
7. If no results are evident, examine the slides from time to time for a period of 30 min. This will help detect weak reactions.

The group O cells added to the crust constitute the control and should show no agglutination. If these cells agglutinate, the results in the test are unreliable and must not be reported.

If the A_1 cells have been agglutinated, the stain contains anti-**A** agglutinin.

If the B cells have been agglutinated, the stain contains anti-**B** agglutinin.

The interpretation of results of the crust test are given in Table 350.

Agglutinin absorption test—Wiener

When the blood dries, the red blood cells lose their agglutinability because the free intact cells are destroyed. For this reason no direct test for agglutinogen content of the cells may be made on dried blood stains. The group-specific substances, however, retain their ability to specifically absorb their respective agglutinins. Therefore, if a serum of known titer is added to an unknown blood stain and is later retested, and if its power to agglutinate the cells has been inhibited or lost, it may be concluded that the stain contained the agglutinogen corresponding to the agglutinin in the serum. Agglutinogen A will absorb agglutinin anti-**A**, agglutinogen B will absorb agglutinin anti-**B**, and agglutinogen M will absorb agglutinin anti-**M**. Ulex anti-**H** will be absorbed by group O cells. The agglutinin absorption test is not used for identification of agglutinogen N nor for any of the agglutinogens or factors of the Rh-Hr system.

The difficulty in identifying the blood group of dried blood stains is well known to those who have attempted it. Although fresh blood can be tested for as many as 30-50 or more different blood factors, only the A-B-O groups can be determined on dried stains, and even these tests have serious limitations, as Wiener et al.[371] have pointed out. The presence of sweat, bacteria, dirt, and other interfering substances on soiled garments hampers the investigation for blood agglutinogens. One of the principal difficulties is differentiating A_2B from group B. Since isoagglutinins disappear rapidly in dried blood, sole reliance is often placed on the absorption test for blood agglutinogens, and it is frequently difficult even by this method to differentiate between blood groups A_2 and O.

Only positive reactions are significant. Negative results may indicate failure of the tests. For example, if, in the absorption test, a stain fails to neutralize anti-**A** and anti-**B** reagents, it is not permissible to identify the stain as

Table 350. *Possible results with blood crust test*

Blood crust + A_1 cells	*Blood crust + B cells*	*Blood crust + O cells*	*Agglutinin present in stain*	*Conclusions*
−	−	−	None	Either stain is group AB or there is lack of reaction due to disappearance of agglutinins
+	+	−	Anti-**A** and anti-**B**	Blood stain derived from group O individual
+	+	+	—	Test is unreliable; agglutination due to nonspecific cause
+	−	−	Anti-**A**	Blood derived from group B, or else group O with failure of reaction with group B cells
−	+	−	Anti-**B**	Blood derived from group A, or else group O with failure of reaction with group A cells

group O, since failure of absorption of the antisera might have occurred due to denaturation of the stain and not to lack of agglutinogens in it. Insufficient stain will also give negative results. If a stain neutralizes anti-**A** but not anti-**B**, a diagnosis of group A is generally justified, if one shows that the adjacent unstained material does not react with the reagents. Likewise, if the stain neutralizes anti-**B** but not anti-**A**, it presumably contains group B blood. The absorption test for group A and group B stains has an internal control, and these 2 groups can therefore usually be identified reliably, as Wiener et al.[371] have noted.

Group A_1B stains neutralize both the anti-**A** and the anti-**B** reagents. However, when one observes neutralization of both reagents, a diagnosis of group AB is not permissible because of the possibility that nonspecific absorption of the agglutinins in the reagents has been brought about by the presence of bacteria or dirt in the stain.

When the absorption method is used for grouping dried blood stains, groups A and B can usually be identified reliably but not group O and A_1B stains because of lack of an internal control. Wiener[372] used anti-**O** reagents prepared from normal bovine sera to provide an internal control in these cases since group O stains neutralize such reagents and group A_1B stains do not, but unfortunately the reactions are not always clear-cut and therefore are not suitable for medicolegal use.

The discovery that saline extracts of certain seeds give reactions similar to those of anti-**O** sera made from animal blood has been utilized in the reliable identification of blood groups of dried stains, including those that have no natural internal control. These reagents, as well as animal sera formerly called anti-**O**, have been designated anti-**H** because they do not react exclusively with group O blood cells. Anti-**H** and animal anti-**O** react in almost equal intensity with cells of groups O and A_2. Cells of group B are less strongly clumped, and A_1 and A_1B give negative or weak reactions. The reagent used by Wiener and associates is prepared from the seeds of *Ulex europaeus.*

*Anti-H reagent**

1. Grind a quantity of *Ulex europaeus* seeds in a pepper mill or, after adding saline solution, in a Waring blendor, using a microblade.
2. Dilute to approximately 10 times the original volume in a mixture of equal parts of physiologic saline and 1% sodium acid phosphate (Na_2HPO_4) solutions.
3. Allow to extract for 24 hr. in a refrigerator.
4. Remove the suspended particles by centrifugation.
5. Pass the supernatant opalescent extract through a Seitz filter to clarify it and to remove bacterial contaminants.
6. Store in a refrigerator until needed.

Standardize by direct titration against human red cells of A-B-O groups and by testing the capacity of saliva from secretors to inhibit its reaction with group O test cells. Table 351 shows results of a sample titration of an anti-**H** reagent against known red cells of various groups at refrigerator temperature. It will be seen that 2 different group O cells gave titers of 8 units and 16 units, respectively, or an average of about 12 units. Group A_2 cells showed approximately the same titer, whereas group B cells reacted to a considerably lower titer and groups A_1 and A_1B showed the weakest reactions.

Dilute the reagent to a titer of not less than 5 and not more than 10 units for group O cells.

Inhibition test—Wiener

Carry out the inhibition test on saliva with saliva from known secretors of each blood group and also from known nonsecretors, using the method on pp. 1543ff with saliva diluted 1:1, 1:4, 1:16, 1:64, and 1:256. The results of the tests are expressed as inhibitor titer units (Table 352). Anti-**H** reagents that give reactions similar to those in Table 351 are satisfactory to use in tests on dried blood stains.

Agglutinin absorption tests for identification of dried blood stains

Preparation of antiserum: Dilute the anti-**A**, anti-**B**, and anti-**H** sera to yield reagents with a titer of between 5 and 10 units. This means that each antiserum must have been titrated and its titer determined before use. To titrate, dilute the antiserum 1:10 by adding 1 drop of antiserum to 9 drops of saline, and then proceed with serial dilutions: 1:10, 1:20, 1:40, 1:80, etc., using the method of diluting given on p. 1476. To each diluted serum (1 drop in its respective tube) add 1 drop of cell suspension containing the agglutinogen corresponding to the agglutinin in the antiserum (A_1 cells to anti-**A**, B cells to anti-**B**, etc.). These tests may be carried out in tubes, or they may be made on slides. The tubes must remain at room temperature for at least 1 hr. before being read. The slides may be read microscopically at the end of 8-10 min. shaking on a rotator. The reciprocal of the weakest dilution of the antiserum that gives a definite reaction is the titer. If the titer of the serum is, for example, 640, then dilute the antiserum 1 part serum plus 63 parts saline to obtain a final titer of 10 units, or 1 plus 127 for 5 units, etc. The antiserum is diluted until a titer of 5-10 units is obtained.

Use the same A, B, and O cells in the agglutinin absorption tests as are used in the titration. The titration thus becomes a control over the cells.

---

*The prepared anti-**H** reagent can be purchased from Certified Blood Donor Service, Inc., Jamaica, L. I., N. Y.

Table 351. *Titration of anti-H reagent (Ulex europaeus) against various human red cells**

Specimen No.	Blood group	Undiluted	Reactions with seed extract diluted 1:2	1:4	1:8	1:16	1:32	Titer
1	O	++±	++	++	+	–	–	8
2	A_2	++±	++±	++	+±	Trace	–	12
3	B	+++	+±	+	Trace	–	–	4
4	O	+++	+++	++±	++	+	–	16
5	A_1B	+	Trace	Trace	–	–	–	1
6	A_1B	Trace	–	–	–	–	–	0
7	A_1	Trace	–	–	–	–	–	0
8	A_1	+±	+±	Trace	–	–	–	3
9	A_2	+++	++±	++	+±	Trace	–	12

*From Wiener, A. S.: Lab. Digest, Feb., 1959.

The strength of the reaction is indicated by the number of plus signs as follows:

+++, one large clump.
++±, several large clumps.
++, many finer clumps.
+±, very fine clumps barely visible to the naked eye.
+, distinct clumping but visible only under the microscope.
±, clumps containing only a few cells each.
–, no clumping.

The titer is the reciprocal of the highest dilution giving a distinct (1 plus) reaction.

*From Wiener, A. S.: Lab. Digest, Feb., 1959.

Procedure:

1. If the blood is in the form of a crust or powder, and sufficient specimen is obtainable, grind it into very fine powder, and add 10 mg. portions to 0.1 ml. of each testing serum (anti-**A**, anti-**B**, anti-**H**) in small tubes.
2. Mix thoroughly with the aid of a stirring rod and then allow it to stand in a refrigerator overnight to complete the absorption. Centrifuge and test the supernatant dark-red fluid for its agglutinin content. (See examination of blood crusts.)
3. If the material has been absorbed, as it will be on clothing, paper, and other articles, cut out portions of the stained and also the unstained areas, of approximately equal size, and use these for the tests and controls. It is essential that controls be run, using material from the unstained portion of material, since this at times contains one or both of the blood group receptors from sweat, urine, or animal material. If the tests for the receptors in the unstained material are positive, the results obtained in tests on the stained area cannot be relied upon.
4. Use glassware and equipment that contain no blood or body secretions. Avoid touching any of the material with the bare hand. Always mark the portion of specimen from which the stain and the unstained areas have been cut, using an indelible pencil, for possible later identification in court.
5. Cut portions of both stained and unstained material of approximately equal size and place in separate small (7 mm. inside diameter) tubes. Prepare 8 tubes for the duplicate sets of tests of the stain (labeled 1, 2, 3, 4,-test) and 4 tubes for the controls on the unstained

portion (labeled 1, 2, 3, 4,-controls). Controls using known dried blood stains containing, respectively, groups A_1, A_2, B, O, and type M blood are described below. These last need not be made each time a test is run, but such controls should be made often enough to check the antisera and the technic of the individual performing the tests.

6. Add enough anti-**A** serum to each tube 1 of the test and control tubes to make the cloth sopping wet; anti-**B** serum to each tube 2; anti-**H** Ulex to each tube 3; and anti-**M** serum to each tube 4. These are the antisera that have previously been diluted to a titer of 10.
7. Prod the contents of each tube with a glass rod to make the cloth absorb the serum. There should be no run-off of the serum when the tube is tilted. A different glass rod should be used for each tube.
8. Refrigerate the duplicate 4 tests and the 4 control tubes overnight.
9. The following day aspirate the serum in each tube by pressing against the cloth with a capillary pipet with a rubber bulb, using a different capillary pipet for each tube, and place the aspirated serum in small tubes properly labeled.
10. To each tube 1 add 1 drop of saline-suspended group A_2 cells (2% concentration).
11. To each tube 2 add 1 drop of saline-suspended group B cells.
12. To each tube 3 add 1 drop of saline-suspended group O cells.
13. To each tube 4 add 1 drop of saline-suspended type M cells.
14. Mix each tube thoroughly and place the tests containing anti-**H** in a refrigerator for 2 hr. Leave the other tests (A, B, M) at room temperature. The A, B, M tests may be made in welled slides.
15. Read for agglutination or lack of agglutination.
16. The control tubes should all show positive reactions. If they do not, the test is unreliable. See Table 354.

The results possible with this test are given in Table 353.

Controls using known dried blood stains: The dried stains are prepared by adding blood of known groups to different pieces of cloth and keeping them refrigerated until ready for use. The cloths are usable as controls for about 2 mo. Each stain is tested with anti-**A**, anti-**B**, and anti-**H** diluted serum, as in the tests. The technic is carried out as outlined above for the unknown stain: a segment of the cloth is put in each of a number of tubes, the proper antiserum is added until the cloth is sopping wet, and the cloth is prodded until it soaks up all the antiserum; then it is left at refrigerator temperature overnight, and the next day tests are made on the serum, using various cells. See Table 354.

When there are large stains not in crust form, the following method may be used. The crust technic (p. 1618) cannot be used unless the stain is fresh, but the **following method may be used on large stains.**

1. Extract the stain to a dark color, using 30-40 drops or more of saline.
2. Express the fluid from the cloth.
3. Centrifuge hard. This is an agglutinin extract.
4. Place 5-10 drops of the fluid in each of 3 small tubes.
5. Add A_2 cells to the first tube, B cells to the second, and O cells to the third.
6. Refrigerate for 10 min.
7. Centrifuge in ice cups.
8. Remove the supernatant fluid and add a drop of saline to each sediment before reading. Read microscopically; see Table 357 and then verify with the Ulex method.

This last method is simply a screening procedure and is not used for conclusive results.

It must be kept in mind that these are methods for detecting indirectly the presence of certain agglutinogens in a blood stain and are not direct tests for blood groups as entities. It may be stated in a report that a stain contains a certain agglutinogen but not that a certain agglutinogen is absent.

Sources of errors in interpreting results of blood grouping tests of dried stains[373, 374]

Numerous errors are possible in interpreting the results in the blood grouping tests of dried blood stains.

1. If the preliminary test for determining

+	−	−	Group B, or O with anti-**A** deteriorated
−	−	−	Inconclusive

the titer of the antiserum used is satisfactory, a +++ or ++ reaction is obtained against the known cells (which are to be used in retesting the serum after absorption), and if in the actual test the control from the unstained area gives only a + or ± reaction, then something containing the group substance—sweat, saliva, urine, etc.—is present, and the activity of the antiserum has been inhibited. Under these circumstances it is not advisable to base any conclusions concerning the group of the stain on the results of the absorption test. If possible, another test of unstained material taken from an area closer to the stain should be made to determine if the interfering material is localized or is to be found all over.

2. If in the preliminary test to determine the titer of the serum a +++ or a ++ reaction is obtained against the known cells which are to be used in retesting the serum after absorption, and if in the actual test after the serum has been submitted to absorption by a known or unknown stain a ± result is obtained, it indicates that the group-specific substance has reduced the reactivity of the serum.

There are 3 possible explanations: (a) the stain is old or has been exposed to conditions unfavorable for the preservation of the group substance; (b) the amount of blood in the stain is insufficient in quantity; (c) the serum used was of too high a titer. In the case of controls, the first 2 reasons may be eliminated by using freshly prepared, adequate samples.

The last possibility may be eliminated by performing another test on another portion of the stain, using serum of lower titer, i.e., by diluting the serum originally used with an equal volume of saline. Clear-cut negative reactions are required in the controls, using blood stains of known type, if the group of a stain is to be based on the absorption test.

3. If the test of unstained material, known group O, and the corresponding known stain in the controls give +++ or ++ results, a ± result with the unknown indicates that the reactivity of the serum has been inhibited. This reduction in titer is attributable to group-specific substances present in the unknown stain.

4. It must be kept in mind that with an unknown stain a positive result may be obtained because of disappearanec of the group factor due to age, exposure to undesirable physical conditions, or other causes. An insufficient quantity of stained material may also account for these results. Identification of an unknown stain as group O by the absorption method then is provisional (except when the reagent anti-**H** Ulex is used, p. 1620). Group O stains may be identified absolutely by testing for and finding both agglutinins present in the stain, as in the crust technic.

5. The $\mathbf{A}_2$ factor is considerably weaker than the $\mathbf{A}_1$ so that a ± reaction or a marked reduction in the titer of the anti-**A** serum (i.e., from a +++ to a + reaction) indicates that only a partial removal of anti-**A** agglutinin has been achieved. Retesting the stain with serum of lower titer will be useful in confirming the A_2 diagnosis.

In the grouping of dried stains, to a degree far greater than elsewhere in forensic blood tests, technic, experience, and the condition of the stain—exposure to elements, age, amount, and where found—are of paramount importance. The absence of group-specific factors in the stain does not necessarily mean that the blood is that of group O. In particular, the possibility of its being an A_2 must be considered. Similarly, if a stain is found to contain the B agglutinogen, consideration must also be given to the possibility of its being an A_2B blood group.

The use of the reagent, anti-**H** Ulex, helps resolve some of these difficulties.

Chapter 83

Medicolegal aspects of blood transfusion

ADDINE G. ERSKINE

This section cannot be closed before considerable attention is paid to an important report by the Committee on Medicolegal Problems of the American Medical Association.[375] This Committee was composed of Alexander S. Wiener, Chairman, and David N. W. Grant, Lester J. Unger, and William G. Workman. They represent a group of outstanding serologists with a vast experience in this field. The following remarks are based largely upon this Report, and although at the time of the report the material is authoritative, one cannot predict from the rapid strides that are now being made whether or not in the future they will necessarily be modified.

The report states that approximately one death in 1000-3000 transfusions has been reported. This makes blood transfusion as important a cause of death as appendicitis or anesthesia.

Errors are frequently made during emergency periods when the regular technician is not at hand, where a certain number of errors are inevitable. They advise that all hospitals should carry liability insurance and that medical schools should devote more attention to blood grouping in their curricula.

Unfavorable results have occurred because blood grouping sera have been inadvertently interchanged and also when 2 patients require transfusions at the same time and the bottles of blood intended for them have been interchanged. In a few cases errors have resulted because the wrong pilot tube was affixed to a bottle of blood. Most transfusion accidents due to mixing up of bloods can be traced to a failure to read labels. Colored grouping sera and labels have the disadvantage that the technician has a tendency to rely on his memory of the colors instead of reading the labels on the bottle of blood.

If a patient dies as a result of a transfusion of blood of an incorrect group or suffers prolonged illness due to injury to his kidneys, the patient's family or the patient himself, if he survives, may be entitled to damages.

One of the commonest causes of hemolytic reactions is the transfusion of blood of an incompatible blood group.

Anti-**A** and anti-**B** isoantibodies in human sera are generally of low titer and avidity, and, if so, an initial transfusion of group A blood to a group O individual might be uneventful or produce only a slight reaction. As a result of such a transfusion of incompatible blood, the isoantibody titer will rise, so that if the error is repeated a fatal reaction could result.

The severity of the reaction in strongly sensitized individuals depends on the amount of blood transfused, fatalities in adults being infrequent with quantities of blood less than 300 ml. Therefore, if this portion of each unit of blood is given slowly and the patient is watched closely during that time for untoward symptoms, it may be possible to interrupt the transfusion in time should a reaction develop. This is unlikely to be detected in patients under anesthesia.

SUBGROUPS OF A

The A_2 agglutinogen is characterized by its weaker reaction with anti-A serum. The reactions are especially weak in the presence of agglutinogen B, so that blood of subgroup A_2B has often been incorrectly classified as group B. The low avidity of most anti-**A** sera for A_2B blood which is responsible for errors in blood grouping also protects the patient receiving such incompatible blood from any dangerous reaction.

Rh FACTOR

For blood transfusion practice it is sufficient to limit the tests on patients to only one of the Rh-Hr factors, $\mathbf{Rh_0}$, the factor that corresponds to the one originally discovered with the aid of anti-rhesus immune animal sera. Generally, the initial transfusion of Rh-positive blood into an Rh-negative recipient is symptomless. In individuals who have been previously sensitized as a result of an injection of Rh-positive blood or a pregnancy with an Rh-positive fetus, even the first transfusion of Rh-positive blood can cause a severe reaction.

By carrying out cross-matching tests by the modern technics, namely, the saline, the conglutination, and the antiglobulin methods, incompatibilities with respect to the other factors of the Rh-Hr systems can be detected should isosensitization be present.

Persons with blood possessing an $\mathbf{Rh_0}$ variant may be incorrectly classified as Rh negative. A transfusion of blood containing an $\mathbf{Rh_0}$ variant into an Rh-negative recipient can give rise to isosensitization.

Under certain conditions Rh-negative blood may seem to react as Rh-positive. For instance, if bloods from pregnant women are tested by the slide technic, rouleaux formation, which often occurs in pregnancy, may be mistaken for clumping. In acquired hemolytic anemia the red blood cells may be coated with autoantibodies, which may be responsible for clumping in tests carried out by the conglutination method.

In most cases of transfusion reactions in which Rh-positive blood is transfused to Rh-negative individuals, the error can be traced to some laboratory error rather than to a peculiarity in the blood itself. A hemolytic reaction occurring after a transfusion of Rh-positive blood into an Rh-negative patient is usually evidence of negligence.

The selection of donors is no longer a simple process. Any blood bank and hospital where blood transfusions are carried out should have a specially trained technician to handle the work under qualified medical supervision. The dangers of transfusion have been summarized by Unger[376] and Wiener.[377]

UNIVERSAL DONORS

Although transfusion of group A blood into a group O recipient may cause a serious reaction, the transfusion of group O blood into a group A recipient is generally harmless. In the former case the small volume of incompatible donor's cells combines with the isoantibodies present in a much larger volume of the recipient's plasma, whereas in the latter instance a limited amount of incompatible donor's plasma is diluted in the recipient's circulation and absorbed by the great mass of the patient's red blood cells. Blood containing incompatible agglutinins is much less dangerous than blood containing incompatible agglutinogens.

Transfusions of group O blood into individuals of other groups may be dangerous. Hemolysis may follow such transfusions when the donor has isoagglutinins of high titer in his serum. Although injection of high-titered group O blood into individuals not belonging to group O may produce an acute hemolytic reaction, the symptoms are usually somewhat different from those that occur when incompatible red blood cells are injected. The use of group O blood as "universal donor" blood should be restricted to emergencies where there is not enough time to determine the group of the recipient reliably.

If it is not always possible to carry out all the tests necessary in cases of emergency, i.e., tests relative to the Rh factor, preferably low-titer group O Rh-negative blood should be used for transfusions, especially in women during the childbearing period. One must balance the danger of hemorrhage against the danger of isosensitization. A suitable entry should be made on the patient's chart to justify the course of action taken.

The transfusion of Rh-negative blood of the proper blood group into an Rh-positive recipient is almost always safe. Careful cross-matching tests must be done to detect incompatibilities aside from those due to the $\mathbf{Rh_0}$ factor (Rh subtypes, **hr′**, etc.).

OTHER BLOOD GROUPS

The sera of certain rare individuals contain irregular isoantibodies for blood group factors other than **A** and **B**, for instance, anti-**M**, anti-**P**, and anti-**Lewis**. In addition, immune antibodies to blood factors besides Rh-Hr may be formed as a result of isosensitization, notably anti-**M**, anti-**Kell**, and anti-**Duffy**. This may cause serious hemolytic reactions.

The Committee does not believe that reactions caused by sensitizations to one of the other blood factors can properly be a cause of action for a lawsuit, provided that the physician and hospital have exercised ordinary care to protect the welfare of the patient.

DAMAGED BLOOD

Blood damaged during storage may break down rapidly in the patient's circulation and give rise to hemoglobin nephrosis. No blood should be used if, after inspection, hemolysis is suspected.

Red blood cells are sensitive to freezing and overheating. Dry ice must not be used. No attempt should be made to warm blood prior to or during its administration. Blood stored too long or improperly can give rise to transfusion hemolysis. The National Institutes of Health permit an expiration date of 21 days for blood stored in citric acid-dextrose solution.

Blood should be kept cold from the moment it is collected until it is used. It should be stored in a refrigerator set preferably at 4°-6° C. The temperature of the refrigerator must be recorded at least once a day.

TRANSMISSION OF DISEASE

One of the most serious dangers is transmitting homologous serum hepatitis to the patient. This may occur once among 200 patients receiving transfusions and may be responsible for the patient's death once among 6000 transfusions. The danger is graver following plasma transfusion.

Homologous serum hepatitis was observed during World War II as a result of the extensive use of pooled dried plasma when treating battle casualties. Pooling increases the hazard of homologous serum hepatitis, because the presence of the virus in a single sample of blood plasma will serve to contaminate the entire pool. The most important difference between homologous serum hepatitis and infectious hepatitis or catarrhal jaundice is the mode of transmission. There is no simple test by which the carrier of the virus can be recognized, and the presence of the virus in the plasma pool can be detected only by testing it on human volunteers.

The National Institutes of Health have required that pooled plasma be irradiated before distribution, and this ruling is still in effect. Recent observations, however, indicate that such irradiation may not always be effective. Irradiation is not applicable to whole blood. The problem of homologous serum hepatitis has not yet been solved.

Syphilis: Transmission of syphilis by transfusion is rarely heard of any longer.* This is mainly due to the development of more sensitive tests for the detection of the disease in prospective donors, whereas another effective factor in preventing the disease is the widespread use of bank blood. According to this report: "Since the agent of this disease cannot live more than a few days outside the body, even at refrigerator temperature, the danger of transmitting syphilis is virtually nonexistent when blood or plasma aged for at least three days is used for transfusions." **No individual with positive serologic tests for syphilis or positive history of the disease should be used as a donor.**

Malaria: Transmission of malaria by transfusion is a difficult problem in regions where the disease is endemic, but until recently it was not an important problem in the United States. For obtaining fresh blood for transfusion, individuals who have had malaria or who have received suppressive therapy for malaria while residing in a malarious region should not be used as donors for a period of at least 2 yr. following the last proved attack or discontinuance of suppressive therapy. The *Plasmodium malariae* can survive in a refrigerator for as long as 5 days, so that bank blood less than 5 days old might be infectious.

Other infectious diseases: Other infectious diseases, such as measles and influenza, have been transmitted by blood transfusion when the donor was in the prodromal stage of the disease at the time his blood was used for transfusion. All prospective donors should be examined to detect the presence of infectious disease.

CONTAMINATED BLOOD

Bacteriologic surveys have shown that as many as 5-10% of bank blood specimens are contaminated with bacteria. No harm results usually because the majority of microorganisms present are gram-positive bacteria relatively low in pyrogenicity, do not grow at refrigerator temperature, and are generally nonpathogenic. Some bacteria grow at refrigerator temperature.* Transfusion of such blood has resulted in death of the patient. At this time it is not considered advisable to add any antiseptic to blood in an attempt to prevent bacterial growth. Prime reliance must be placed on stringent aseptic technic when collecting and storing blood.

---

*Elsewhere in this section (p. 1568) will be found Gradwohl's views on this subject. His views are based upon experiences, not with blood bank blood, but with fresh blood from individual donors.

ACCIDENTS FOLLOWING TRANSFUSION

Embolism: During storage of blood or plasma, precipitation of fibrin gradually occurs, and if such blood or plasma is transfused unfiltered, multiple embolization into the lung bed may occur, or into the viscera or brain if the recipient has a cardiac septal defect. All bank blood and stored blood should be filtered during transfusion.

Rapid transfusion of blood by pumping air under pressure into the blood reservoir has caused a number of deaths from air embolism. This type of transfusion should be condemned.

Allergic reactions: About 1% of blood transfusions are followed by reactions of an allergic type. These reactions are mild and consist merely of urticaria. Angioneurotic edema is a more serious allergic manifestation which may be dangerous if it involves the larynx. It is best not to use allergic individuals for blood donors.

Pyrogenic reactions: Pyrogenic reactions have been caused by growth of bacteria in the water used for preparing solutions or in moisture adherent to the apparatus before they are sterilized.

Methods have been developed for preparing pyrogen-free solutions and apparatus, which are readily available commercially. (See pp. 1593ff on pyrogenicity.) Therefore, pyrogenic reactions should no longer be an important problem.

Overloading: Too rapid transfusion or transfusion of too much blood may cause death from congestive cardiac failure or cerebral hemorrhage. A certain number of deaths from too rapid transfusions still occur, especially when transfusions are given to infants.

Citrate reactions: The sodium citrate which is introduced during transfusion is rapidly metabolized and excreted. The amount of citrate administered with 500 ml. blood is harmless to the adult. When massive transfusions are given in a short period of time, sodium citrate may accumulate in the blood stream, so that signs of hypocalcemia may result, namely, a drop in blood pressure and tetany. This may happen when adults with massive hemorrhage require more than 1 L. of blood. If 10 ml. 10% solution of calcium gluconate are injected slowly intravenously after every 1000 ml. citrated blood, hypocalcemia may be prevented. When performing exchange transfusions on erythroblastotic babies, some transfusionists inject 1 ml. 10% calcium gluconate after every 100 ml. citrated blood; others meet the problem by removing part of the citrated plasma from the blood to be used for the transfusion.

INTRAMEDULLARY TRANSFUSION

In adults, bone marrow transfusion is made through the sternum. In infants and small children in whom the sternum is too thin, the tibial route is used. The Committee believes that the intramedullary route for ordinary transfusions is not recommended because of the danger of fat embolism, especially in children. The procedure has resulted in osteomyelitis and fractures of the tibia. Intramedullary transfusion has its main application in instances of extensive burns or in patients with skin diseases, which makes intravenous therapy difficult.

OTHER ROUTES

Transfusion into the longitudinal sinus in inexperienced hands may be dangerous because the blood may be injected extradurally. Nobody any longer advocates the use of intraperitoneal or penile routes.

HOW TO PROTECT THE BLOOD DONOR

If a donor gives blood too frequently, there is likelihood of secondary anemia, a danger greater in women than in men. Donors should not be permitted to donate a pint of blood more often than every 6 wk. or until the blood attains a hemoglobin concentration of at least 12.5 gm./100 ml., or a specific gravity of 1.053 or higher.

A sterile lancet, preferably expendable, should be used when obtaining blood for measuring hemoglobin concentration, to avoid transmission of hepatitis virus.

Fainting: Donors often faint when blood is taken or when they see other blood taken. Aside from the psychic aspect, the cause is sudden reduction in blood volume. The in-

---

*Stevens et al.[378] reported a fatal transfusion reaction due to cold growing *Pseudomonas* sp. in stored blood.

cidence of fainting can be reduced by screening out unsuitable donors by physical examination to exclude those with low blood pressure or a low hemoglobin level or with a small body size. A donor who has been without food for a long time or who makes his donation after coming off a night shift may be a candidate for fainting. He should be given a light snack before taking his blood. After the donation the donor should be kept in a supine position until he has apparently recovered. The nervous donor should have his attention diverted from the procedure by pleasant conversation. The room should be light and dry, and smoking should not be permitted in it or in the resuscitation room. On hot days the donors may be given some isotonic sodium chloride solution before the bleeding. If the donor faints, keep the head low, loosen the clothing, and provide with fresh air. In rare cases intravenous infusions of sodium chloride may be required.

Syncope occurs sometimes after the donor has left the hospital. He may fall and lacerate his scalp or even fracture his skull or become involved in a serious accident if he falls in the street. Donors involved in hazardous occupations should be advised not to return to work for at least 12 hr.

Thrombosis and infections: In rare cases thrombophlebitis or abscess formation has occurred at the site of the puncture. It is wise for the blood bank physicians to protect themselves with suitable insurance to prevent a lawsuit.

Donation of a pint of blood by a healthy adult is safe.

PREPARATION OF BLOOD DIAGNOSTIC SERA

Blood grouping tests are possible only when potent and specific diagnostic sera are available.

Men are used more often than women for the preparation of diagnostic sera. No Rh-negative woman should be immunized with Rh-positive blood to prepare anti-Rh sera if there is any chance of her becoming pregnant later. Similarly immunization of a group A woman against agglutinogen B or vice versa might cause obstetric complications. More common sera, such as anti-**A**, anti-**B**, and anti-$\mathbf{Rh}_0$, can be prepared by immunization of male volunteers, but this technic is not applicable to weaker factors such as **rh′**, **rh″**, **hr″**, **Kell**, and **Duffy**. To prepare anti-**A** and anti-**B** sera, a number of different immunization procedures are used.[379] Intravenous injection of blood group specific substances prepared from horse and pig stomach carries the possibility of anaphylactoid reactions in allergic subjects. This can be avoided by using deproteinized preparations and by administering them intramuscularly instead of intravenously. Some workers also use human plasma to prepare anti-**A** and anti-**B** sera. Some subjects complain of pain along the course of the vein during the injection or have a mild rise in temperature later. The former can be avoided by diluting the plasma with sterile physiologic saline solution and injecting it more slowly, the latter by having the donor take 5 gr. or 0.32 gm. acetylsalicylic acid at the time of the injection or by reducing the dosage. Look out for the danger of homologous serum hepatitis.

Before injecting blood into any volunteer, explain the purpose. The sensitized Rh donor should be given a suitable identification card. He should be warned that only Rh-negative blood should be used for any transfusion he may require in the future. A signed release should be secured from the donor.

Occasionally, volunteers immunized against the Rh factor have developed antibodies against other antigens, most frequently agglutinogen M. This can be avoided by testing all subjects for the M-N types and using only type N, Rh-positive blood for Rh-negative donors of type N.

Physicians are urged to enlist the cooperation of patients whose plasma contains rare blood group antibodies so that their blood can be used for the preparation of diagnostic sera. Insurance companies specialized in malpractice insurance can aid the work by providing riders on policies of physicians specializing in this field.

Every hospital should have one or more qualified individuals responsible for the transfusions performed there. These should see that the residents are properly trained to perform transfusions and should be available to advise and assist them when problems of unusual difficulty arise. When nurses or technicians are used in the blood banks for blood withdrawal, this should be under the direct supervision of a qualified physician.

Section One

TISSUE CUTTING AND STAINING

The purpose of preparing stained sections of tissue is to present the slides to the pathologist for microscopic examination. These slides become permanent records of the living patient and of autopsies performed on the cadaver. It is of the utmost importance that tissues be properly handled from the time of removal from the body to presentation of the slides to the pathologist. Proper fixation must be carried out at once to prevent cellular changes and shrinkage. Infiltration of the tissue, embedding, sectioning, mounting, and staining all require critical technical manipulation. The sections must be cut as thin as possible, there must be no shrinkage, no folding, and no bubbles, and the differentiation of the cells and cellular nuclei must be distinct. As a rule, there should be but a single layer of cells in the section. The clarification of sections to permit passage of light through them is of vital importance. Each step in the preparation of tissue sections for pathologic examination must be thoroughly mastered, since the correct reading of the tissue depends to some extent on the final product submitted for examination. Strict adherence to technic is essential until the various processes are completely mastered, after which the preparation of tissue sections becomes more an art than a science.

The handling and examination of pathologic tissues have constituted for many years most important steps in the development of the hospital laboratory. Every piece of tissue removed at the operating table must be submitted to a pathologic investigation both macroscopic and microscopic. One of 3 methods is generally used: the paraffin, celloidin, or frozen section technic. The celloidin method is often used only in specialized work. The most commonly employed method is the paraffin technic. Frozen sections are made in some institutions as a routine procedure and in others only in emergencies.

Chapter 84

Tissue fixation

ARAM A. KRAJIAN

The term **tissue fixation** means the preservation of the normal structure of a tissue as closely as possible to its condition during life. It is necessary, therefore, to fix and harden tissues intended for microscopic examination as soon as possible after removal from the body either during life or after death. The immediate fixation of the tissue not only preserves the cells and intracellular substances but also prevents changes that take place after death because of the putrefactive action of bacteria.

The principal purpose of the fixation is to cause coagulation or precipitation of protoplasmic substances, which renders the cells and tissue elements resistant to such further chemical effects to which they are subjected before microscopic sections are prepared. The most commonly used fixative is a solution of formaldehyde, a gas, which is soluble in water to the extent of 40% by weight. It is called **formalin.** It has the advantages of penetration and fixation with great speed, thus enabling one to cut and stain frozen sections as well as paraffin sections. The best strength is a 10% solution.

Some fixatives, such as **Zenker fluid,** act as mordants, which cause a particular staining reaction. Other fixatives, such as alcohol or isopropanol, have a hardening effect. Zenker solution is very reliable because it preserves nuclear structure, bacteria, and fibrils of all kinds.

Stowell[1] has made a distinct contribution to the effect on tissue volume of fixation, dehydration, and embedding. He found that all fixatives showed specific differences. Susa and Bouin fixatives gave the best general results and neutral formalin mixtures, especially pyridine-formalin, the poorest results. Isotonic saline is superior to distilled water as a formalin diluent because it reduces tissue swelling during formalin fixation. Reagents producing marked decreases in tissue volume render such tissues less susceptible to shrinkage during subsequent procedures. Shrinkage of tissue during dehydration and infiltration with hot paraffin may exceed that produced by fixation alone. Excessive heat causes tissue distortion and shrinkage. Infiltration with hot paraffin causes considerable shrinkage; with hot nitrocellulose, less shrinkage; and with cold nitrocellulose, the least shrinkage.

Alcohol hardens and dehydrates tissue at the same time. Tissues kept in alcohol, however, cannot be immediately used for frozen section work. Alcohol has a tendency to produce too great hardness in tissue, rendering it difficult for sectioning purposes. It does not penetrate as well as formaldehyde so that the tissues must be cut in very small blocks.

In general, all tissue for fixation must be of a size sufficient for penetration. The **volume of the fixative** solution must be at least 25 times that of the tissue. The smaller the tissue, the smaller the receptacle need be to obtain this 25:1 ratio.

When formaldehyde is used as a fixative, the tissues are placed in 15% formalin for the first 24 hr.; then they are properly trimmed into square or rectangular blocks, placed in 10% solution, and permitted to remain there. When tissues are **fixed in Zenker solution** or other chrome salt solutions, the solution need not be changed.

To fix eye specimens after enucleation, inject the tissue with 10% formalin and place the tissue in a similar solution for 10 days before trimming for microscopic section.

Tissues previously fixed in alcohol can be washed under running tap water for 15 min. and then placed in 10% formalin for 24 hr., after which frozen sections may be cut.

FORMULAS FOR TISSUE FIXATIVES OR HARDENERS

The fixatives selected depends on the nature of the pathologic lesion in the tissue. All types of fixatives are not compatible with all staining methods; some fixing reagents act as mordants for a particular staining process, whereas others inhibit certain stains. In general, Bouin, Zenker, mercuric bichloride–formaldehyde combination, mercuric chloride, and Carnoy fluid allow most of the staining, whereas formaldehyde prevents carmine staining, Regaud-fixed tissues stain poorly with carmine, alcohol fixation causes weak staining with formulas employing stains other than carmine, and osmic acid prevents carmine staining.

It is well to keep stock solutions of various fixatives on hand since most of the fixing solutions are stable.

Zenker fluid:

Stock Zenker solution:

Mercuric chloride	5 gm.
Potassium dichromate	2.5 gm.
Sodium sulfate	1 gm.
Distilled water	100 ml.

Dissolve by heat.

Zenker solution for use:

Stock Zenker solution	100 ml.
Glacial acetic acid	5 ml.

Add the acetic acid when ready for use and mix.

1. Fix tissues for 12-16 hr.; then wash overnight under a gentle stream of tap water to remove all the excess potassium dichromate.
2. Transfer to 70% alcohol and allow tissues to remain in 70% alcohol until ready to be dehydrated, cleared, and embedded.
3. Simple washing is not always sufficient to remove the mercury. **To remove the mercury,** place the tissue in 70% alcohol with enough iodine to give it a good port-wine color, and leave it in this solution until all the iodine color disappears. Renew the iodine after it disappears and leave the tissue in the solution. Continue renewal of the iodine until the tissue no longer decolorizes it, at which time all the mercury has been removed from the tissue.
4. Then place in 70 or 80% alcohol until all the iodine color leaves the tissue, and proceed from this step in the usual manner for dehydration, clarification, and embedding.

Helly fluid: Helly fluid is a slight modification of Zenker fluid. Helly omitted the glacial acetic acid and replaced it with 10% formalin, which is added to the mixture at the time of use.

Mercuric chloride	5 gm.
Potassium dichromate	2.5 gm.
Sodium sulfate	1 gm.
Distilled water	100 ml.
Formaldehyde, 40% (formalin)	10 ml.

1. Fix tissues for 8-16 hr. Wash for 12-16 hr. under a gentle stream of water.
2. Transfer to 70% alcohol. Allow to remain until ready to embed.

Regaud formol dichromate fluid: Regaud solution gives excellent results with mammalian tissues. It costs less and penetrates better than chrome-osmium fixatives. It is unstable and must be prepared fresh at the time of use.

Potassium dichromate, 3%	80 ml.
Formalin	20 ml.

1. Fix tissues for 4 days, changing the fluid every day.
2. Wash in running water for 16-24 hr.
3. Transfer to 70% alcohol.

Formaldehyde (formalin): Formaldehyde is a gas, soluble in water to the extent of 40% by weight. It has been in general use for many years as a fixing reagent. It penetrates and fixes the tissues quickly, thereby enabling one to cut and stain satisfactory frozen sections. Formaldehyde preserves fat, myelin, nerve fibers, amyloid, hemosiderin, and various organisms. The best strength is a 10% solution of formalin prepared by adding 1 vol. commercial 40% formaldehyde (formalin) to 9 vol. tap water or saline. To prevent development of formic acid, which is injurious to the tissue, add 5-10 gm. calcium carbonate, lead oxide, or bicarbonate of soda to 1 gallon stock formalin. When specimens are to be kept for long periods, it is essential to place a few marble chips in the container.

Formaldehyde vapor is injurious to the eyes, nasal mucosa, hands, and other exposed parts of the body, and contact should be avoided as much as possible. Allergic persons may develop formaldehyde dermatitis, which may become very serious. The lesions persist for months.

The following solution will **relieve the lesion caused by formaldehyde:**

Urea crystals, c.p.	5 gm.
Ammonium phosphate, c.p.	1 gm.
Distilled water	100 ml.

For protozoologic work, fixation in Bouin or Schaudinn solution is preferable.

Picric acid: Picric acid coagulates protoplasm. It is used as a saturated aqueous solution. Solubility is between 0.5 and 1% at room temperature.

Bouin fluid:

Picric acid, saturated aqueous solution	75 ml.
Formaldehyde, 40%	25 ml.
Glacial acetic acid	5 ml.

This solution keeps well. It has considerable penetrating power and causes very little shrinkage. Picric acid, which stains the tissue yellow, is extracted in the dehydration process. It is not a good fixative for cytologic work or for inclusions such as Golgi bodies and mitochondria because it distorts or dissolves them. It is a good fixative for small skin lesions.

Schaudinn solution:

Mercuric chloride, saturated aqueous solution	2 parts
Absolute or 95% alcohol	1 part

Glacial acetic acid in proportion of 10%.

Alcohol: Alcohol hardens and dehydrates tissue at the same time, preserves bacteria, fibrin, pigments, and elastic fibers, and is the only reagent (absolute alcohol) to preserve glycogen.

Tissues to be kept for a considerable period in alcohol should be placed in dilute (70%) alcohol. If left longer than 48 hr. in absolute alcohol, they become so hard that section cutting is almost impossible.

The material fixed in alcohol should not be over 0.5 cm. thick. Strong alcohols, 95% or absolute, harden only the surface of the tissue, so that deeper parts are not penetrated. To avoid this a 70% alcohol, gradually increased to 95%, should be used.

Alcohol-formalin mixture:

Alcohol, 95%	100 ml.
Formalin	50 ml.

Isopropanol: Anhydrous isopropanol has been successfully substituted for absolute ethyl alcohol as a dehydrator in the preparation of paraffin blocks and staining procedures. It is recommended for its economy. It may be obtained through any laboratory supply house.* It must be understood, however, that it cannot be used successfully in the preparation of alcoholic solutions, such as acid alcohol, ether-alcohol mixture for dissolving celloidin, or alcoholic dye solutions.

Bichloride of mercury and formaldehyde combination: A saturated solution of bichloride of mercury, when used alone, causes serious shrinkage of the cells. A combination with formaldehyde has been found to be a very useful fixing reagent.

Bichloride of mercury, saturated aqueous solution (8 gm. to 100 ml. water)	90 ml.
Formaldehyde, 40% commercial	10 ml.

1. Fix thin pieces of tissue from 6-12 hr.
2. Place in 70% alcohol, dehydrate, and embed in the usual manner.

Osmic acid solutions: Osmic acid is an expensive reagent. It is sold in sealed glass tubes of 0.5 and 1 gm. The solution is prepared by dissolving 1 gm. osmic acid crystals in 100 ml. pure, dust-free distilled water. The solution of osmic acid is easily spoiled by formation of black precipitates. This can be partially remedied by the addition of a few drops of 10% chromic acid or 10 vol. hydrogen peroxide. The vapor of osmic acid is irritating to the eyes.

Osmic acid is used to demonstrate fat, but its penetrating power is poor. For this reason Flemming and Marchi have combined osmic acid with other reagents, such as chromic acid and potassium dichromate, to increase its penetrating power.

Flemming solution:

Osmic acid, 2% aqueous solution	20 ml.
Chromic acid, 1% aqueous solution	75 ml.
Glacial acetic acid	5 ml.

1. Fix thin blocks of tissue, not over 2 mm. thick, for 12-24 hr.
2. Wash under a gentle stream of water overnight, place in 70% alcohol, dehydrate, and embed in the usual manner.

The stock solution keeps poorly; therefore, it is best to keep the osmic and chromic acid solutions in separate bottles and mix them at the time of use. The amount of solution should be about 5 times the volume of tissue.

Marchi fluid:

Potassium dichromate	2.5 gm.
Sodium sulfate	1 gm.
Water	100 ml.

1. Mix 2 parts of this solution with 1 part 1% aqueous osmic acid.
2. Fix thin blocks of tissue, not over 2 mm. thick, 5-8 days. Wash under running water overnight, place in 70% alcohol, dehydrate, and embed in the usual manner.

The stock solution is not stable; therefore, these solutions should be mixed at the time of use.

Potassium dichromate: Potassium dichromate forms insoluble compounds with cell proteids and lipoidal bodies. A 3% solution in distilled water is employed. Saturation point is about 12 gm. in 100 ml. distilled water.

Xanthydrol reagent: Acetic acid combined with xanthydrol is used to preserve and demonstrate urea crystals in tissue and smears.

Xanthydrol crystals	5 gm.
Glacial acetic acid	100 ml.

1. Fix blocks of tissue, not over 2 mm. thick, for 6 hr. cold or 1½ hr. at 70° C.
2. Wash under running water for 5 min. and place in 10% cold formalin for 12 hr. or ½ hr. at 70° C.

Acetone: Acetone as a fixative has limited application. It is used as a rapid fixing solution of brain tissue for the diagnosis of rabies and as a fixative for enzymes.

Susa fixative:

Mercuric chloride	4.5 gm.
Sodium chloride	0.5 gm.
Trichloracetic acid	2 gm.
Glacial acetic acid	4 ml.
Formalin	20 ml.
Distilled water	80 ml.

1. Place the tissue in Susa fixative 5-48 hr., depending on the size.
2. Wash in tap water 3-5 hr., changing the water frequently. Place in 50% alcohol for half a day, changing the alcohol several times.
3. Transfer to 70% alcohol for half a day, changing several times.
4. Transfer to 95% alcohol for half a day, changing alcohol several times.
5. Place in absolute alcohol not longer than 1 hr.
6. Clarify in pure xylol. The tissue must become transparent.
7. Embed in the usual manner.

This fixative is used for sections to be stained by Giemsa stain (Schilling method, modified by Gradwohl).

Acetic acid fixative:

Solution A:

Acetic acid	1 part
Absolute alcohol	3 parts

---

*Union Carbide & Carbon Co. product has been found superior.

Solution B:

Acetic acid	1 part
Absolute alcohol	6 parts
Chloroform	3 parts

Solution B is good for lymph and glandular tissues. The chloroform helps penetration, and the tissue is fixed more rapidly. When using alcohol-containing fixatives, omit all steps preceding the solution of the strength of alcohol used.

Wash out the acid alcohol with 95% alcohol.

If tissue is submitted in alcohol, put it in 95% alcohol or in the acid alcohol solution above, since the exact strength of the alcohol fixative must be known.

Mueller solution:

Potassium dichromate	2.5 gm.
Sodium sulfate	1 gm.
Water	100 ml.

Orth mixture:

Formalin	1 part
Mueller solution (above)	9 parts

DEFORMALINIZATION

To remove formalin from formol-fixed sections and tissues: At times it becomes necessary to refix formol-fixed tissues or sections in some other fixative, such as Zenker fluid, for special stains. The following technic has given satisfactory results in the majority of cases.

For sections:

1. Deformalinize for 1 hr. in ammonia water, 40 drops of strong ammonium hydroxide to 100 ml. water.
2. Wash 1 hr. in running water.
3. Fix 1 hr. in Zenker or Helly fluid.
4. Wash 1 hr. in running water.
5. Stain with desired method.

For blocks:

1. Deformalinize for 2 days in an oven at 40° C. in ammonia water, 40 drops ammonium hydroxide to 100 ml. water.
2. Wash for 24 hr. in running water.
3. Fix in Zenker fluid for 12 hr. or in Helly fluid for 5 hr.
4. Wash for 12 hr. in running water.
5. Place in 70% alcohol until ready to embed.

DECALCIFICATION

Bone tissues to be decalcified should be sawed with a fine saw into thin slices so that they will decalcify quickly. Very dense and hard bones should not be more than 2 or 3 mm. thick; softer tissues need not be less than 4-6 mm. thick.

1. Fix bones and calcareous tissues thoroughly in alcohol-formalin mixture, 10 parts formalin in 90 parts 95% alcohol, or in Zenker fluid. Leave in alcohol-formalin solution 2-4 days or in Zenker fluid 16-24 hr. before submitting to the decalcifying process.
2. After decalcification, remove the acid with with a weak solution of lithium carbonate, sodium sulfate, or any suitable neutralizing reagent and place in 70% alcohol or isopropanol to prevent further swelling.
3. For the preparation of frozen sections, remove from 70% alcohol, and fix in 10% formalin for 24 hr.

Formic, nitric, hydrochloric, acetic, picric, sulfurous, trichloracetic, and sulfosalicylic acids and others are used alone or in combination with other chemicals for decalcification purposes.

Of all the reagents, formic, trichloracetic, and nitric acids are the most useful and important. Formic acid combined with trichloracetic acid acts quickly without swelling the tissues and does not interfere with any of the staining processes. The nuclei of the cells stain beautifully with the hematoxylin-eosin method. Nitric acid also acts quickly and without much swelling but affects the staining property of the cells, and often the nuclei fail to retain the blue hematoxylin stain.

Decalcification of bone for paraffin sections

1. Place a specimen in a large volume of 5% nitric acid and change daily until the specimen becomes soft. This requires up to 5 days. Be sure to use a very large quantity of solution.
2. Wash in running water 24 hr.; then dehydrate in alcohols from 80% to 95% to absolute.
3. Place in cedarwood oil for clearing until the specimen becomes transparent and sinks.
4. Place in xylol for 30 min.
5. Place in paraffin in oven for 2 hr.
6. Embed in paraffin and cut sections as usual.
7. Stain preferably with eosin-methylene blue.

Instead of using 5% nitric acid and washing in running water for 24 hr., the following decalcifying solution may be used, taking care to use 100 times the volume of tissue:

Hydrochloric acid	4 ml.
Glacial acetic acid	3 ml.
Chloroform	10 ml.
Water	10 ml.
Alcohol, 95%	73 ml.

Pass tissue immediately into fresh absolute alcohol (2 changes) and then into cedarwood oil; the rest of the technic is as above.

Rapid method of decalcification:

Formalin	1 part
Nitric acid	1 part
Water	9 parts

1. Place in this solution for fixation.
2. Wash in running water and then begin dehydration in 80% alcohol and continue through the alcohols a little more slowly.

Bone tissue or calcified nodules

Decalcify in 5% nitric acid or in the following solution:

Formaldehyde, 40%	10 ml.
Distilled water	90 ml.
Nitric acid	20 ml.

If the bone is not too large, keep in the solution for 2-3 hr. It may be kept in the solution as long as 48 hr. without harm. There should be at least

10 times as much solution as tissue. Change the solution frequently.

1. Wash in running water 12-24 hr.
2. Place in 80% alcohol.
3. Proceed as for paraffin embedding.
4. If tissue is soft, it is ready for processing.

Decalcification of temporal bones—Krajian

This method employs a controlled shaking machine and a modified decalcifying fluid. It is applicable to smaller bones.

Decalcifying solution:

Formic acid, 88%	500 ml.
Nitric acid, concentrated	100 ml.
Tergitol (sodium heptadecyl sulfate)	2.5 ml.

1. Dilute the formic acid with 1000 ml. tap water.
2. Add the Tergitol and mix well.
3. Dilute the nitric acid with 900 ml. tap water.
4. Mix thoroughly with the dilute formic acid.

Warning: Do not mix formic and nitric acids in concentrated form, otherwise an explosion will occur.

Decalcification method:

1. Place temporal bones in a 200 ml.–capacity specimen bottle, and fill the bottle with the decalcifying solution, pouring the solution slowly. As the fluid comes into contact with the bone, immense amounts of bubbles arise. Wait for the bubbles to disappear.
2. Stopper the bottle tightly and place on a shaking machine at 35 oscillations. The shaking machine is the standard Kahn shaker controlled with Variac.*
3. Change the solution twice at 8 hr. intervals.
4. Prick the specimen superficially with a needle once a day.

It requires 8-12 changes for a temporal bone to be completely decalcified depending on the amount of calcium present and hardening of tissue due to other causes.

This method is also applicable to smaller bones removed at surgery or autopsy and requires only 1 or 2 changes for complete decalcification.

5. After complete decalcification neutralize the specimen by placing it in 1% lithium carbonate for 24 hr.
6. Wash for 16-24 hr. under gently running tap water.
7. Place in 40% ethyl alcohol until ready for dehydration and embedding.

This is the most efficient fluid ever devised for decalcifying. If a shaking machine is not available, the fluid may be used by changing the solution twice a day until the bone tissue is completely decalcified. Refer to p. 1753.

Chapter 85

Equipment for cutting sections

ARAM A. KRAJIAN

MICROTOMES

The instrument used for cutting thin sections of tissue or other material for preparation for microscopic examination is called a microtome. These instruments are designed to cut material extremely thin, from 1 to 60μ, and may or may not be provided with mechanical feeding mechanisms. There are various types of microtomes. The **rotary type** is used for cutting paraffin-embedded sections. The **sliding microtome** is used for frozen sections and for special purposes, principally for cutting celloidin-embedded and large, refractory paraffin material. In this microtome the knife moves against the object, a slow but steady motion being required to manipulate the instrument.

The **freezing microtome** is used to cut unembedded, formalin-fixed tissues, which are frozen to the proper consistency with carbon dioxide. This microtome is operated by rotation of the flywheel, causing a reciprocal motion of the knife over the block, the thickness of the section being automatically regulated by a ratchet-feed wheel. See Figs. 520 and 524.

The Minot **simplified rotary microtome** was designed in accordance with the wishes of the late Dr. Charles S. Minot of Harvard University, to provide an instrument with the efficiency of the more elaborate rotary microtomes but of simpler construction. The rotation of the large wheel causes the block holder to move vertically, up and down, through a distance of about 3 in. The object holder consists of a disk 25 mm. in diameter which can be oriented to any angle and which moves on a vertical slide actuated by a crank that is operated by the drive wheel. The knife is held in a fixed position at the base. This position is adjustable to and from the object and from side to side to permit the use of nearly the entire cutting edge. The feeding apparatus operates automatically and may be adjusted to cut any thickness from 2 to 26μ, at intervals of 2μ.

There is a specially designed microtome for frozen sections. It is known as an **automatic microtome** with a swinging carriage. The peculiar motion of the knife makes this microtome especially desirable for cutting celloidin sections, when equipped with freezing attachment. It is not adapted for paraffin work. The extreme ends of the knife rest in the carrier, and as the lever handle moves the swinging arms, the knife describes a flattened curve, corresponding to the double movement of freehand sectioning. The knife used with this microtome should be 110 mm. long. The automatic feed mechanism may be used or, by means of a lever extending to the graduated scale on the front of the main frame base, it may be thrown out of action. Better results are obtained in frozen sections if the automatic feeding mechanism is detached and the microtome is operated by hand.

Complete diagrammatic sketches are supplied with each microtome, giving directions for use.

MICROTOME KNIVES

There are 3 types of microtome knives: (1) the plane-wedge knife used for cutting frozen sections, (2) the biconcave type, used for paraffin work with the rotary microtome, and

Text continued on p. 1650.

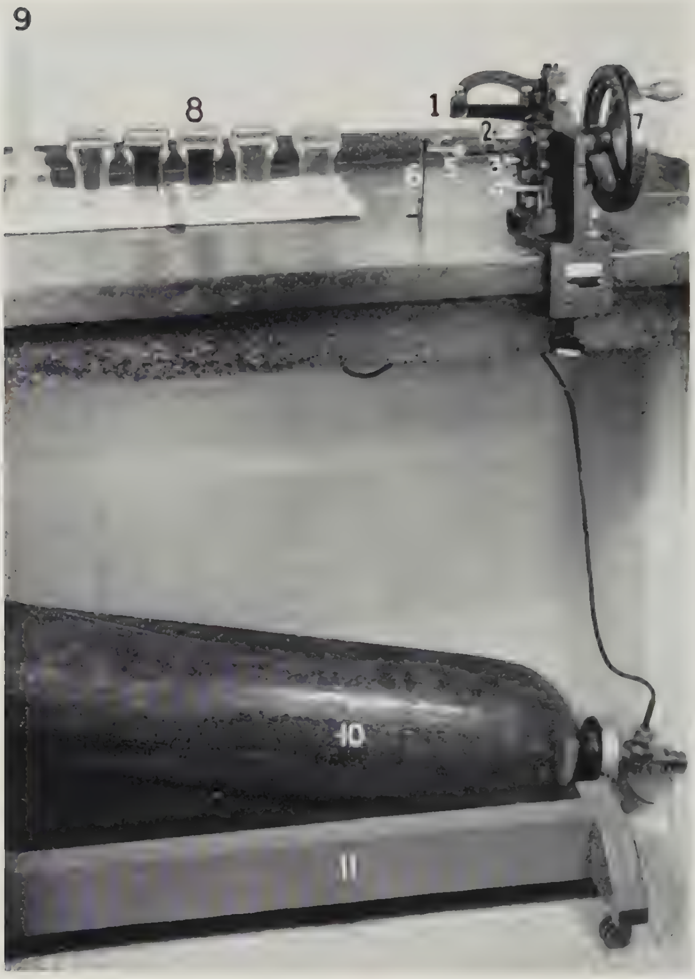

Fig. 520. Freezing microtome. **1,** Knife mounted on a sliding arm and tightened with 2 screws at an angle of about 45°; **2,** block holder directly under the knife; **3,** screw to tighten the block holder; **4,** ratchet feed wheel; **5,** small valve to admit CO_2 into chamber of block holder; **6,** copper feed pipe connecting CO_2 gas to microtome; **7,** flywheel; **8,** staining dish; **9,** large Pyrex test tube for boiling formalin; **10,** cylinder containing 50 lbs. liquid CO_2; a tank using solid CO_2 (dry ice) is also available; **11,** wooden stand for cylinder. (From Krajian, A. A., and Gradwohl, R. B. H.: Histopathological technic, St. Louis, 1952, The C. V. Mosby Co.)

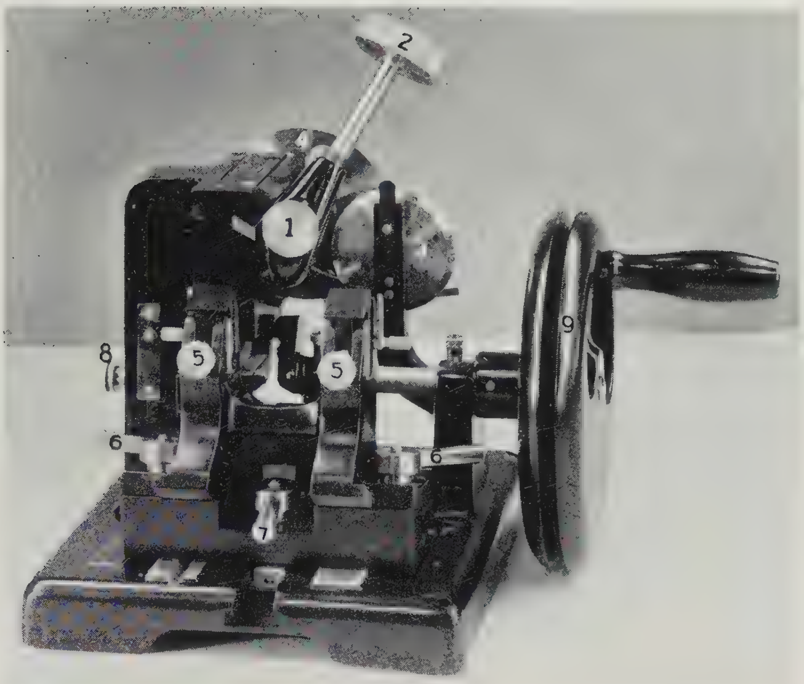

Fig. 521. Paraffin microtome (small type). **1,** Metal block holder; **2,** block holder locking screw; **3,** micrometer adjustment for thickness of section; **4,** ratchet feed wheel; **5,** knife-holder screws; **6,** clamp nuts for knife stand regulator; **7,** knife stand clamp nut; **8,** pillar locking pin; **9,** flywheel. This microtome is operated in same manner as the freezing microtome. (From Krajian, A. A., and Gradwohl, R. B. H.: Histopathological technic, St. Louis, 1952, The C. V. Mosby Co.)

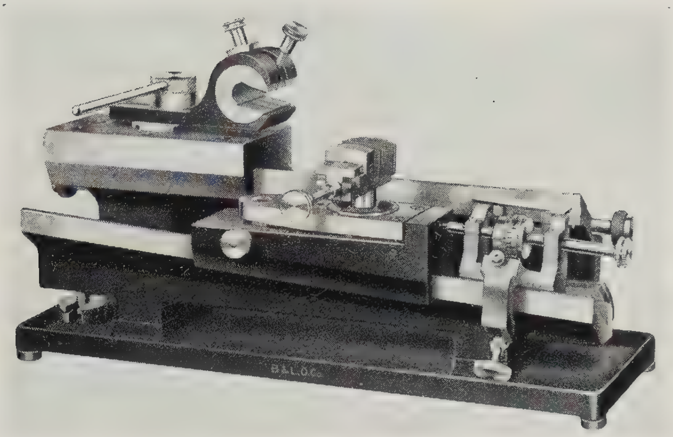

Fig. 525. Celloidin microtome showing knife, knife-holder screws to regulate the angle of the knife, screw to regulate the block holder, screw to regulate the angle of the block holder, micrometer adjustment for thickness of the section, ratchet feed wheel, and fly-wheel. This microtome is operated in the same manner as the paraffin microtomes. (From Krajian, A. A., and Gradwohl, R. B. H.: Histopathological technic, St. Louis, 1952, The C. V. Mosby Co.)

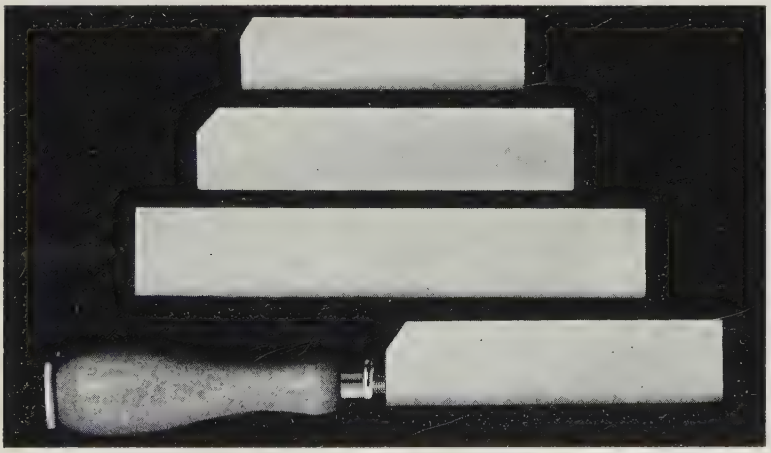

Fig. 526. Microtome knives, various sizes, one with handle attached. (Courtesy Bausch & Lomb, Inc., Rochester, N. Y.; from Krajian, A. A., and Gradwohl, R. B. H.: Histopathological technic, St. Louis, 1952, The C. V. Mosby Co.)

(3) the plane-concave type, used for celloidin work with the sliding microtome. Standard size knives are supplied for freezing and celloidin microtomes. For the paraffin microtome it is better to have a larger knife, for after one position of the edge becomes dull it will be necessary to move along the knife and bring a sharper edge into action. This will save the time and trouble of frequent honing and stropping. Razor blades in special holders have been found unsatisfactory.

To sharpen a microtome blade*†: Prepare the microtome knife for honing by screwing the handle into the threads provided at one end of the knife; then slide the sharpening back onto the knife. This sharpening back raises the knife and establishes the correct angle of the cutting facets. Take care to put the proper back onto the knife. Each knife has its own sharpening back; these backs should not be interchanged between knives.

Look at the cutting edge of the blade under the low-power objective of the microscope to examine for nicks. If the edge is appreciably nicked or not straight and even, it may be straightened by rubbing gently on a smooth stone, holding the knife at right angles to the stone. This will establish a straight flat surface along the cutting edge. Now hold the knife so that a strong nearby light reflects from the cutting edge. There will be a broad line of reflected light. Honing will remove small amounts of the metal first from one side of the edge and then from the other until nothing is left but the sharp cutting edge.

Use a fine hone or a piece of plate glass with appropriate abrasive. Lubricate the hone with a solution of neutral soap. Pass the knife over the stone, the cutting edge forward. In other words, proceed forward with the cutting edge of the blade, turn the knife over **across its back,** not over its edge, and bring it back, maintaining sufficient pressure to hold the edge evenly against the hone. If no pressure is used, the hone does not take hold well. If too much pressure is used, the edge is rounded. Gauge the amount of pressure in accordance with the hardness of the knife and the fineness of the hone. By watching the reflection of light from the edge of the knife, the progress of honing may be ascertained. When the reflection is very slight, examine the knife under the microscope to make sure that the edge is smooth and well sharpened.

The glass plate should be at least ⅜ in. thick or preferably thicker. Use plate glass 12-14 in. long and at least 1 in. wider than the length of the knife. The **abrasive** may be purchased graded to size, or it may be prepared by making a suspension in water and setting it in a tall cylinder. The heavy particles fall rapidly to the bottom; the lighter particles fall more slowly. The time of standing must be gauged by experience. Use the middle portion containing particles of proper size. For grinding, use an average size of 20μ, with none larger than 40μ. For final polishing of the facet, particles averaging 4μ and less than 8μ may be used. Suspend the particles in a solution of neutral soap (about 1%). Gradation of abrasives is accomplished by pouring the supernatant liquid of the abrasive preparation serially from one container to another. The final supernatant liquid contains the finest particles.

To smooth the edge when nicks must be removed, No. 303 or 304 corundum may be used. Levigated alumina or No. 305 corundum is suitable for ordinary sharpening and after the above grinding compounds. Diamantine or similar material should be used for the final polishing of the cutting facets.*

To polish a microtome blade: Prepare the knife as for honing. Use the finer abrasive. Very little is required. Proportions are soon learned by experience. Avoid too much abrasive. Wash the plate free from abrasive occasionally to rid it of large particles and any bits of steel freed from the edge of the blade. Hold the edge evenly against the glass; do not force against it, or the edge will become round rather than sharp. If the facets are irregular, the grinding or polishing is uneven. Use fresh abrasives from time to time during the polishing operation. Toward the end use more dilute abrasives than at the beginning. Examine under the microscope. If the edge shows that the knife is well honed, stropping is unnecessary.

To strop a microtome knife: Do not strop too much or the edge may become curved. Strop the knife from heel to toe. Clean the strop and free it from any abrasive larger than about 2μ. The strop should be mounted on a board or held against some other surface so that it will not give as the knife is pulled over it. If the strop gives or if the knife is pressed against the strop, the edge will be rounded and spoiled. Hold the knife firmly against the strop, with light pressure. After a few strokes, first on one side and then on the other, examine the edge under the microscope. Discontinue stropping just as soon as an edge appears smooth. It is unnecessary to test the knife with the fingernail, hairs, or other material; this only tends to dull the knife. The test of the knife is whether or not it cuts effectively.

If a knife needs touching up but does not need a thorough honing, use a strop with one side embedded with diamond dust or other coarse abrasives. Then strop on the smooth side.

After the knife has been used, it must be cleaned and wiped dry; then put away in its proper place. If the atmosphere is corrosive, it may be necessary to oil the knife to prevent corrosion. Use only a good grade of light neutral oil.

---

*The Micro Sharp Co., Niagara Falls, N. Y. and Toronto, Ontario, Canada, does excellent work in sharpening microtome blades. The author recommends this company to those who do not sharpen their own blades.

†For much of the material on the care and use of microtome we are indebted to Dr. O. W. Richards, Research Biologist, of American Optical Co., Scientific Instrument Division; this material is contained in a pamphlet by Dr. Richards, "The effective use and proper care of the microtome," published by Spencer Lens Co., Buffalo, N. Y.

*Dr. A. Klein, Norton Co., has suggested that a good polishing compound similar to Diamantine may be made by calcining pure ammonia alum in an **unglazed** clay or fused silica crucible for 30 min. at 2300° F. The crucible should be only ¼ full as the alum swells during heating. The yield is about ⅛ of the original weight.

If the knife is in such poor condition that it must be ground, it must be sent back to the manufacturing house that supplied it*; grinding should be done only by experts.

Krajian's method of sharpening a microtome blade: If the knife is dull but free from nicks, it may be sharpened by stropping. Frequent stropping of the blade usually keeps it in good condition. If, however, the knife is used for a great many blocks, stropping alone will not keep it sharp enough, and one must resort to honing. If the knife must be ground, it should be sent back to the supply house where it was purchased*; grinding should be done only by experts.

For honing use a No. 108 carborundum stone. Before honing, cover the surface of the stone with fine machine oil. Be sure that the back is in place on the knife and that the handle is firmly screwed into the blade. Place the knife at one end of the hone; then without any pressure except that caused by the actual weight of the knife gently push it to the other end so that the sharp edge is proceeding forward. Turn the knife over (against the back, not across the cutting edge) and push it back on its other side to the other end of the hone. Continue until the nicks are gone or until it feels sharp to the thumb. This honing can be accomplished in about 5-10 min. if properly carried out. If there are deep nicks in the knife, then exert firm pressure while honing.

Use a strop with both rough and smooth sides. When stropping, turn the knife over at the end of every stroke so that both sides are stropped in turn. Usually it requires about 1 dozen strokes on the rough side and about 2 dozen strokes on the smooth surface to obtain the proper cutting edge. Strokes should be gentle. Do not exert pressure. The weight of the blade is sufficient when stropping.

GENERAL FACTS ABOUT CARE OF MICROTOMES

Microtomes should be kept free from dust. Always cover when not in use.

Be sure that all sliding parts are clean. Oil these parts occasionally with a good grade light machine oil. Be careful not to over-oil or to add the lubrication to dirty mechanisms. Place oil on the main bearing block through the oil inlet provided. Occasionally oil the feed screw.

Like all other precision instruments, the microtome requires gentle handling. Do not put undue pressure on the flywheel or other portions of the apparatus which are handled frequently. If the alignment of the microtome is interfered with by constant pressure at certain points, the instrument will have to be sent back to the manufacturer for repair. To tighten connections use a smooth wrench, not a pair of pliers. We have seen instruments literally "chewed up" with the erroneous use of pliers on the soft metal.

After considerable use[2] the microtome may cut sections irregularly because of wear. Turn the handle of the feed mechanism. A distinct drag or tension should be felt. When it turns freely, it should be tightened. This usually stops the irregularity of the cutting. Tighten the friction screws on the friction bracket one full turn at a time until the friction is regained. If the feed pawl drags over the teeth of the ratchet wheel, adjust the friction block in the pawl lever by turning the 2 screws to be found back of the ratchet wheel. Turn these screws one at a time until the pawl lifts out, clear of the teeth of the ratchet wheel on the down stroke.

Do not disturb the feed screw mechanism. Exercise great care in returning the feed screw to its initial position after it has reached the end of its excursion and stopped advancing the specimen. Avoid use of force when handling the feed screw.

---

*See footnote on p. 1650.

Chapter 86

Special technics and specimen mounting

ARAM A. KRAJIAN

METHODS OF AFFIXING SECTIONS TO SLIDE

Mayer albumin fixative

This method was first described by Von Henniguy. It was later modified by P. Mayer and still later by Von Reinke.

Procedure:

1. Beat the white of an egg until it is stiff and dry. Let stand until clear.
2. Filter through filter paper.
3. Add an equal volume of glycerin.
4. A crystal of thymol may be added as a preservative if desired.

To use the fixative:

1. Rub a drop of the fixative briskly over the surface of a slide but do not allow to dry.
2. Tease the section onto the slide in a drop of water. Remove the excess water by gentle blotting and place the section at 37° C. in an incubator overnight or gently warm in a flame, or let the section stand at room temperature overnight.

Preferred method:

1. Use equal parts of egg white and glycerin.
2. Beat thoroughly with a glass rod and filter through several thicknesses of gauze.
3. Add a crystal of thymol as a preservative.

Alternate method:

1. Mix equal parts of blood serum and glycerin with 10% formalin. To use, place a faint trace of the mixture on a slide.
2. Warm gently in a Bunsen burner, keeping the heat at about 70° C.
3. Pour distilled water over the slide.
4. Place the section in the distilled water and straighten it.
5. Remove the excess water with filter paper.
6. Place the slide in an incubator at 37° C. for 3-4 hr. or have the section in slightly warm distilled water.
7. Float a cover glass on the section to pick it up.
8. Heat the preparation to 70° C. and continue as described below.

Schneidau method[3]

Schneidau method 1

Albumin solution—Schneidau:

Egg white	from	1 egg
Glycerin		50 ml.
Sodium salicylate		1 gm.
Distilled water		1500 ml.

Mix thoroughly and filter.

1. Place the solution in a narrow-mouthed jar equipped with a 2-hole rubber stopper. Through 1 hole fit a bent glass siphon to which has been attached a rubber hose containing a small pipet at the end, and a spring clamp. Place the apparatus on a shelf several feet higher than the laboratory table, start the siphon, and then shut off the flow with the spring clamp.
2. To use, assemble slides, squeeze the clamp, and allow just enough fluid to run onto each slide to float the section. Float sections by means of a section lifter, spread out by heating, and blot up excess fluid. Set aside to dry.

With this method the danger of using too much or too little fixative is practically eliminated. The sections do not entirely dry because of the glycerin and may be left on the slides for months before mounting without danger of drying or cracking.

Schneidau method 2

1. Float the sections onto the surface of slightly warmed water to spread them and then place them on the slides and dry without using any albumin.
2. Use a pan of approximately 15 × 10 × 3 in. Fill it with water and heat to about 40° C. While the water is heating, cut the ribbon of sectioned tissue into squares of one section each.
3. Take the sections up one at a time on a section lifter and drop them onto the surface of the water. Take care that one section does not fall on top of another, since they cannot be separated once they are in the water. No more than 100 sections should be worked at one time in a pan of the dimensions listed.

4. Dip a slide into the water at an angle of about 50° until the water level is about 0.5 cm. above the midline of the slide.
5. Take a straight probe or needle, and, catching any of the sections by one edge, pull it over and hold it against the slide with the needle and pull both slide and needle out of the water together. The water will run out from under the section and leave it in about the center of the slide, depending, of course, upon how close to the center the section was held with the needle.
6. Repeat until all of the sections have been placed on slides; then place the slides in a drying oven overnight. If no drying oven or incubator is available, then let the slides stand for 3 days to ensure complete evaporation of the water.

Contrary to the belief of many, the sections will not wash off the slides provided they have completely dried and do not receive rough handling in the staining and mounting processes. One precaution to be observed is to see that there are no bubbles on the surface of the water that is used, since a bubble under a section will cause it to crack when dry or to wash off of the slide.

This method is essentially a time-saving method but is not as reliable as the first method described. However, if done carefully, it should not cause any trouble.

SPECIALIZED PREPARATION OF TISSUE

Technic of making large sections of organs as originated by Christeller

A specially constructed sliding microtome* with a large freezing table is used.

Slides are photographic plates 9 × 12 cm. Cover glasses slightly smaller* are used. These are approximately 8½ × 11 cm. Staining dishes are rectangular-shaped museum jars. There should be about 12 of these. Tissues should be hardened in 10% formalin.

Procedure:

1. Place a moistened piece of good grade lens paper on the microtome block.
2. Place the tissue to be cut on this paper and press down.
3. Cover with the freezing hood and freeze slowly.
4. When the tissue is frozen, remove hood and cut.
5. Moisten the fingers. Cut one slice at a time, lifting the slice with the fingers as you cut. Be careful not to cut your fingers during this process.
6. After removing from blade place the sections in water, using your fingers.
7. Place sections on plates with bent glass rod with blunt end. This is not easy. It takes several days' practice to become efficient in this process. There must not be a single bent place on the section.
8. Dehydrate with absolute alcohol. Use a large quantity of alcohol.
9. Press out all air bubbles with rod.
10. Dehydrate 3 or 4 times.
11. Cover with a thin layer of very thin celloidin. (Make this celloidin from stock solution, using 2 ml. to 100 ml. of equal parts of alcohol and ether.) Let it be thin enough when placed on the back of the hand to make an extremely thin coating. Run excess back into bottle.
12. Wait until it is almost air dried but **not** dried.
13. Place solutions for staining in museum jars (11 × 15 cm.).
14. Lay the specimens in water directly.
15. Place in Boehmer hematoxylin for 3-4 min.
16. Then place in distilled water.
17. Place in hydrochloric acid-alcohol, 1 ml. hydrochloric acid to 100 ml. 70% alcohol.
18. Place again in distilled water. Repeat in fresh water to remove acid. Section becomes blue.
19. Stain in aqueous eosin solution.
20. Wash in distilled water; then carry through:
21. Alcohol 70%, 1 min.
22. Alcohol 95%, 1 min. Do not use absolute alcohol, since this redissolves the celloidin.
23. Terpene oil (Kahlbaum) or carbolxylol, 1 min.
24. Xylol.
25. Canada balsam. Put balsam in middle of plate and slightly bend the cover glass to the middle; let it down on both sides and press and put weight on it overnight.
26. Label.

Preparation of small pieces of skin tissue[4]

1. Fix tissues in Bouin solution (p. 1641) overnight. Twenty-four hr. is the maximum fixing time.
2. 9:00 A.M. Wash in 50% alcohol.
3. 10:00 A.M. Wash in 70% alcohol containing 3 drops of saturated solution of lithium carbonate.
4. 12:00 noon. Put in 70% alcohol. The tissue can be left over the week end in this solution.
5. 3:00 P.M. Place tissues in 80% alcohol.
6. 5:00 P.M. Place tissues in 95% alcohol and leave until the following day.
7. Next day, 9:00 A.M. Place in absolute alcohol.
8. 10:30 A.M. Place in amyl acetate.
9. 4:00 P.M. Place in paraffin in the paraffin oven.
10. 5:00 P.M. Pour off the paraffin and leave the tissues outside of the paraffin oven. Never leave tissues in oven overnight. Never re-use any paraffin.
11. Next day, 9:00 A.M. Put in second paraffin.
12. 12:00 Noon. Put in third paraffin.
13. 2:00 P.M. Embed in paraffin.
14. Cut and stain with routine hematoxylin and eosin stain (pp. 1691 and 1692).

Amyl acetate can be used for clearing formalin-fixed tissues as well as those fixed in Bouin fixative.

If the tissue is fixed in formalin, first wash in water from 9:00 A.M. until 10:30 A.M. Then place in 50% alcohol and then in 70% alcohol until 12:00 noon. Follow the technic for Bouin-fixed tissue from this point.

---

*E. Leitz, Inc., New York, N. Y.

This method is especially recommended to make satisfactory sections of very small pieces of skin, biopsy, etc.

Preparation of serial slices of the breast

Method of Ingleby-Holly[5]

In relation to diagnosis of disease of the breast it is of paramount necessity to examine as large portions of this organ as possible in order to come to the proper conclusion concerning the pathologic anatomy. In other words, the organs as a whole must first be studied, and later any special area should be minutely examined.

Procedure: Specimen is brought from the operating room or autopsy table.

1. Suspend specimen in a jar of 10% formalin in order to fix it with the normal contour preserved as nearly as possible. Suspending the specimen can be accomplished by means of a gauze sling.
2. Place the jar containing the breast in the refrigerator room and leave it there for at least 24 hr.
3. Remove from the solution, wrap in a wet cloth, and freeze. Freeze rapidly. Use a commercial ice cream freezer for the purpose or place in a freezing unit.

Ingleby and Holly recommend a slicer* that cuts even slices down to about 0.5 mm. in thickness. With this slicer, freezing of the tissue is not absolutely necessary; however, better results are obtained if the specimen is frozen before slicing, especially if the specimen is of soft or uneven consistency, such as fatty breast where skin is present.

4. Stack sections in order. They may be put back into formaldehyde for further fixation or they may be tagged and numbered at once. Some sections are difficult to handle. Receive these in a bowl of water and float onto numbered pieces of paper, and stack. In this way sections can be kept perfectly flat during further fixation.
5. Fix for a few hours, then wash 1 hr. or more in running water, rinse in distilled water, and place in a single layer in the following filtered solution:

Harris hematoxylin	5 ml.
Distilled water	100 ml.

6. Stain for 24 hr., turning once during this time to ensure even staining.
7. Differentiate in acid alcohol.
8. Wash until blue.
9. Place in

70% alcohol . .	1-2 hr.,
95% alcohol . .	6-8 hr. (2 changes),
absolute alcohol .	2-4 hr. (2 changes),
benzine	2-4 hr. (2 changes).

10. Store in mineral oil until required for use. Then transfer to 2 parts oil of wintergreen and 1 part benzol benzoate for about 1 hr. They are then ready to be examined under the dissecting microscope.

An alternative stain is Masson iron hematoxylin. This gives excellent results where material to be stained is not too dense. It is the method of choice if photography is contemplated.

Sections must be returned to the mineral oil after study. Oil of wintergreen is an excellent clearing agent, but it extracts the hematoxylin and the sections fade rapidly. In some cases sections may be examined in mineral oil without clearing. Occasionally, especially with the ordinary microscope, mineral oil gives better results than the more brilliant oil of wintergreen.

Advantages of method:

1. It is possible to examine grossly every part of the tissue. In this way small lesions are not missed, and if it is not desired to stain whole sections, suitable pieces for paraffin blocks are easily picked out.
2. A 3-dimensional view is obtained and structural relations are beautifully shown; no lesion of any importance can be missed.
3. The method is a rapid one. A whole breast could be ready for examination in 5 days or less.
4. Paraffin sections can be made at any time from any part should higher magnification be desirable.

MOUNTING REAGENTS

For the preparation of permanent mounts, Canada balsam and gum damar are in most general use. The author has been using gum damar for many years as a mounting medium for permanent microscopic tissue sections and has prepared more than 250,000 sections in this time. Gum damar has proved to be superior in every way to Canada balsam. The balsam slides dry slowly, and after years of curing they still have a tendency to stick together when stored in contact. The balsam has turned yellow at the edges and under the cover slips after storage, and at the edges of the sections, in a 2 or 3 mm. zone, there is complete decolorization of the nuclear stain. Slides mounted in gum damar are much cleaner, dry more quickly, do not stick together if allowed to dry for a few months before stacking, do not discolor, and do not fade.

Gum damar: Gum damar may be purchased in the crude state from supply houses.

Dissolve the gum in neutral histologic xylol.* Place the ingredients together in a large stoppered bottle in an incubator and stir with a glass rod several times daily until of a syrupy consistency—about 1 wk.

Strain through 4 layers of clean gauze and store in a dark bottle. If the resultant solution is too thin, leave the unstoppered bottle in an incubator until it evaporates to the right consistency. If it is too thick, add more xylol.

---

*American Slicing Machine Co., Chicago, Ill.

*That prepared by Eastman Kodak Co. is especially good.

Canada balsam: Prepare a good grade of Canada balsam like gum damar or purchase from any reliable supply house.

Euparol: Euparol is either colorless or green. Use the green for hematoxylin-eosin stains only. It intensifies the microscopic picture. Very often poorly stained sections mounted in green euparol are intensified after mounting.

To mount, take the tissues directly from 95% alcohol, omitting absolute alcohol and xylol steps.

Chloroform and balsam: Dissolve the balsam in chloroform. Use as a mounting medium for sections stained with osmic acid since other mounting reagents for osmic acid preparations cause the stain to fade. The mixture should be of a heavy syrupy consistency.

Cedar oil: Use cedar oil to mount sections stained by the Giemsa method, and use only thick cedar oil.

Clarite: Clarite is a resin dissolved in toluene or in xylol. It should be purchased from a supply house.

Permount: Permount should be purchased from a supply house. It is a very satisfactory mounting reagent.

Colophonium: Colophonium is sold in solid form. Dissolve in oil of turpentine. It is used for mounting blood films stained with Wright stain. Prepare it in the same way as gum damar.

Glycerin jelly—Kaiser:

Gelatin (French sheet)	10 gm.
Distilled water	60 ml.
Pure glycerin	70 ml.
Liquid carbolic acid	1 ml.

1. Heat the water in a beaker and dissolve the gelatin.
2. Add the glycerin and carbolic acid and stir until smooth.
3. Filter through wet absorbent cotton while hot and store in a cork-stoppered bottle.
4. To melt, place the bottle in a paraffin oven for 15 min.

Gum arabic:

Pure gum arabic	50 gm.
Pure cane sugar	50 gm.
Distilled water	50 ml.
Thymol crystals	0.5 gm.

1. Dissolve the gum arabic and sugar separately and mix together.
2. Add the thymol crystals.
3. Keep in a well-stoppered bottle. It sets quite hard.

Temporary mounting media: For temporary mounts use cedar oil or glycerin and discard the slides after emergency examination.

CLEARING REAGENTS

Clearing reagents are used to make the tissue sections transparent so that they may be seen and differentiated under the microscope. Various reagents of different chemical properties are used. The choice depends mainly on 2 factors, the kind of stain used and the materials in which the tissues have been fixed and embedded.

Most clearing reagents can be used after hematoxylin stain. For celloidin sections, oil origanum and oil of bergamot are recommended. For aniline stains, xylol is the best clearing reagent, but it clears only from absolute alcohol and butyl alcohol.

Carbolxylol: Carbolxylol has a dark straw color. It does not dissolve celloidin and it does not affect hematoxylin. It clears directly from absolute and butyl alcohols, and it will clear from 95% alcohol also if the section is blotted in filter paper before it is placed in carbolxylol. Sections should not be left more than 5 min. in this mixture.

All glassware must be clean and **dry.**

Add 3 parts xylol to 1 part **liquefied** carbolic crystals (phenol) and mix. Do not use liquid carbolic acid since it contains a small amount of water.

Xylol: Xylol is colorless, does not dissolve celloidin, does not affect aniline dyes, clears directly from absolute or butyl alcohols, and will also clear from 95% alcohol if the xylol is used in several applications, the section blotted after each.

Oil origanum: Oil origanum is straw to brown colored and affects aniline stains slowly. It clears celloidin sections very slowly.

Oil of bergamot: Oil of bergamot is light green, clears from 95% alcohol, does not dissolve celloidin, and affects aniline stains slowly, except eosin, which it extracts very quickly.

Oil of cloves: Oil of cloves is straw colored, clears from 95% alcohol, affects aniline stains, especially methylene blue, and dissolves celloidin slowly.

Aniline oil: Aniline oil is colorless when pure and fresh, but it oxidizes rapidly and turns brown. It does not dissolve celloidin, clears from 80% alcohol, and affects aniline stains slowly. A mixture of equal parts of aniline oil and xylol is used to decolorize sections stained by the Gram-Weigert method as well as the Flexner stain for Hansen's bacillus and to clear sections stained for myelin sheaths by the Courville-Krajian method.

Oil of cedarwood: Oil of cedarwood has a pale straw color, clears from 95% alcohol, does not affect aniline stains, and clears celloidin sections very slowly.

Beechwood creosote: Beechwood creosote, formerly much used to clear celloidin sections, is replaced with carbolxylol.

Chloroform: Chloroform has long been used to clear tissues after dehydration. It absorbs a good deal of moisture left in tissues and renders them less brittle.

Benzine: Benzine is too volatile for clearing purposes. Some workers prefer it to chloroform or xylol because it clears quickly, makes the tissue more transparent, and evaporates rapidly from the paraffin bath.

IDENTIFICATION NUMBER UNDER COVER SLIP

A convenient method of labeling slides is shown in Fig. 527. Letter the laboratory specimen number or the name of the patient in

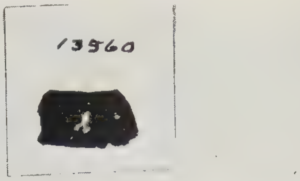

Fig. 527. Identification number under cover slip. (From Krajian, A. A., and Gradwohl, R. B. H.: Histopathological technic, St. Louis, 1952, The C. V. Mosby Co.)

small letters on very fine tissue paper with India ink (Higgins) and cut out a square. Put a drop of gum damar over the section, place the printed number alongside it, and cover the slide with a cover slip.

PLASTIC MOUNTING OF HISTOLOGIC SECTIONS

Tissue sections may be mounted on 35 mm. film instead of on glass. The sections are then covered with a hardening plastic spray instead of the conventional glass cover slips. The method was devised by Pickett and Sommer.[5a]*

Procedure:

1. Cut film strips of any desired length from the stock roll.
2. Clean by dipping in acid alcohol and dry with a soft cloth. Do not use gauze.
3. Coat the surface of the film with a thin layer of egg albumin while the film is spread out on a clean surface.
4. Cut paraffin sections 5-10μ thick and place a ribbon on the water bath.
5. Maneuver the film under the ribbon and pick up the sections.
6. When the film is covered to capacity, label with a diamond pencil and place in an oven at 56° C. If the films are exposed for a short time to hot water under the film, the sections flatten by themselves.
7. When dry, load the film into 35 mm. film-developing reels.
8. Stain the sections on films in the usual manner. They may also be deparaffinized with xylol, placed in absolute alcohol for 1-2 min., then in 0.5% celloidin 5 min., dried in the air 3-4 min., and placed in 80% alcohol 5 min., then washed and stained as usual.
9. Dehydrate through 95% alcohol and 2 changes of a mixture of ⅓ chloroform and ⅔ absolute alcohol; clear in xylol.
10. Remove one film strip at a time and place face up on a blotter, but do not allow to dry. Be sure the film lies flat to prevent an uneven plastic coat.
11. Apply the plastic spray from one end to the other 2 or 3 times until the surface appears to be smooth. Hold the can containing the plastic approximately 6 in. above the film.
12. Allow the plastic to harden 5-10 min. Repeat 2 or 3 times and leave to dry. A uniform and even spread may be obtained by placing the film strips on the inside of an open revolving drum and, while the drum is spinning rapidly, applying the spray and leaving to dry. The plastic coat may be removed by dipping into xylol if desired.
13. Label the dry film with India ink.
14. Place the sections in the holder supplied with the kit to keep the sections flat during microscopy.

These sections may be filed in special cabinets, stapled to records, suspended from racks, or filed individually after cutting a film strip apart. Before filing let the film strips dry for about 3 wk.

---

*The 35 mm. film is Cronar, P-40B leader film, E. I. DuPont de Nemours & Co., Inc. The plastic spray is Krylon Plastic Spray, No. 1302, from Krylon, Inc., Norristown, Pa. The reel to carry the sections on film through staining solutions is the Nikor 35 mm. developing reel, made of stainless steel. It is available from photographic supply houses. A Slide-strip Kit containing all necessary apparatus is available from Carolina Biological Supply Co., Burlington, N. C.

Chapter 87

Staining solutions

ARAM A. KRAJIAN

INTRODUCTION

No satisfactory explanation has been advanced for the various staining effects of tissue and organisms except that these depend on chemical and physical factors. Advances in stain technology have resulted in a better understanding of the characteristics of tissue elements and structures, their affinity for numerous dyes, and with the aid of certain metallic and chemical mordants many specific staining methods have been developed.

The foundations for microscopic anatomic study were laid long before the staining methods were devised. In the early and midnineteenth century tissues were sectioned by hand in a crude manner, stained in various coloring solutions, and examined under cover slip preparations. Although the technics used at that time were crude and temporary, accurate observations of the material enabled the histologists to describe the arrangement of cells and tissue components in various organs of the body.

It was impossible, however, to study the cytologic elements and interlacing connective tissue and fibers of the central nervous system or structures of the special sense organs until the advent of staining methods. Cytology became a recognized science with the introduction of special stains which made it possible to color selectively certain elements of the cells such as chromosomes, mitochondria, and Golgi bodies.

The use of dyes in histologic microscopy began about 1850. Carmine stain was first introduced by botanists Göppert and Cohn[6] in 1849. Indigo, iodine, fuchsin, aniline red, aniline violet, and other dyes were used in simple solutions. Hematoxylin was first used by Waldeyer[7] to stain axis cylinders in aqueous solution. In 1865 Boehmer[8] combined hematoxylin with alum, thereby increasing its value as a histologic stain. Ehrlich,[9] Flemming,[10] and Unna[11] introduced both the aniline and hematoxylin series, opening the way for many more combination stains. About 1890 the differential stains were introduced as a result of combining various dyes and chemical reagents. Progress continued, and each year new important staining methods were announced. Mallory[12] developed his famous aniline blue stain for connective tissue; Heidenhain[13] developed his iron hematoxylin stain for protozoologic work; Levaditi[14] and Manouelian discovered a stain to demonstrate *Treponema pallidum* in tissue; Cajal[15] revolutionized the subject of neuropathology by his investigation and discovery of the value of silver nitrate for staining nerve fibers in the central nervous system.

Krajian developed more rapid and selective methods for the identification of such elements as myelin sheath, argentaffin cells, gram-positive and gram-negative organisms, parasites and inclusion bodies in tissue, urea crystals in brain tissue, reticular fibers, *T. pallidum* and other types of spiral organisms in tissue sections and smears, differentiation of carcinoma and sarcoma, elastic tissue, connective tissue, mucin, acid-fast organisms, zymogen granules, and others.

In the past half century great progress has been made and astonishing results accomplished in selective staining.

Staining solutions for specialized staining will be described with the specialized technic for which they are used.

HEMATOXYLIN STAINS

Hematoxylin is one of the oldest and most valuable histologic stains. Hematein, the active coloring agent, is formed by oxidation, which requires a number of days or weeks. In alum hematoxylin the selective staining power is due to the combination of hematein with alum. Mayer, Unna, and Harris have shown that it is possible to oxidize and ripen the alum hematoxylin by adding a little mercuric oxide or hydrogen peroxide. As alum hematoxylins become older they stain more quickly. Addition of 3 ml. glacial acetic acid to 95 ml. hematoxylin solution at the time of use helps sharpen the nuclear staining of the cells.

Harris hematoxylin:

Hematoxylin crystals	1 gm.
Alcohol, 95%	10 ml.
Ammonium or potassium alum	20 gm.
Distilled water	200 ml.

1. Dissolve the hematoxylin in the alcohol in a mortar with a pestle.
2. Dissolve the alum in water, with heat.
3. Add hematoxylin solution to alum solution.
4. Bring to a boil as quickly as possible.
5. Add 0.5 gm. mercuric oxide. The solution at once assumes a dark purple color. As soon as this occurs remove from the flame and cool as rapidly as possible in a bath of running or frequently changed cold water. When cool, the solution is ready for use.

Addition of 3 ml. glacial acetic acid to 95 ml. of solution at the time of use will increase its nuclear staining properties.

The stain is stable. It is one of the best routine histologic stains.

Filter before use.

Delafield hematoxylin:

1. Prepare a saturated solution of ammonium alum in distilled water.
2. Dissolve 4 gm. hematoxylin crystals in 25 ml. 95% alcohol.
3. Add 400 ml. saturated solution of ammonium alum.
4. Place in a Mason jar, with the cover on lightly, and put in the light and air for 1 or 2 wk.; then filter.
5. Add 100 ml. methyl alcohol, acetone-free, and 100 ml. glycerin.
6. Keep in a bottle exposed to the sunlight until ready for use. It usually takes at least 1 mo. for the hematoxylin to ripen.
7. **For quick ripening** add the methyl alcohol and glycerin to a freshly prepared and filtered hematoxylin solution; then add 400 mg. sodium iodate. The solution will darken and can be used immediately.

Delafield hematoxylin keeps well and is potent as long as it has a purplish cast.

Mallory phosphotungstic acid hematoxylin:

Hematoxylin or hematein ammonium	1 gm.
Phosphotungstic acid crystals	20 gm.
Distilled water	1000 ml.

1. Dissolve the hematoxylin in a small amount of water by heat.
2. Dissolve the phosphotungstic acid in the remaining water.
3. Allow the hematoxylin solution to cool and add it to the phosphotungstic acid solution.
4. If the solution stains weakly at first, it may be ripened by adding 5 ml. of freshly prepared 0.25% aqueous potassium permanganate for every 100 ml. stain, or it may be allowed to stand for several weeks until it ripens spontaneously. If hematoxylin is used instead of hematein ammonium, use 10 ml. permanganate solution/100 ml. When hematoxylin is used, addition of 0.177 gm. potassium permanganate/100 ml. solution may be substituted for the 0.25% $KMnO_4$.

Mallory phosphotungstic acid hematoxylin solution is especially useful to demonstrate fibrin as well as the fibroglia and myoglia fibrils of neuroglia. It also brings out the detail of mitotic figures, including spindles and centrosomes.

Heidenhain hematoxylin:

Formula 1:

Hematoxylin	1 gm.
Ethyl alcohol, 95%	10 ml.

1. Dissolve in a mortar and add 100 ml. of distilled water. Ripen several days.

Heidenhain hematoxylin, combined with iron and ammonium alum (see below), after suitable fixation, is used to demonstrate chromatin, nuclei, nuclear membrane, and centrosomes. The fixatives generally used are chrome salts and mercuric chloride.

Formula 2:

Hematoxylin	0.5 gm.
Ethyl alcohol, 95%	10 ml.

1. Dissolve in a mortar and add 100 ml. of distilled water. Ripen several days.

MacCallum hematoxylin:

Hematoxylin, 10% in absolute alcohol and ripened	2 ml.
Ferric chloride, 10% aqueous	3 ml.
Sodium iodide, 10% aqueous	5 ml.
Alcohol, 50%	50 ml.

Mix in the order indicated.

This is used for staining elastic tissue. The stain keeps 1 wk.

MacCallum hematoxylin—Krajian modification (Krajian iron hematoxylin):

Hematoxylin crystals	3 gm.
Ferric chloride	3 gm.
Ferric ammonium sulfate	3 gm.
Potassium iodide	3 gm.
Alcohol, 95%	25 ml.
Distilled water	25 ml.

1. Dissolve the hematoxylin in the alcohol.
2. Dissolve the other chemicals in the distilled water.
3. Mix the 2 solutions.

The resulting solution stains elastic fibers and myelin sheaths blue black, acts as a mordant in van Gieson stain, and stains bacteria.

This is used in the Krajian modification of MacCallum stain for elastic tissue.

Weigert-Pal hematoxylin:

Solution A:

Hematoxylin crystals	10 gm.
Absolute alcohol	100 ml.

1. Dissolve the hematoxylin in the alcohol and ripen for 2 or 3 wk.

Solution B:

Lithium carbonate, concentrated aqueous solution	7 ml.
Distilled water	93 ml.

1. Dissolve.
2. Mix 1 vol. solution A and 9 vol. solution B just before use.

This formula is used to stain myelin or medullary sheath.

Spielmeyer hematoxylin:

Ripened 10% hematoxylin in absolute alcohol	5 ml.
Distilled water	100 ml.

This is a myelin sheath stain.

Pal-Kulschitzky hematoxylin:

Ripened 10% hematoxylin in absolute alcohol	10 ml.
Acetic acid, 2%	90 ml.

The hematoxylin solution must be at least 6 mo. old.

This is a myelin sheath stain.

Fuller hematoxylin:

1. Dissolve 1 gm. hematoxylin in 90 ml. hot distilled water.
2. Cool and add 10 ml. glycerin and 10 ml. 95% alcohol.

This is used in staining acid-fast organisms.

Boehmer hematoxylin:

Solution A:

Hematoxylin crystals	1 gm.
Absolute alcohol	12 ml.

Solution B:

Alum	20 gm.
Warm distilled water	200 ml.

1. Filter when cool.
2. Mix the 2 solutions after 24 hr. Place in a wide-mouthed bottle and expose to the air for 8 days; then filter through filter paper.

Ehrlich hematoxylin:

1. Combine the following, dissolving the hematoxylin in the mixture of alcohol and acetic acid:

Hematoxylin crystals	2 gm.
Absolute alcohol	10 ml.
Glacial acetic acid	10 ml.

2. Add alcohol to glycerin as follows and mix:

Absolute alcohol	90 ml.
Glycerin	100 ml.

3. Add the hematoxylin solution to the alcohol-glycerin mixture.
4. Dissolve 10 gm. potassium alum in 100 ml. distilled water with heat.
5. Cool and add the alum solution to the hematoxylin–alcohol–acetic acid–glycerin mixture, stirring constantly.
6. Expose the solution to light and air to ripen for 4-6 wk.

If it stands in a warm place and is shaken occasionally, oxidation is facilitated, and the ripening process is aided materially. The ripe solution should have the color of port wine.

Mayer hematoxylin:

Distilled water	1000 ml.
Hematoxylin crystals	1 gm.
Ammonium or potassium alum	50 gm.
Sodium iodate	0.2 gm.
Citric acid	1 gm.
Chloral hydrate	50 gm.

1. Dissolve the hematoxylin in 1000 ml. distilled water that has been heated to 55°-60° C. and rotate until all the stain is in solution.
2. Add the alum and sodium iodate, taking care that the 0.2 gm. sodium iodate has been accurately weighed.
3. Rotate until the alum has dissolved; then add the citric acid and the chloral hydrate. The order of mixing must not be changed.
4. Allow the solution to stand overnight before use.

This solution is stable for 2 mo. if the staining time is gradually increased from an initial 6 min. to 8 min. after prolonged use. Occasional filtering may be necessary to remove accumulated cellular debris. It is used in the Pharr, Wood, and Traut modification of the Papanicolaou stain.

CARMINE STAINS

The active staining principle in the carmine solutions is carminic acid. All alkaline and acid solutions made with carmine owe their staining properties to carminic acid combined with aluminum.

Lithium carmine:

Carmine	2.5 gm.
Lithium carbonate, saturated aqueous	100 ml.
Thymol	1 crystal

The carmine dissolves at once in the cold solution. This solution should be carefully filtered, especially when used as a counterstain in the Gram-Weigert method.

Best carmine stain for glycogen:

Stock solution:

Carmine	2 gm.
Potassium carbonate	1 gm.
Potassium chloride	5 gm.
Distilled water	60 ml.

1. Boil several minutes, cool, and add:

Concentrated ammonium hydroxide	20 ml.

2. Keep this stock solution in well-stoppered bottles in a dark cool place. Filter before use. It keeps a month or less.

Differentiator:

Absolute methyl alcohol	40 ml.
Absolute ethyl alcohol	80 ml.
Distilled water	100 ml.

Mayer mucicarmine:

Carmine	1 gm.
Aluminum chloride	0.5 gm.
Distilled water	50 ml.

1. Heat in a Pyrex beaker for several minutes until completely dissolved.

2. Then add 50 ml. 95% alcohol and mix. The solution keeps well.

Mayer mucicarmine—Krajian modification:

Carmine	1 gm.
Aluminum chloride	0.5 gm.
Distilled water	25 ml.
Alcohol, 95%	25 ml.

1. Boil and dissolve the aluminum chloride in the distilled water.
2. Add the carmine slowly, stirring the mixture constantly for 3 min.
3. Cool, filter, and add 25 ml. 95% alcohol.

Azocarmine:

Azocarmine	1 gm.
Distilled water	100 ml.

1. Heat 20 min., cool, and filter.
2. Acidify with 1 ml. of glacial acetic acid.

Azocarmine-fuchsin: Mix 1 part of azocarmine stain (above) with an equal volume of 2% aqueous solution of acid fuchsin.

ANILINE DYES AND SOLUTIONS

Aniline dyes are sold as powders or in crystalline form. Most of the dyes keep well. There should be on hand saturated alcoholic solutions of certain dyes since the stains are fairly stable in such form and are ready for use when needed. This is particularly true of methylene blue, basic fuchsin, and methyl violet.

Aniline dyes are derived from aniline or toluidine or from both. They are salts with basic or acid properties. The basic dyes stain the cell nuclei and bacteria; acid dyes stain diffusely.

The basic dyes most often used are methylene blue, fuchsin, methyl violet, and safranin. The most commonly used acid dyes are eosin, picric acid, and fuchsin.

Loeffler methylene blue:

Saturated alcoholic solution of methylene blue	30 ml.
1:10,000 potassium hydroxide	100 ml.

1. Make 1:10,000 KOH by adding 2 drops 10% KOH to 100 ml. distilled water.

This is a useful aniline stain. It keeps well without losing much staining power.

Unna polychrome methylene blue:

Methylene blue	1 gm.
Potassium carbonate	1 gm.
Distilled water	100 ml.

1. Dilute 1:5 or 1:10 at the time of use.
2. The solution requires months for oxidation at room temperature. The time is greatly shortened if heat is applied.

This formula is extremely valuable as a stain for plasma cells and as a general stain combined with eosin, which should be used first. It is one of the older alkaline methylene blue formulas.

Acid polychrome methylene blue—Goodpasture:

Methylene blue	1 gm.
Potassium carbonate	1 gm.
Distilled water	400 ml.

1. Dissolve the ingredients and boil in a flask for 30 min. As the methylene blue is polychromed, most of it will precipitate.
2. Cool and add 3 ml. glacial acetic acid; shake thoroughly until the precipitate is dissolved.
3. Boil gently for 5 min. or until the solution is concentrated to a volume of 200 ml.
4. Cool in tap water.

The stain may be used immediately. It keeps indefinitely.

Modified Mallory aniline blue:

Aniline blue, water-soluble	0.5 gm.
Orange G	2 gm.
Oxalic acid	2 gm.
Distilled water	100 ml.

1. If necessary, heat to dissolve.

Mallory aniline blue–orange G–acetic acid solution:

Aniline blue, water-soluble	0.5 gm.
Acetic acid, glacial	8 ml.
Orange G	2 gm.
Distilled water	100 ml.

1. Heat and filter after cooling.
2. Dilute with as much water as there is stain.

Krajian aniline blue for elastic fibers:

Resorcinol	3 gm.
Aniline blue, water-soluble	1.5 gm.
Orange G	2.5 gm.
Phosphomolybdic acid	1 gm.
Distilled water	100 ml.

1. If necessary, heat to dissolve.

Borrel methylene blue:

1. Dissolve 1 gm. methylene blue in 100 ml. distilled water and heat in a water bath.
2. Dissolve 0.5 gm. silver nitrate in 100 ml. distilled water, placing the solution in a 500 ml. flask.
3. Dissolve 3 gm. sodium hydroxide in 100 ml. distilled water and add slowly to the silver solution, shaking the flask constantly. A brown precipitate of silver oxide is formed. Discontinue adding the sodium hydroxide solution as soon as no more precipitate is formed.
4. When the precipitate settles, discard the supernatant fluid, wash the precipitate by shaking in distilled water, and repeat the entire process several times until the distilled water is no longer alkaline to litmus paper.
5. Pour off the distilled water and add the 1% methylene blue solution.
6. Boil the mixture gently for 5 min. and cool. The solution becomes dark violet when cold. If still blue, boil further to oxidize the methylene blue. If it remains reddish, add a little more methylene blue until it becomes violet.
7. Filter and store in a glass-stoppered bottle.
8. To use, dilute 1 part stain with 5 parts distilled water.

Unna pyronine–methyl green:

Methyl green	0.15 gm.
Pyronine	0.25 gm.
Alcohol, 95%	2.5 ml.
Glycerin	20 ml.
Carbolic acid, 0.5% aqueous	100 ml.

1. Mix the alcohol and carbolic acid.
2. Dissolve the methyl green in the alcohol-phenol.

3. Mix the glycerin and distilled water.
4. Dissolve the pyronine in this mixture.
5. Mix the 2 solutions.

This solution is used principally in one of the chromatin methods.

Basic fuchsin solutions: A saturated alcoholic solution of basic fuchsin should be kept in stock.

Basic fuchsin	3.5 gm.
Alcohol, 95%	100 ml.

1. Grind in a mortar to dissolve.
2. Filter after 24 hr.

Basic fuchsin of superior quality, called "new fuchsin," is highly recommended for its deep staining of acid-fast organisms.

Ziehl-Neelsen carbolfuchsin:

Saturated alcoholic solution of basic fuchsin	10 ml.
Carbolic acid, 5% aqueous	90 ml.

1. Make the carbolic acid solution by adding 5 ml. melted carbolic acid crystals to 95 ml. distilled water. Shake.

This carbolfuchsin is quite powerful. It keeps well and stains well. Shake the bottle before use.

Krajian carbolfuchsin mixture for mucin stain:

Carbolfuchsin	15 drops
Acetic acid	3 drops
Formaldehyde, 40%	3 drops
Distilled water	2 ml.

The solution does not keep and therefore should be prepared fresh before use.

Fuller aniline fuchsin: Mix 16 ml. saturated alcoholic solution of basic fuchsin with 84 ml. aniline water.

Goodpasture fuchsin solution:

Formula 1:

Alcohol, 30%	100 ml.
Basic fuchsin	0.59 gm.
Aniline oil	1 ml.
Phenol crystals	1 ml.

Formula 2:

Alcohol, 20%	100 ml.
Pure phenol	1 ml.
Aniline oil	1 gm.
Basic fuchsin	0.5 gm.

The finely powdered or granular dye is easily dissolved, and the solution is ready for use.

Acid fuchsin solution: Keep a 1% aqueous solution of acid fuchsin on hand. Acid fuchsin is used in connective tissue stains, van Gieson formula.

Aniline acid fuchsin:

Acid fuchsin	2 gm.
Aniline water, 5%	10 ml.

Altman aniline fuchsin:

1. Prepare a saturated solution of aniline oil in distilled water by shaking the 2 together. Filter.
2. Add 10 gm. acid fuchsin to 100 ml. filtrate.
3. Use after 24 hr. It deteriorates in a month.

Mallory basic fuchsin:

Basic fuchsin	0.3 gm.
Alcohol, 95%	50 ml.
Distilled water	50 ml.

1. Dissolve the dye in the alcohol and add the water.
2. Filter after 24 hr.

Fuchsin-methylene blue:

Basic fuchsin	1 gm.
Methylene blue	0.5 gm.
Glycerin	50 ml.
Alcohol, 95%	50 ml.

1. Dissolve the fuchsin and methylene blue in alcohol, add the glycerin, and mix thoroughly.
2. Dilute for use, 1 part with 30 parts distilled water.

Fuchsin-methylene blue—Frothingham:

Saturated alcoholic solution of basic fuchsin	6 drops
Saturated alcoholic solution of methylene blue	4 drops
Distilled water	30 ml.

1. Add the dyes to the distilled water and mix.

Weigert iron-fuchsin stain for elastic tissue: This is also known as Weigert elastic tissue stain.

1. Mix 2 ml. melted phenol crystals and 1 gm. basic fuchsin; then dissolve in 100 ml. distilled water.
2. Bring to a boil; then gradually add 12.5 ml. 30% ferric chloride solution. A precipitate forms. Continue boiling at least 5 min. to render the precipitate more granular.
3. Cool and filter.
4. Wash the precipitate on filter paper with distilled water until no more color is seen. Dry the precipitate in a paraffin oven at 55° C. Keep the dry powder in a bottle as the stock dye.
5. To prepare the staining solution dissolve 0.75 gm. of the dry powder in 100 ml. 95% alcohol.
6. Boil in a water bath in a flask plugged with cotton wool for 20 min. Cool, filter, and add 2 ml. concentrated hydrochloric acid.

This is an excellent stain for demonstration of elastic fibers.

Methyl violet: A 1% aqueous methyl violet solution should be kept on hand. It keeps well.

It is used for staining bacteria and amyloid. With methyl violet, amyloid stains pink but fades after mounting.

Gentian violet: Gentian violet is a mixture of crystal violet, methyl violet, and dextrin. A product called "gentian violet improved" has been found satisfactory.

Sterling gentian violet:

Gentian violet improved	5 gm.
Alcohol, 95%	10 ml.
Aniline oil	2 ml.
Distilled water	88 ml.

1. Dissolve the aniline oil in the distilled water by shaking, and filter through filter paper. Add this to the gentian violet dissolved in alcohol.

The solution keeps well for several weeks or months and is highly recommended for demonstration of bacteria, fungi, and fibrin in tissue.

Carbol gentian violet:

Saturated alcoholic solution of gentian violet	10 ml.
Carbolic acid, 1%	90 ml.

1. Mix and filter after 24 hr.

Gentian violet saturates at 5 gm./100 ml. 95% alcohol.

Bensley neutral gentian violet:

1. Dissolve 1 gm. gentian violet in 25 ml. distilled water.
2. Dissolve 1 gm. orange G in 25 ml. distilled water.

3. Mix the 2 solutions and shake. A precipitate is formed.
4. Filter; wash the precipitate on the paper once with distilled water and dry.
5. Dissolve the dried precipitate in 25 ml. absolute alcohol. This is a stock solution.
6. For staining add a sufficient amount to 20% alcohol to give a deep violet color.

Kuhne crystal violet:

Saturated alcoholic solution of crystal violet	9 parts
Ammonium carbonate, 1% aqueous	1 part

1. Use absolute alcohol for making the saturated solution.
2. Mix just before use.

Eosin: Eosin is used principally as a counterstain following hematoxylin and at times methylene blue. It may be obtained as "eosin soluble in water" or as "eosin soluble in alcohol." It is used in strengths from 0.5% to 5%, at times dissolved in alcohol and at times in distilled water. Use eosin Y, water- and alcohol-soluble. When used before an aniline dye such as methylene blue, it should have a concentration of 5%. For counterstaining with hematoxylin a 1% aqueous solution is satisfactory. In the form of eosinol it gives excellent staining reactions, and eosinol is the recommended counterstain for routine sections.

0.5% Alcoholic eosin solution: Dissolve 0.5 gm. eosin Y in 100 ml. 95% alcohol.

1% Alcoholic eosin solution: Dissolve 1 gm. eosin Y in 100 ml. 95% alcohol.

2.5% Aqueous eosin solution: Dissolve 2.5 gm. eosin Y in 100 ml. distilled water. Place the eosin in a mortar, add a small amount of water, grind, add more water, and continue until all the eosin is in solution.

5% Eosin solution: Dissolve 5 gm. eosin Y (water- and alcohol-soluble) in 100 ml. distilled water or 95% alcohol.

Eosinol (for counterstaining, dehydrating, and clearing tissue at the same time): Krajian's method of hematoxylin and eosin staining consists in the dehydration of the section before counterstaining and the application of eosin as a solution in carbolxylol. Then, since the tissues pass afterward through xylol only, there is no opportunity for decolorization. Alcohol is saved because dehydration can be commenced in the stronger alcohol, discarding the lower gradations. The solution of eosin in carbolxylol, which constitutes the principal element of modification, is called eosinol.

1. Combine the following, dissolving the eosin in the water in a small beaker.

Eosin Y, water-soluble	5 gm.
Distilled water	10 ml.

2. Precipitate the eosin by adding:

Glacial acetic acid	10 ml.
Concentrated hydrochloric acid	2 ml.

3. Mix thoroughly with a glass rod. Incubate the resulting coagulum at 56° C. until all the water has evaporated. This may require several days.
4. Dissolve the dehydrated acid eosin in 10 ml. absolute alcohol mixed with 20 ml. acetone.
5. Stir with a glass rod for several minutes.
6. Cover the beaker tightly (aluminum foil may be used) and place in a paraffin oven (58°-60° C.) for 2 hr.
7. Let the undissolved portion, which is to be discarded, settle to the bottom of the container, 10 min. or more.
8. Remove the clear portion with a clean dry pipet and add it to 1500 ml. carbolxylol (1 part melted phenol crystals and 3 parts xylol).
9. To obtain the entire eosin yield, transfer solution remaining in the beaker to a test tube; then centrifuge and add whatever eosin solution (supernatant fluid) remains to the carbolxylol. Some precipitate may eventually form in the eosinol. Use only the clear supernatant fluid.

The solution keeps indefinitely. All glassware must be dry.

Because the various brands of powdered eosin do not have uniform staining power, it may be necessary to standardize the solution by staining control sections and adjusting the staining time or the strength of the solution.

Phloxine: Phloxine is used as a counterstain after hematoxylin. Some believe it to be superior to eosin. It stains more intensely, but differentiation is not as complete as with eosin stains.

A 1% solution is used for counterstains.

Picric acid solution: Keep a saturated solution of picric acid in stock. It is used most often in van Gieson stain and Bouin fluid.

Orcein solution: Orcein is a vegetable dye, which is used mainly for elastic tissue stain. It is soluble in alcohol. It is used in either neutral or acid alcoholic solutions.

Tincture of iodine (alcoholic solution): Tincture of iodine is used principally to dissolve the mercury precipitates that form in tissues fixed in mercuric chloride or other fluids containing bichloride, such as Zenker fluid.

Lugol solution:

Iodine	1 gm.
Potassium iodide	2 gm.
Distilled water	100 ml.

1. Rub up the iodine and potassium iodide in a mortar until thoroughly blended.
2. Add the water, a small amount at a time, until the iodine is completely dissolved.

Lugol solution is used as a test for glycogen, amyloid, and corpora amylacea.

Gram's iodine:

Iodine	1 gm.
Potassium iodide	2 gm.
Distilled water	300 ml.

1. Prepare as with Lugol solution.

This stain is used in the Gram-Weigert method of staining microorganisms and fibrin in tissue.

4% Aqueous Congo red: Dissolve 4 gm. Congo red in 100 ml. distilled water.

Krajian Congo red stain:

4% Aqueous Congo red	8 ml.
Glycerin, c.p.	2 ml.

Scharlach R (scarlet red)—Krajian modification:

Scharlach R	5 gm.
Acetone, pure	50 ml.
Alcohol, 70%	50 ml.
Benzoic acid	1 gm.

1. Dissolve the benzoic acid in the alcohol, then add the acetone, and saturate the dye in the combined solutions.

The stain is stable. After use it may be poured back into the bottle and used over and over. Filter before use. The benzoic acid intensifies the staining property of fats and prevents rapid deterioration of the stain.

Giemsa stain: The methods of making the stock and dilute Giemsa stain are given on pp. 1139 and 1140ff. The diluted stain must be prepared immediately before use. The stock stain is stable.*

Van Gieson stain:

Saturated aqueous solution of picric acid	100 ml.
Acid fuchsin, 1% aqueous . .	5 ml.

This solution keeps fairly well. If the stain weakens by long standing, restore by adding a few drops of fresh acid fuchsin.

---

*Certified Giemsa stain made by Gradwohl Laboratory Supply Co., St. Louis, Mo., is recommended.

Chapter 88

Frozen sections

ARAM A. KRAJIAN

It is essential to eliminate as completely as possible all lost time and lost motion from laboratory methods. The specialty is already so overcrowded with procedures that any saving of time, especially with promise of increased exactitude, should be welcomed by the practicing clinical pathologist and laboratory technician.

The advantages of the frozen section method are (1) ease of manipulation, (2) saving of reagents, (3) lack of change in the normal structure of tissues, (4) definite saving of time, which allows for more rapid diagnosis and permits the technician more time for other procedures, and (5) less expense in preparation. Slides are permanent.

PREPARATION OF TISSUE FOR FROZEN SECTIONS

Blocks of tissue: In order that the fixing solution penetrate thoroughly, it is essential that the blocks be fairly regular and thin.

Fixing solution: The blocks should be immersed in 15% formalin for 24 hr. This kills bacteria and initiates the hardening and preservation of the tissue. Immediate fixation is essential.

Trimming blocks: After 24 hr. fixation the blocks should be trimmed to about 1.5-1.75 cm. square by 3-5 mm. thick and placed in 10% formalin (neutral) (p. 1641).

Rapid fixation: For rapid fixation, in cases in which one is sectioning tissue from biopsy at the operating table, drop the tissue in boiling 10% formalin for 30 sec. and then in dioxane for 30 sec., and freeze immediately. For rapid fixation of autopsy material use formalin that has been brought to the bubbling point in a test tube; then pour it on the tissue in a bottle, which reduces the temperature of the formalin to about 65° C. Allow it to remain in an oven at 56° C. 20-30 min. Shrinkage will be not more than 5%.

Washing: Have handy a beaker or glass dish about 6 in. in diameter and about 3 in. high. A 250 ml. beaker will suffice. Fill with tap water. Place the tissue blocks in the water for a short period only. This removes the formaldehyde which is detrimental to the skin and which could prevent the block from adhering to the holder. If the tissue is left in water for several hours, it becomes soft and good sections cannot be obtained.

Orienting the block: With forceps place the block on the block holder as follows:

Place a drop of water on the holder.

Place the edge of the block facing the knife parallel to the cutting edge, the smaller width of the block facing the cutting edge of the knife. If a capsule, skin, or mucous membrane is present, it must face the knife either on the shorter width or on the left on the longer edge so that the cut is made from the capsule into the tissue; otherwise the capsule may be torn off.

Freezing the block

Place the index finger on the block and turn on the CO_2 gas slightly for temporary holding. Too much gas is wasteful and also results in too rapid freezing.

Press down firmly but gently all around to fix the tissue to the holder and release more gas gently until the freezing line, which can be noted on the side of the block, has passed upward through about ½ of its depth. Even freezing is essential to prevent holes in the section. Any unfrozen portion will break during the cutting process. It is most important to press the block to the holder firmly, releasing the gas slowly.

Excess water may be removed with a towel while freezing. It is not necessary to use a continuous flow of gas.

Preparing to cut frozen section

Cut off the upper ⅓, that is, the unfrozen portion, and drop it back into the specimen bottle. Then shave down to establish a smooth, level surface on which to begin sectioning. If the block is small, it should be frozen throughout and sectioning begun by shaving off the top. If the tissue is too hard, it is likewise better to begin shaving from the top of the block; otherwise the block may be dislodged. If the surface is too soft, the section will have holes. The ideal is a hard, pliable surface so that a section cut therefrom will show no tendency to break as it piles up over the cutting edge of the knife.

If holes appear in the block while cutting, touch all parts of the cut surface gently with the fingers to warm it and melt it slightly; then refreeze. In this way the holes in the unfrozen parts will become filled with frozen moisture and there will be no fragmentary parts of the tissue.

Cutting frozen section

Operating microtome (Figs. 520 and 524): It is important that the cutting be done by placing the hand on the rim of the flywheel, turning it slowly and evenly to cut a smooth, regular section. If the handle of the flywheel is used and the cutting is done automatically and rapidly, the sections are cut too fast and tend to curl or break into shreads. Such speed does not allow sufficient time to adjust the tissue surface to the proper temperature and consistency; in other words, the slower procedure permits warming of the cut surface of the block, which alone is the controlling factor in procuring a pliable section, free from undulations. This pliability prevents disintegration of the section when placed in water.

On the average, 3 notches indicate that the section will be about 10μ thick and 1 notch indicates about 3μ, due to freezing and thawing action. However, variations in tissues cause variations in thickness of cut sections; e.g., if lung and uterus tissues are each cut at 3 notches, the latter will be close to only 2 notches thick because the tissue is firmer, offers greater resistance, and tends to raise the edge of the knife. Hence, it may be necessary at times to use 4 or 5 notches when cutting uterine tissue.

Uneven sections are usually the result of freezing the block too hard and applying too much speed and unnecessary pressure, especially on firmer tissues.

Removing section from knife: Wet the tip of the little or ring finger with water, and with the finger carefully remove the section from the edge of the knife, with a downward movement at about a 45° angle to the knife blade. Place the section in water. The tissue will float out on top of the water. Keep the knife edge dry. Water left on the edge thaws the tissue with which it comes in contact, causing a hole in succeeding sections. Place the sections in a large dish of water, about 3 in. deep, on a black background.

Variations in tissues:

Fatty or mucoid tissues: Cut fatty or mucoid tissues 15μ thick. Leave the section on the edge of the knife. Apply 2 or 3 drops of 95% alcohol to dissolve the fat and leave about 1 min.

Remove the section with the tip of the finger and place it in water, where the surface tension will cause the fatty and mucoid tissue to spread out.

If this procedure is not satisfactory, it is sometimes helpful to place the section in alcohol for 30-45 min. and then into water.

If difficulty is still encountered, place the entire block in equal parts of acetone and 95% alcohol for 24 hr., refix in 10% formalin, and proceed as above.

Aorta, intestine, and stomach: Cross sections are the rule. To orient the block of aorta tissue the intimal surface should be to the left. Tissues with serosal surface must be placed on the block with the serosal surface to the left. The block has but a small base and freezing surface; hence freeze ¾ of the block and begin shaving off the very top of the block for sections.

Transferring frozen sections to glass slide: Clean the slide by dipping in acid alcohol and wipe dry. The dish in which the sections are floated should

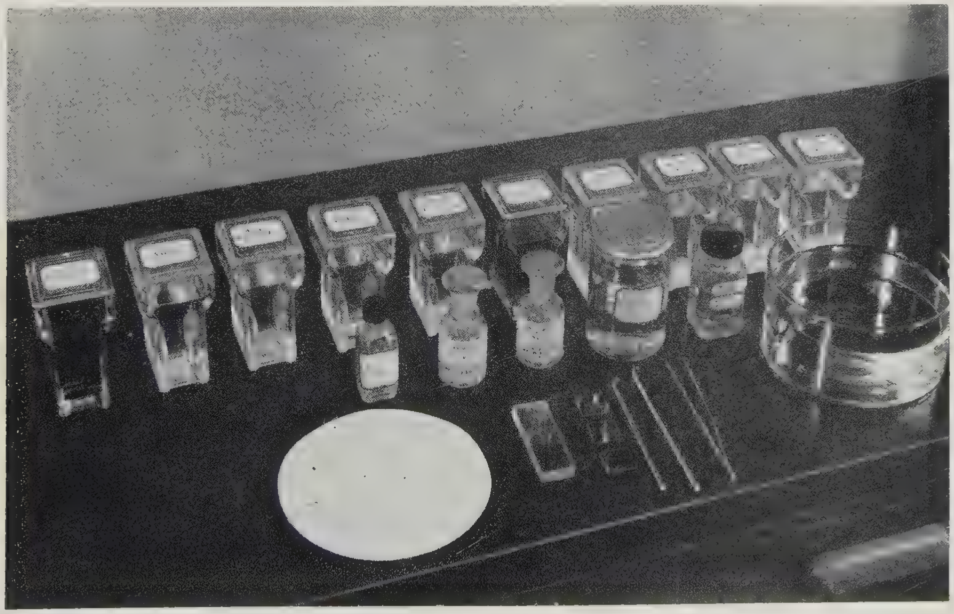

Fig. 528. Equipment and reagents for staining frozen sections.

be at least 7 cm. deep and 15 cm. in diameter. The operator should be seated so as to prevent any direct reflection from the slide to the eyes.

A glass rod, pointed or slightly bent, should be used to transfer the sections of delicate internal tissues to the slide. Teasing needles may be used for sections of firm tissues but not when one is staining for iron or using silver solutions for staining. See Fig. 528.

Anchor the section to the slide at about a 45° angle, with ¾ of the length of the slide under the water, in such a way that the edge of the water basin will afford support to either the slide or the fingers, thereby aiding in steadying the slide. By means of the glass rod pick up a good section, bringing it to the surface of the water immediately above the center of the slide.

When the section is centered, hold one corner at the upper and farthest side of the slide in place with the glass rod and slowly raise the slide out of water, always keeping the farthest edge of the slide slightly higher. Do not try to straighten out all folds under water. To eliminate any folds that may be present, place the edge of the slide with the folded portion of the section under water. With the aid of the water and the use of the glass rod, if necessary, the folds are readily eliminated. Care must be exercised in this procedure; first, keep the edge of the slide above the water wiped dry, and, second, keep the upper edge of the section above the water so that the section will not float away from the center of the slide.

After the folds have been removed tilt the slide against a staining dish at a 45° angle, face down, so that the water may partially drain. Do not permit it to dry, since drying may distort the section and shrink the cells. Time for draining depends upon the humidity of the atmosphere; this is usually from 15 sec. to 1 min. or more.

DEHYDRATING FROZEN SECTION

Holding the slide at a slight angle, drop at short range to prevent breaking the section 2 drops of anhydrous isopropanol or absolute alcohol on the section. Blow the breath over the section until the isopropanol or alcohol appears to have evaporated. The section becomes white. Blot twice with Whatman No. 2 filter paper.

Flood the slide with isopropanol or alcohol for 1-10 min.; then pour off the dehydrating agent, taking care not to disturb the section. Repeat if necessary. In fatty tissues, such as liver, brain, etc., fat is dissolved by alcohol and the section may tend to slip away from the slide. Under these circumstances blow over the surface of the section gently and remove the remaining alcohol by evaporation to keep the section on the slide.

Blot twice with several thicknesses of Whatman No. 2 filter paper.

Dip twice into a jar of thin celloidin (see below), in and out rapidly but carefully, taking care not to change the position of the slide.

Blow gently over the surface, again taking care not to change the position of the slide **until the celloidin is dry.** When thoroughly dry, place immediately into the staining solution. Mayer albumin fixative is not recommended.

Sections of mucoid tissue, after being properly drained, are dehydrated with isopropanol for 5 min.; then without blotting they are dipped in celloidin, dried by blowing over the surface, and stained. No filter paper is used to blot the sections because they are likely to stick to the paper.

Thick celloidin: Prepare a thick celloidin* as a stock solution by dissolving 30 gm. dry celloidin in 200 ml. of a mixture of equal parts of ether and absolute alcohol.

Shake the container several times a day for a week or longer, and stir the sediment with a heavy glass rod at least once a day until solution is complete.

Thin celloidin: Add about 7-8 ml. thick celloidin to a mixture of 45 ml. ether, 45 ml. absolute alcohol, and 10 ml. acetone in a dry container. When thoroughly dissolved, add 1 ml. saturated alcoholic solution of gum mastic to strengthen the adhesive qualities, make the sections smooth, and prevent rapid deterioration.

Medium celloidin: Mix equal parts of thick celloidin and ether-alcohol (equal parts) mixture.

PREPARATION OF LARGE FROZEN SECTIONS—CHRISTELLER METHOD

A sliding microtome† with large freezing table is used.

Slides are photographic plates 9 × 12 cm. and cover glasses† are 8½ × 11 cm. Staining dishes are rectangular-shaped museum jars. There should be about a dozen of these. Tissues should be formaldehyde fixed.

Follow the procedure described in detail for routine frozen sections.

ROUTINE STAINING OF FROZEN SECTIONS

Reagents:

1. Harris hematoxylin. See p. 1658.
2. Acid alcohol.
    - (a) Add 1 ml. concentrated hydrochloric acid to 100 ml. 70% ethyl alcohol.
3. Ammonia-isopropanol.
    - (a) Add 5 ml. ammonium hydroxide, c.p., to 100 ml. anhydrous isopropanol.
    - (b) If the ammonia volatilizes off the solution during use, replace with fresh ammonium hydroxide.
4. Eosinol. Refer to p. 1662.
5. Carbolxylol. See p. 1655.

Procedure:

1. Keep solutions in staining jars in proper order. Have on hand a drop bottle containing anhydrous isopropanol.
2. Put the slide (section mounted under celloidin, see above) in Harris hematoxylin for 3-10 min., or for rapid work dip in and out carefully about 50 times or until the section is the proper color.
3. Place in tap water until blue (4 min.).

---

*Celloidin is that furnished by DuPont or Schering, or Parlodion made by Mallinckrodt Chemical Works, St. Louis, Mo.

†E. Leitz, Inc., New York, N. Y.

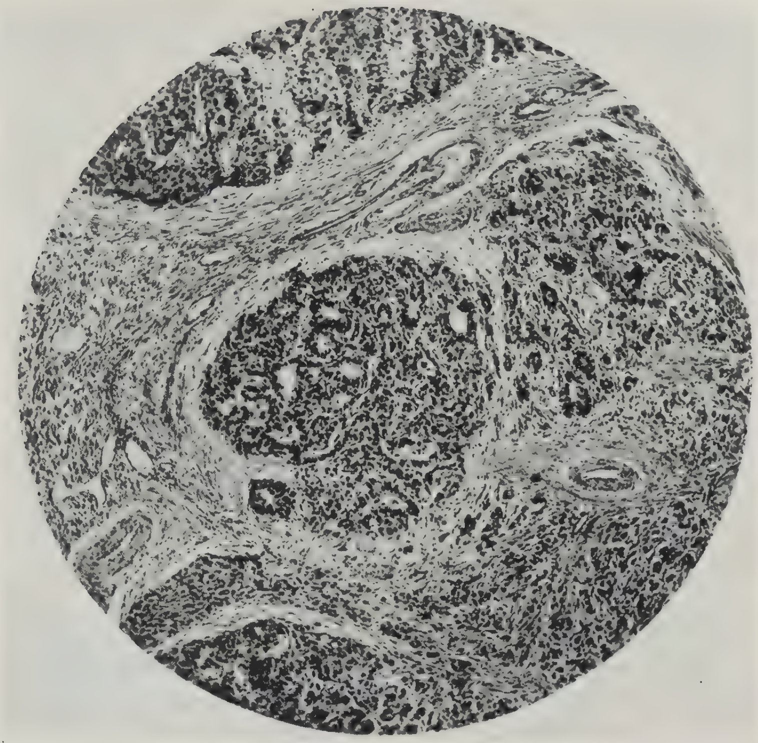

Fig. 529. Cirrhosis of liver. Hematoxylin-eosinol stain. Frozen section. (From Krajian, A. A., and Gradwohl, R. B. H.: Histopathological technic, St. Louis, 1952, The C. V. Mosby Co.)

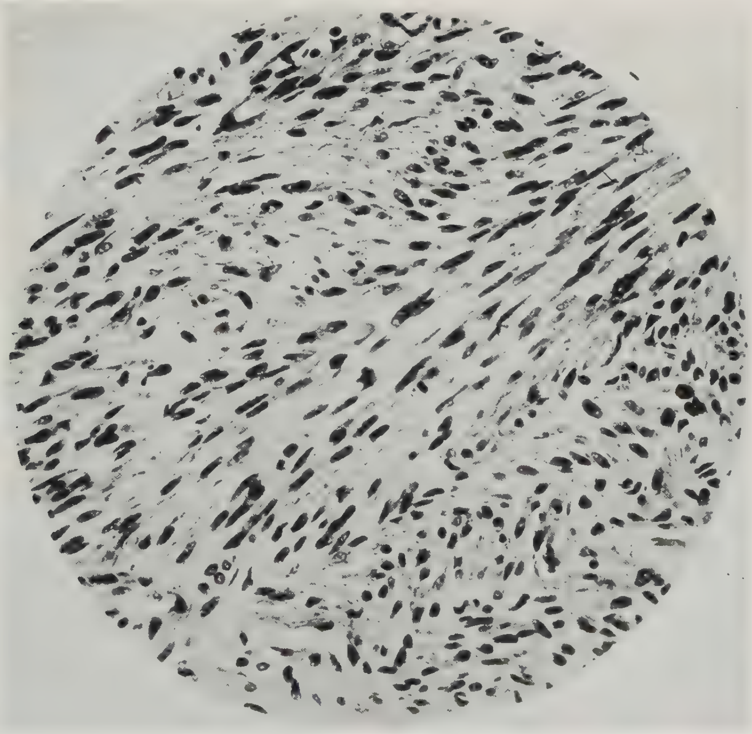

Fig. 530. Fibroma of uterus. Hematoxylin-eosinol stain. Frozen section. (From Krajian, A. A., and Gradwohl, R. B. H.: Histopathological technic, St. Louis, 1952, The C. V. Mosby Co.)

4. Decolorize in acid alcohol by dipping the slide in and out of the jar, turning for even decolorization, until no more salmon pink solution runs off the tissue. Be sure to decolorize thoroughly, but do not overdecolorize.
5. Dip in distilled water to stop the decolorizing.
6. Place slide in ammonia-isopropanol until every part of the tissue is a good blue color. If desired, examine under the low power of the microscope to see if the nuclei are a good blue. Do not rush this step.
7. Pour anhydrous isopropanol over the slide (allowing it to flow into the ammonia-isopropanol jar to save it) to dehydrate the tissue. Several drops are sufficient, if repeated twice. Remove excess liquid from the back of the slide.
8. Dip in and out of eosinol several times, turning the slide for even staining and watching the staining in the air over a white background until the section is stained evenly red. This requires 10-30 sec. or more, depending on the strength of the eosinol.
9. Place in carbolxylol for 3-4 min. or dip in and out of carbolxylol until clear (about 30 sec.).
10. Drain and place for 1 or 2 min. in the first xylol or dip in and out of the xylol for several seconds.
11. Place in the second xylol for 2 min., then into the third xylol to clear.
12. Mount in neutral gum damar. Do not allow the xylol to dry before mounting.

SPECIAL FACTS ABOUT THE RAPID FROZEN SECTION METHOD

In all cases in which sections are transferred from one solution to another be sure to drain off as much of the solution as possible, especially with carbolxylol. Carrying of carbolic acid into xylols will cause fading of nuclear stains.

If the sections occasionally fall off because of swelling, flood them with isopropanol for 2-5 min., pour off, blow section dry, blot, dip twice in celloidin, and resume the process from that point on. This may occur with sections of liver, brain, cartilage, or spleen.

If sections do not clear properly, the isopropanol is not anhydrous, the carbolxylol has been used too long, or the tissue has not been properly dehydrated. Try new solutions.

If the sections are cut unevenly, the microtome may be at fault or the section was frozen too hard.

If a section has been recelloidined, it must be dehydrated with isopropanol before placing in xylol.

When gum mastic is old or in solution, it deteriorates. It is necessary in such cases to use more gum mastic than the method calls for.

If the celloidin covering the section takes the stain during the staining process, the stain may be removed by dipping the slide back into thin celloidin until clear again.

Always be sure the celloidin has been blown dry before staining, to prevent artifacts. The celloidin must completely penetrate the tissue before stain is applied; otherwise the cells will not take the stain.

Air bubbles in the section form because the section is too thick, there is not sufficient gum damar, the gum is too thin, or the cover slip may not be properly laid down.

Hard tissues such as uterus and others of fibrous structure may be softened by the application of several drops of dioxane at the time of cutting. Then refreeze. If the block is still too hard, the dioxane may be applied twice again. Never apply dioxane more than 3 times.

Soft tissues such as gelatinous carcinoma of lung tissue, if soaked in dioxane 15-30 min. before cutting, give good consistency.

Striated muscle fibers are best shown with the spirochete stain.

If sections show shrinkage, it is usually caused by drying of the sections before they are dehydrated and celloidined. Watch every section very carefully during the draining process, and if any one is even slightly dried, dip that portion back in water and begin the dehydration immediately.

If the outside walls of appendices turn over, it may be due to the drying of the specimen before it was fixed, and nothing can be done about it.

If the hematoxylin-eosinol stain is satisfactory, the nuclei will be clear under high power, the blues will be blue and not purple or lavender, while the eosin will be pink or red but not lavender or purple. If the blues have a purple cast, the section was not properly decolorized in acid alcohol nor the blue brought out properly in ammonia-isopropanol.

It is necessary occasionally to add more ammonium hydroxide to the ammonia-isopropanol to replace that lost by volatilization.

If the hematoxylin develops a sediment, pour off the supernatant liquid and continue to use it. A scum may be dissolved with a little glacial acetic acid.

If the celloidin peels off the slide or falls away from the tissue, this may be caused by using celloidin that is too old or that is contaminated with extraneous material. Make new celloidin. Or it may be due to the fact that some of the solvent has evaporated, resulting in a thickening of the celloidin. Either thin the celloidin with a mixture of alcohol, acetone, and ether in proper proportion or, better, make fresh thin celloidin.

If the absolute alcohol or anhydrous isopropanol dissolves the celloidin and loosens the section, blot and then dip again in celloidin as previously.

Do not allow the section to dry at any step. If the section becomes dry, dip it back into the solution from which it has just been taken.

METHOD OF REMOVING WRINKLES FROM CREASED FROZEN SECTIONS

Sometimes sections of brain, liver, and spleen are creased when submitted to clearing in carbolxylol or in fresh xylol. To flatten them, blot the section thoroughly, dip in thin celloidin twice, place in carbolxylol for 1 min., blot thoroughly in filter paper, clear in xylol in the usual manner, and mount in gum damar.

RAPID FROZEN SECTIONS AT THE OPERATING TABLE—PERMANENT MOUNTS (KRAJIAN)

Tissues or biopsies removed during surgery are brought to the laboratory to be examined for malignancy in cases in which rapid diagnosis is of prime importance.

1. Place thin pieces of tissue in a 50 ml. Pyrex tube containing about 30 ml. 10% formalin and boil immediately over a free flame for 15-30 sec.
2. Pour off the formalin, wash the tissue thoroughly in tap water, and make sections in the usual manner on the freezing microtome.

If desired, instead of washing the blocks of tissue after boiling in formalin, drop in dioxane for ½ min. and freeze and cut sections directly from the dioxane.

3. Place on slides.
4. Add a few drops of isopropanol (anhydrous) from a drop bottle and blow dry. Repeat and let evaporate.
5. Cover the slide with isopropanol for about 30 sec., drain off excess, and blot between several layers of Whatman No. 1 filter paper.
6. Dip into thin celloidin (p. 1666) twice. Wipe the back of the slide dry. Blow the breath over the surface of the slide to dry the celloidin. **Do not change the direction in which the slide is held during the celloidining process until the celloidin is dry.**
7. Have all reagents in staining jars.
8. Dip in and out of Harris hematoxylin about 50 times.
9. Wash in tap water for a few seconds.
10. Decolorize in 1% acid alcohol as in the routine method.
11. Dip in tap water to stop decolorizing and place immediately in the ammonia-isopropanol mixture until blue (p. 1666).
12. Drop a few drops of isopropanol over the surface of the slide to dehydrate it, catching the isopropanol in the jar of ammonia-isopropanol mixture.
13. Dip in and out of eosinol several times until the tissue is a good pink color. This requires only a few seconds.
14. Dip in and out of carbolxylol to clarify. About 20-30 dips usually suffice.
15. Dip in xylol for a few seconds, about 30-50 times.
16. Repeat in 2 more changes of xylol.
17. Remove excess celloidin from around the tissue and mount in gum damar.
18. If the specimen becomes elevated on the slide at any time, dip in celloidin again, then back into xylol, and proceed.

EMBEDDING METHOD FOR FROZEN SECTIONS

Embedding methods for frozen sections are intended for fragmented and loose-textured tissues, such as curettings, brain abscesses, and body fluids.

Embedding mass:

1. Mix 10 gm. powdered gelatin and 3 gm. Bacto-agar thoroughly.
2. Dissolve in 100 ml. boiling water containing 0.5 ml. liquefied phenol. This keeps well in a stoppered bottle.

To embed:

1. Fix the tissue in 10% formalin.
2. Liquefy the mass in a boiling water bath.
3. Dry the tissue with a towel, place and arrange it in a paper box containing the liquefied mass, and incubate at 50° C. for 2 hr. to allow penetration.
4. Allow the pool to solidify in a cool place or in a refrigerator for 2 hr. or longer.
5. Remove the blocks and trim.
6. Fix the block in 10% formalin 3 hr. or longer.
7. Make frozen sections, mount on a slide under celloidin in the usual manner, and stain as for frozen sections.

SERUMIZING METHOD FOR LOOSE-TEXTURED TISSUES—KRAJIAN

One of the principal objections to the use of frozen section methods has been the impossibility of securing satisfactory sections of fragmentary and loose-textured tissues, such as curettings, brain abscesses, and body fluids. Krajian[16] has overcome this objection by applying his serumizing method as follows:

Fix in 10% formalin in the usual manner for 24 hr., or longer if necessary. Trim the blocks. Wash several times in tap water to remove the formaldehyde. Place the tissue in a small Stender dish or specimen bottle containing uncontaminated human or animal serum. Fresh serum obtained from the day's serologic specimens is ideal for this purpose. The serum should completely cover the tissue. Cover the dish or bottle tightly and put in a warm place overnight. The top of the paraffin oven is a good place for it. Cover any floating tissues such as lung or fatty material with absorbent cotton in order to keep all parts submerged in the serum.

The following morning decant the excess serum. Without washing add sufficient dioxane to cover the blocks. Allow it to stand for 3-5 hr. or until the serum is completely coagulated. Fix in 10% cold formalin overnight or in hot formalin in a paraffin oven at 56° C. for 2 hr. Immediately freeze on the freezing microtome with carbon dioxide gas and cut, stain, and mount sections in the usual manner.

Since dioxane will eventually shrink the tissues, they cannot be kept in this solution indefinitely. Keep the blocks in 10% formaldehyde for permanent storage.

For emergency examination use very thin blocks of formaldehyde-fixed tissues. Place in serum in a paraffin oven at 56° C. for 1-2 hr.; then coagulate in dioxane for 1 hr. Then freeze, cut, stain, and mount.[17]

This method has been used in our laboratories frequently. It causes very little shrinkage and no curling or shriveling of sections such as other embedding processes intended for frozen sections. This serumizing process makes hard tissues, such as bone and uterus, soft and pliable, giving better sections.

Store the serum in small bottles and preserve by the addition of 2 ml. commercial 40% formaldehyde to 50 ml. of the fluid. This keeps well at room temperature indefinitely without contamination.

THE MICROTOME-CRYOSTAT*

The cryostat is a "cold-knife" refrigerated microtome for the preparation of frozen sections. It provides a rapid means of preparing large, thin, often unwrinkled sections of single or multiple pieces of fresh frozen tissue. It also permits rapid preparation of biopsies for surgical pathology. Like other instruments, proper manipulative skill must be developed by practice before the cryostat can be operated efficiently.

Approximately 4 hr. are needed for the microtome-cryostat to reach the required temperature. Before connecting the unit to the electrical circuit, lubricate all moving surfaces with the arctic oil provided. If the microtome becomes difficult to operate because of insufficient lubrication, place a few drops of alcohol on the moving surfaces. The technician should practice manipulation of the microtome and accessories before proceeding to refrigeration.

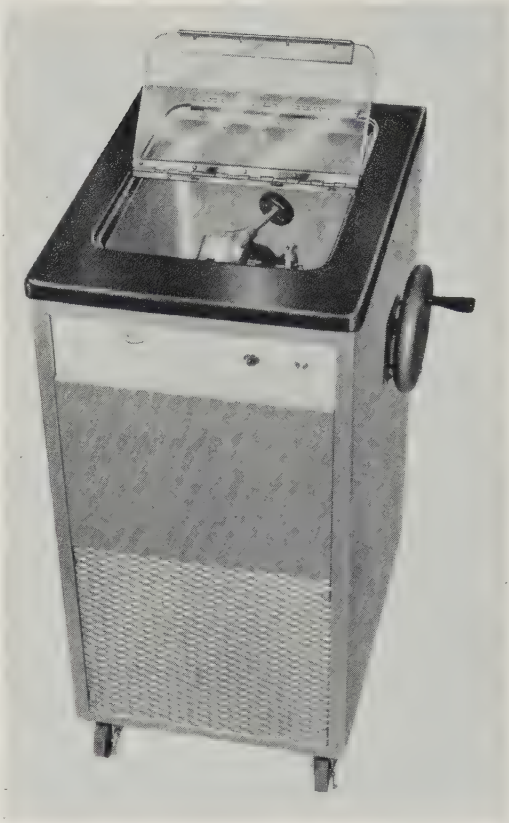

Fig. 531. Harris-International microtome cryostat, model CT. (Courtesy Arthur H. Thomas Co., Philadelphia, Pa.)

Place the microtome knife in an open knife box so that it may reach the equivalent temperature of the apparatus. The temperature of the knife should not be higher than −5° C., and the angle ordinarily used is approximately 30°. Too shallow an angle results in lack of sectioning, whereas too steep an angle gives rise to compression or splintering of the tissue if soft proteinaceous tissues are cut at too low a temperature.

Cutting technic:

1. Protect the hands from the cold with cotton or canvas household gloves.
2. Set the cold knife at approximately a 30° angle.
3. Set the thickness scale of the microtome. Each division on the scale is equal to 2μ.
4. Close the transparent top cover until subsequent steps have been carried out.
5. Select unfixed, previously refrigerated or fresh tissue blocks. The blocks should be several mm. deep to keep the knife edge clear of the metal object holder, and they must be cut so as to have parallel flat top and bottom surfaces. If minute or shallow tissues are presented for section, these may be supported on a thick slice of fixed, soft tissue.
6. Fill the ring cavities of the object holder with

---

*Information on the model CT cryostat has been furnished by the International Equipment Co., Needham Heights, Mass., from the Handbook on the microtome-cryostat by John R. Baker, Director of Histology and Histochemistry, Bio-Research Consultants, Inc.

distilled water from a plastic washing bottle or a dropper.

7. Gently place the tissue on the wet holder, hold it in place with forceps, without squeezing, add a wall of water to surround the tissue, and freeze with the CO_2 attachment, with dry ice, or with Freon aerosol. The tissue adheres to the holder as the water turns to ice.
8. If the tissue needs support, add water around it to build a supporting wall of ice.

When the tissue is frozen sufficiently, the entire block becomes opaque. This is an extremely rapid operation. If the tissue is frozen in the cryostat chamber, ice crystal artifacts and desiccation of the tissue may occur. In emergencies, cover the tissue and holder with Saranwrap to prevent undue loss of moisture due to slow freezing.

9. Transfer the frozen tissue and object holder to the microtome head, which should be in the upper position with the drive wheel locked.
10. Tighten the rubber-covered head clamp sufficiently to hold the object holder firm.
11. Pull back the knife-holding clamp so that there is 1/4 in. clearance between the subsequent down travel of the block and the knife.
12. Release the lock of the drive wheel and bring the tissue block close to the knife; then adjust the specimen holder and tissue so that its travel is approximately plane to the knife edge.
13. Bring the knife to within 1-2 mm. of the tissue and make the final plane adjustment of the block to the knife, which must be precisely parallel. This adjustment is critical.
14. Bring the tissue face almost into contact with the knife edge, release the ratchet from the micrometer wheel at the rear of the microtome, advance the wheel clockwise by hand, a fraction of a turn, until the tissue begins to section, and continue trimming off the face of the tissue until the desired cutting plane is reached.
15. Return the ratchet to the teeth of the micrometer wheel.
16. Clean the knife entirely free of tissue and condensation debris.
17. Turn the drive wheel slowly until the leading edge of the section begins to cut.
18. With a red sable-hair water color brush, size 6 or smaller, gently stroke the section onto the microtome blade as it makes its downward travel from continued slow movement of the drive wheel and smooth and flatten the section if necessary.
19. Transfer the section to a "warm" slide or a slide at cryostat temperature, depending on the subsequent technic. Brush the knife clean and dry it between each section cut.

Mounting sections on "warm slides": Place a clean slide, at room temperature, a fraction of an inch over the frozen section on the cold knife. The section is attracted directly to the warm slide and transfers itself from the cold knife to the slide. Direct pressure causes distortion or stretching and is to be avoided. Once mounted on a warm slide, the sections are ready for immediate staining or cold storage.

Mounting sections on "cold slides": Place clean slides in a small, open-slotted box within the cryostat chamber until they reach cryostat temperature, which requires only a few minutes.

Place the frozen section on the cold slide, smooth and flatten with the brush, and then remove the slide to room temperature.

Place a finger under the section on the undersurface of the slide. The slight warmth causes the section to flatten out and adhere to the slide. Unless the section is brushed out absolutely flat prior to thawing, there is possibility of trapping minute air bubbles under the tissue. Once it has been thawed and adheres to the slide, continue as previously.

Fixation of the section: The cryostat permits rapid fixation. A 2-10 min. immersion in chilled (+5° C.) fixative is sufficient for most purposes. The recommended fixatives are acetone, acetic-alcohol, alcohol-ether (equal parts), formal-alcohol (formalin 10, absolute alcohol 80, distilled water 10), Carnoy, and neutral 4% formaldehyde (10% formalin). For the study of fats, only the formalin fixative may be used. In enzyme histochemistry, where fixation is permitted, 2 min. fixation is often sufficient.

For rapid biopsy technic apply fixative at room temperature for 30-60 sec. A rapid and suitable fixative consists of 1 part formalin to 9 parts ethyl alcohol.

Staining the section:

1. Rinse briefly in 70% alcohol, then in 50% alcohol, and then in distilled water.
2. Stain for 1 or 2 min. in well-ripened Ehrlich hematoxylin (p. 1659).
3. Rinse in distilled water.
4. Immerse in 0.1% sodium borate for a few seconds until the tissue turns blue.
5. Rinse in distilled water 30 sec.
6. Stain in 1% eosin for 10 sec.
7. Dehydrate through 3 changes of ethyl alcohol, 5 sec. each; then transfer to equal parts of absolute alcohol and xylol.
8. Clear in xylol and mount.

Another method is to stain briefly (a few seconds) in 1% aqueous methylene or toluidine blue, or in Paragon frozen section stain, rinse rapidly in water, dehydrate rapidly, and clear and mount. The section may be viewed directly from water if desired.

Chapter 89

Paraffin sections

ARAM A. KRAJIAN

GENERAL FACTS ON PREPARATION AND EMBEDDING OF PARAFFIN SECTIONS

Paraffin sectioning differs from frozen section methods in that, with this method, the water in the tissue is replaced in the section by paraffin and then thin sections are cut. In order to remove the water and entirely replace it with paraffin, the tissue, after proper fixation, must first be dehydrated. This is accomplished by carrying it through increasing strengths of alcohol or isopropanol, beginning usually with 70% strength. The water is gradually replaced with the dehydrating agent until all the water has been removed and 100% (absolute) alcohol or anhydrous isopropanol is present in its place. The alcohol is then replaced by xylol, which clarifies the tissue; the xylol permits the penetration of the tissue by paraffin, which then replaces the xylol. This entire process of dehydrating, clarifying, and embedding may require several days, at the end of which time the tissue is embedded in pure paraffin, then cut into sections of appropriate thickness, and stained.

Before the sections can be stained they must first be affixed to the slide. The paraffin must then be removed, which is accomplished by the use of xylol. The section then passes through gradually decreasing strengths of alcohol or isopropanol, which removes the xylol and eventually restores the original water content of the tissue. The section is now ready to be stained.

Paraffin embedding is useful when very thin sections are desired. For good results the tissue blocks should be small, preferably not more than 2 or 3 mm. thick. The time of dehydration varies according to the size and consistency of the tissue. The amount of alcohol used should be much greater than the bulk of the object. The alcohols should be kept in pint or quart bottles. They are prepared by diluting 95% alcohol or isopropanol to desired strength.

Staining processes are quite similar to each other. The section is first submitted to hematoxylin stain, decolorized in an acid to remove the dye from all portions of the tissue except the nuclei, the blue color restored with an alkali, and then the section counterstained with a contrasting color (red, of the eosin); the nuclei remain blue; other portions take the eosin dye.

The tissue must again be dehydrated since it is to be clarified and mounted in a material immiscible with water. Alcohols of increasing strengths are used, followed by xylol as a clearing agent, after which the tissues are mounted under a cover glass. By the use of eosinol (p. 1662), the dehydration, counterstaining, and clarification process are combined in one step.

Preservation of tissue

Tissues should be kept in alcohol fixatives not longer than the time specified in the particular method. If they must be kept some time before embedding in paraffin, preserve them in 70% alcohol. Lower alcohol concentrations macerate tissues; higher grades harden them excessively. Prolonged preservation of specimens in alcohol affects the staining property of the nuclei. Formalin-fixed tissues should be kept in 10% neutral formalin.

The **formalin-alcohol-paraffin method** can

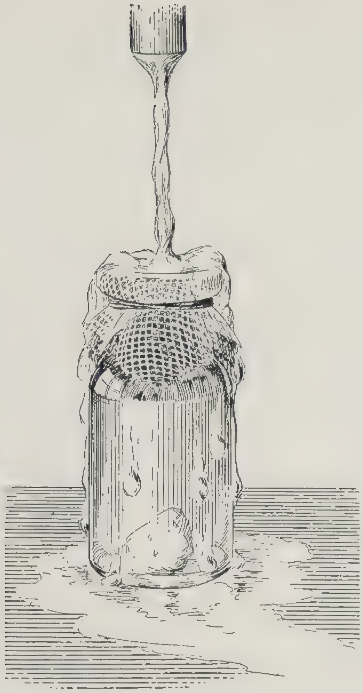

Fig. 532. Washing tissues.

be used on all tissues. Formalin kills, fixes, and hardens the tissue, so that the tissue remains intact, undergoing no further change. The formalin does not shrink the tissue nor expand it. It penetrates all parts equally well, including fat.

After fixation, the tissue should be washed in running water or placed in a bottle of water, changing the water frequently. All formalin must be removed. The underlying principle by which penetration of the tissue is accomplished by the various solutions is the principle of osmosis. The various steps must not be taken too rapidly.

Identification tags

The bottle containing the specimen should be labeled with a tag around the neck; it is safer to place a small pencil-marked label inside the vessel containing the tissue. This prevents confusion and mistakes if many different pieces of specimens are handled at the same time. The tag around the neck of the bottle is used not only for identification but also for the record of the solutions through which the objects are being passed.

Clearing process

The reagents employed in clearing tissue are chloroform, benzine, xylol, cedar oil, dioxane, and butyl alcohol. To clarify, the absolute alcohol is discarded and a large volume of clearing reagent is added to the bottle containing the specimen. For a large object the clearing solution should be changed at least once. The time required for clearing varies according to the size and consistency of the tissue and the particular clearing reagent used. Xylol rapidly removes alcohol and clears the tissue. Tissues should be kept in xylol for a minimum time only, since prolonged treatment causes the tissue to become brittle.

Chloroform enables the paraffin in the mixture to partially infiltrate the tissue and then rapidly evaporates from the pure paraffin bath. Its hardening effect is very much less than that of xylol.

Benzine clears quickly, makes the tissue more transparent, and evaporates rapidly from the paraffin bath without much hardening.

Cedar oil does not harden the tissue even by prolonged immersion. It clears from 95% alcohol but has the disadvantage of slow penetration and subsequent difficulty of elimination in the paraffin bath.

Paraffin embedding process

An electrically controlled paraffin oven is needed. The temperature should be maintained slightly above the melting point of the paraffin used. A temperature of 56°-58° C. suffices for most purposes.

Paraffins with a high melting point are hard when allowed to cool; those with a low melting point are soft. (1) For hard objects it is essential to use hard paraffin in order to support the tissues during section cutting. A lower melting point paraffin is used for soft objects. (2) The degree of hardness of the paraffin block containing the object depends on the surrounding temperature. In summer or in tropical climates it is necessary to use high melting point paraffin to obtain the correct consistency for sectioning. For ordinary work in temperate climates paraffin with a 48°-50° C. melting point is satisfactory. For hard objects or for section cutting in warm weather, it is necessary to use paraffin of 55° C. melting point.

Paraffin with different melting points is available from a number of laboratory supply houses.* Refer to p. 1674.

---

*Pure paraffin is made by Arthur H. Thomas Co., Philadelphia, Pa., Matheson-Coleman & Bell Division, the Matheson Co., Inc., E. Rutherford, N. J., or Fisher Scientific Co., New York, N. Y.

Infiltration of paraffin

After tissues have been dehydrated and thoroughly cleared it is necessary to remove the clearing reagent and infiltrate with paraffin. This is done by adding an equal amount of melted paraffin to the clearing reagent and placing it in a paraffin oven. As the clearing medium warms, it dissolves the paraffin and permeates the objects with the mixture. When infiltration is completed, the clearing and paraffin mixture are discarded, and the tissues are soaked in melted paraffin, in a paraffin oven. The paraffin is changed at least once. The duration of time in the paraffin baths depends on the size and thickness of the object, more time being required to penetrate a large, dense object than a thin, loose-textured tissue.

The object must be kept in the oven just long enough for complete paraffin infiltration. Any traces of clearing reagents remaining in the tissues or the failure of the paraffin to penetrate the tissues indicates insufficient time in the paraffin bath and prevents proper section cutting. Prolonged treatment in the paraffin oven must be avoided because this causes shrinkage and hardening of tissue and makes section cutting very difficult. The complete removal of the clearing reagent from the object requires a sufficient number of changes of paraffin.

Casting or embedding process

The tissues are first placed in molds of the correct size filled with melted paraffin, the side of the tissue which is to be cut facing the bottom of the mold. The paraffin mold is then allowed to harden by cooling.

There are several types of molds for paraffin, such as the metal boxes made with pairs of variously sized L-shaped metal pieces and hand-folded paper boxes. The L-shaped metal pieces are set one against the other on a glass or metal plate. The shape and size of the block can be varied with the shape and size of the object.

Procedure for embedding

1. Fill the boxes with melted paraffin.
2. Using warmed forceps, place the tissue in the bottom of the paraffin with the side to be cut facing the bottom of the box.
3. Label the boxes with the case number.
4. Either set the box on a wet towel or gently immerse it in a basin of ice water so as to cool the paraffin rapidly. Or permit the paraffin to harden at room temperature.
5. Do not attempt to trim the block before the paraffin has completely set. Small blocks of tissue should be left in water 15 min. or longer to ensure complete solidification of the paraffin. Large blocks require 30 min. or more.

Making the paper box or "boat"

Make the box from paper or aluminum foil about 0.1 mm. thick. Fold the paper according to the diagrams in Figs. 533 and 534. If aluminum foil is preferred, simply fold it around a small wooden block with a rectangular surface.

Paraffin used for embedding tissues

Special paraffin is manufactured for embedding purposes. Different samples of paraffin have different melting points and also different "plastic points."* Paraffin is a mixture of hydrocarbons that solidifies into char-

acteristic types of crystals, varying to some degree with the proportion of harder and softer hydrocarbons present. The peripheral crystals are oriented with respect to the cooling surface while the center of the mass forms a meshwork (Dempster, 1941). The "plastic point" is the lowest temperature at which permanent deformation may be made without fracture. A paraffin with low plastic point appears more translucent, is less brittle, but compresses more in sectioning. The hardness of paraffin depends on its plastic point which lies a few, but variable number of, degrees below the melting point. Consequently, the plastic point or, more roughly, the melting point of the paraffin has to be adapted to the temperature of the room in which the sectioning is being done.[18] Warm rooms require a higher melting point paraffin than do colder laboratories. The alternative is to condition the paraffin by the addition of various materials. Bayberry wax, rubber, and other waxes may be added to paraffin to improve its plasticity and cutting qualities.

In addition to matching the hardness of the paraffin to the temperature at which it is to be sectioned, it is necessary to match the hardness of the paraffin to the hardness of the tissue. The hardness of the tissue depends upon the preparatory treatment and its structure. The actual process of sectioning leads to distortion so that the sections will be slightly thicker and a little shorter than the block itself. This distortion results from the nature of the paraffin, the tissue, and the action of the knife. Large crystals are sectioned or pushed apart by the wedging of the knife, especially when the paraffin is brittle and has a high plastic point. This upsetting of crystals gives the velvety appearance to the topside of the section.

When the crystals are not of proper size to fit closely to the tissue, they cannot support the tissue adequately, and local deformation will occur, giving a section which cannot be completely flattened out. Small folds show when the thin parts are smaller than the size of the paraffin crystals and compress less than the paraffin. The crystals show clearly in polarized light. All microtomists should examine a section from each batch of paraffin with a polarizing microscope. A finer crystalline paraffin gives adequate support.

Warm paraffin shrinks as it cools and compresses the tissue in the block. Tissue that is harder than the paraffin withstands this pressure, but soft or spongy tissue may be under considerable strain. When sectioned, the tissue tends to expand to the shape and size it had before compression, and if confined by the paraffin around it, pleating or wrinkling results. Stowell reported that Parowax shrinks in volume 14.3% on cooling from 59° to 20° C.

Unless the hardness of the paraffin is adapted to the temperature at which the cutting is done and the nature of the tissue, good sections may not be expected, regardless of the excellence of the microtome and sectioning knife. When the material has been properly dehydrated, it is possible to re-embed it in another paraffin should the first not prove satisfactory. Poorly prepared tisue can rarely be salvaged. Several changes of the melted paraffin should be used to wash out the former paraffin.

Fisher Tissuemat: Fisher Tissuemat* is an embedding compound that will neither crumble nor crack while being cut on the microtome. It is well adapated for ribbon sections and is more convenient to use than paraffin cakes because it is supplied in granular form. It melts rapidly and obviates cutting large cakes. The granules are protected by an inner container of cellophane.

Histowax: Histowax† is an excellent substitute for paraffin, will not crumble or crack during the cutting process, and is well adapted for making ribbon sections.

CUTTING AND MOUNTING PARAFFIN-EMBEDDED SECTIONS

Cut out the tissue blocks embedded in the paraffin pool, in the paper boxes, by trimming away the paper with a scalpel or other sharp knife; then shape them into square blocks. Leave at least 1 mm. of paraffin around the blocks and keep the upper and lower surfaces parallel. Then place the blocks in pillboxes bearing their proper case numbers and store in a cool place or refrigerator until ready to cut.

When ready to cut sections, place the blocks in ice water.

Metal or wooden object holders are used to mount the paraffin block on the microtome. Warm the holder enough to melt the paraffin, heating it in a Bunsen flame for a few seconds. Press the paraffin block onto the holder; then pass a hot needle around the edges of the base of the block to aid in firmly attaching it to the holder. If the blocks are large, it may be necessary to run a hot needle under the center of the block to aid in attaching it.

---

*Fisher Scientific Co., Pittsburgh, Pa.

†Matheson-Coleman & Bell Division, The Matheson Company, Inc., E. Rutherford, N. J.

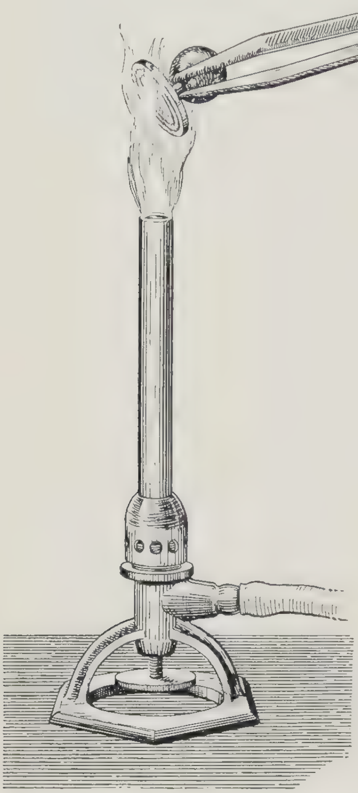

Fig. 535. Heating the paraffin microtome pivot.

When the block is firmly attached to the holder, quickly dip it into the ice water to cool and harden. When sectioning is completed, remove the remainder of the block from the holder, label it with an adhesive type label, and store in a refrigerator.

When the object holder and paraffin block have cooled, proceed with the cutting. Set the microtome knife at a 90° angle to the direction of the cut (no slice angle) and tilt it to as little clearance as will give good sections (2°-6°). Be sure the knife is sharp and shows no serrations.

Use the pencil type of camel's-hair brush to handle the ribbon (unless single sections are to be made). Sometimes it is necessary to hold the first few sections onto the knife with gentle pressure of the brush until the ribbon forms. Set the automatic lift on the mircotome for the desired thickness of the section and begin the cuttting process. Raise the end of the ribbon with a dissecting needle over the brush. Withdraw this from the knife (with the left hand) as the ribbon lengthens, turning the microtome wheel with the right hand. Speed of cutting varies with the tissue. Proceed until the ribbon lengthens to a point at which it is too long to handle. Place the ribbon lengths on smooth paper or in a shallow box until they are mounted on slides. Experience is required to cut serial sections without the loss of parts of the ribbon. Do not allow the brush to come in contact with the knife or it will be spoiled. Do not use a dissecting needle in place of the brush, since in case of accident of this type the knife will be damaged.

One great inconvenience of paraffin sectioning, particularly in winter or if the atmosphere is dry, is the flying of sections and their sticking to parts of the microtome and other nearby objects because of static electrical charge generated by the friction of cutting. Raise the humidity by boiling water in the room or burning a Bunsen burner near the microtome to alleviate this difficulty. Sometimes it is necessary to ground the microtome to a nearby water pipe, using a wire or a chain.

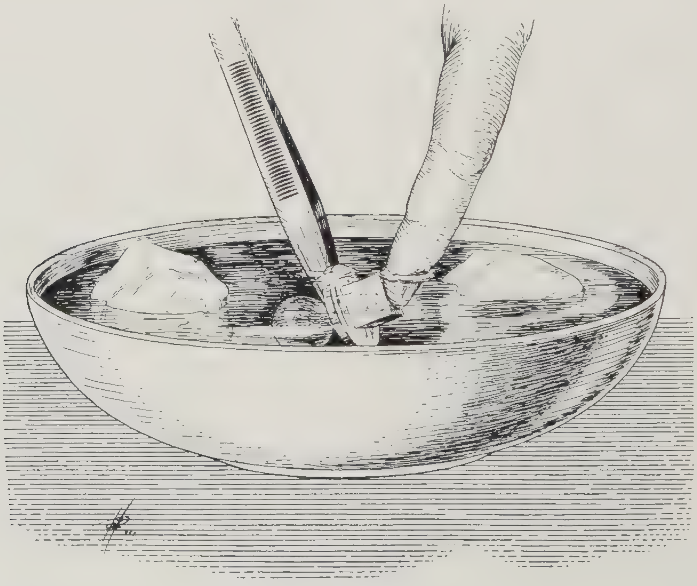

Fig. 536. Cooling the paraffin block after mounting it on the pivot.

After cutting the ribbon it must usually be flattened before the sections may be attached firmly and evenly to the slide.

Flattening the ribbon: Cut the ribbon into convenient lengths. Place on the slide containing albumin fixative. Add a few drops of water to the slide, and warm it gently until the sections expand to their full size.

Place the pieces of the ribbon onto warm water, allow to expand, and recover them by placing a slide containing a fixative under the tissues to pick them up.

Water used for "floating out" should be 5-7° cooler than the melting point of the paraffin. Commercial wetting agents may be added to the water if desired. Do not stretch the section with needles or by gravity by holding the slide perpendicular when draining off the excess water.

Cutting individual sections: Individual sections are cut in the same manner as above, but removed by means of a brush or teasing needle and spread on warm water. Routine sections are cut 7-10μ thick, but for research purposes they should vary between 3 and 5μ. Small foldovers and wrinkles can be flattened out by stretching the section with a teasing needle.

Tissue flotation bath: The tissue flotation bath with automatic temperature regulation is an excellent and convenient apparatus for floating and spreading of tissue sections embedded in paraffin, preparatory to mounting. Bath temperatures can be controlled to within ±1° C. in the range from room temperature to 60° C. It consists of a Pyrex glass tray, 10½ in. long by 6½ in. wide by 2 in. deep, and a low, insulated, Monel metal stand with flat copper top and built-in heating unit, thermoregulator, and pilot lamp. The top has raised edges, and a black oxidized finish, which aids in the in-

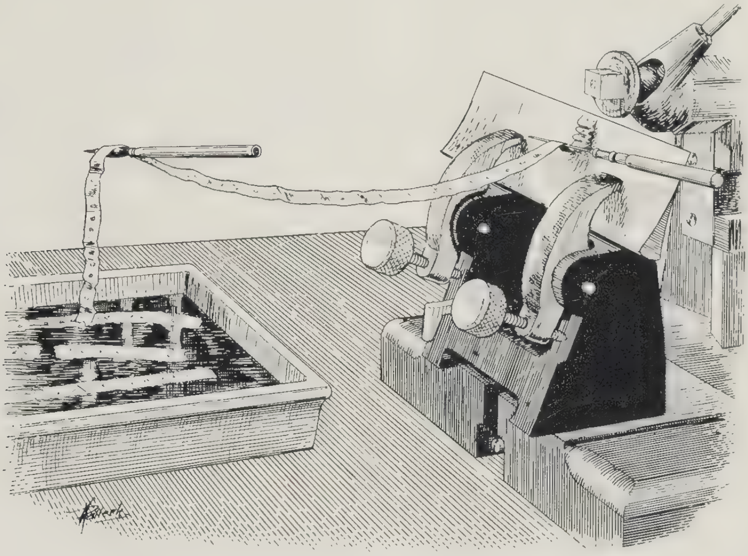

Fig. 537. Cutting paraffin sections and floating the ribbons on warm water

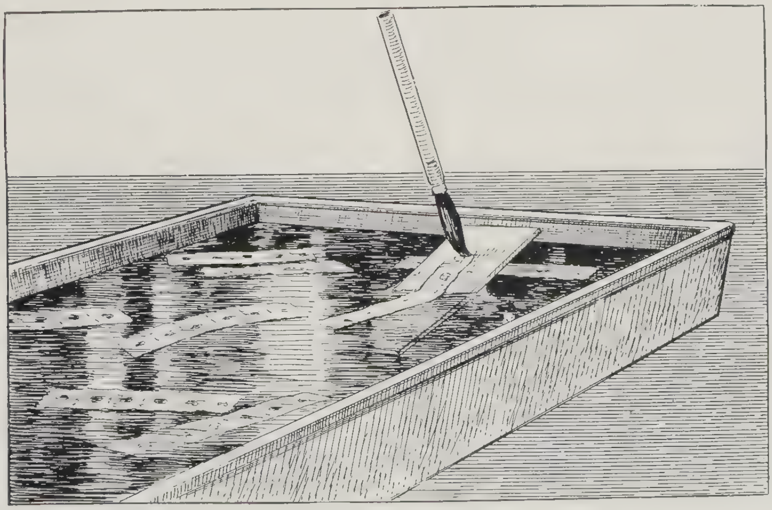

Fig. 538. Placing paraffin sections on a glass slide.

spection of translucent sections. The glass tray is readily removable for cleaning. The power consumption is 225 watts.

Affixing sections to slides: Have ready some clean slides and a diamond pencil for marking them. When mounting ribbons, cut to the desired lengths.

Rub the surface of a slide with a drop of egg albumin fixative.

Pick up the first strip of the ribbon on the slide and let the water drain off. Repeat the process for every strip. Mount single sections as directed on p. 1677.

Number each slide with its proper case number and place it in a slanting position in a wooden box holding 25 slides.

At times it is necessary to flatten out sections before subjecting them to the drying process. Hold the sections over a Bunsen burner at a temperature several degrees below the melting point of the paraffin, about 45°-50° C. Dry the sections by placing them in a paraffin oven at 55° C. for 3-5 hr. to coagulate the egg albumin fixative thereby causing them to adhere firmly to the slide.

If sections are to be stained in aqueous solutions for many hours, the drying must be prolonged or they will fall off the slide. Using thin celloidin as described on p. 1666 will prevent loss of sections.

When the sections are properly dried, stain by a standard staining method.

Faults in dehydration, clearing, and embedding, and the remedies

If the tissues are insufficiently dehydrated, they cause the clearing reagent to turn milky. To correct this, dehydration with absolute alcohol should be repeated.

If the tissues are insufficiently cleared, they become opaque and section cutting is impossible because of the presence of alcohol. Repeat the process of clearing, leaving the tissues in the clearing reagent for 2 hr.

The room temperature and the condition and the position of the knife and paraffin block markedly affect the cutting of good sections. The morning is preferable in warm weather, as the temperature is more favorable. It is essential to have a basin containing chipped ice ready to keep the paraffin blocks cool.

In cutting paraffin sections, sometimes the ribbons are curved instead of straight. This is caused by lack of parallelism of the surfaces of the blocks and may be remedied by unscrewing the block holder and trimming the block properly.

Sometimes sections are cut well individually but do not adhere to one another to form a ribbon. This is due to too cold a block. Warming the knife over the flame or in warm water corrects this condition.

Crumbling of the sections is caused either by too soft paraffin or too dull a knife. This may be prevented by cooling the block in ice water and sharpening the knife by stropping.

Irregular cutting of the sections, sometimes thick and sometimes thin, is caused by improper adjustment of the knife or block holder and may be corrected by tightening the screws of the block holder and the knife. If scratching of the section occurs as a result of nicks on the knife, the nicks should be removed by honing.

Difficulties in cutting paraffin sections

1. As block is being cut, there is a gritty feeling or a scratchy noise. Paraffin oven was too hot, there is dirt in the paraffin, or fixing agent may have crystallized and was not washed out with water.

2. Sections jam on the knife: knife is dull, or paraffin is too soft, or paraffin has accumulated on the edge of the knife. Clean with xylol.

3. Paraffin rolls: knife is dull, or sections are too thick.

4. Objects crumble and drop out of the paraffin: insufficient paraffin penetration before embedding.

5. Ridges on specimen: nicks in knife or paraffin accumulated on edge of knife.

6. White patches near tissue in paraffin: caused by xylol carried into paraffin. Reembed if near tissue. Cut off if near edge of block.

Difficulties in cutting ribbons of paraffin sections

1. Ribbons fail to form. (a) Room is too cold or paraffin is too hard. Use softer (lower melting point) paraffin; warm knife slightly by blowing the breath on it or immersing it in warm (not hot) water; or place a desk lamp so that the light and heat fall on the knife and block. (b) Tilt the knife less. (c) Cut thinner sections. (d) Knife may be too dull—resharpen. (e) Dip block into a softer paraffin and trim so that a thin layer remains on the upper and lower edges of the block. (f) Unroll the section and hold it lightly against the knife with a camel's-hair brush. If the first few sections can be held down, the ribbon will often form and follow.

2. Crooked ribbons. (a) When sections are wedge shaped, the sides of the block are not trimmed parallel. (b) Edge of block may not be parallel to knife edge. (c) Try another part of the knife—sometimes irregularities of the

knife edge cause crooked ribbons. (d) Or the paraffin at one side of the block may be softer than at the other side, especially if the material has been re-embedded in a paraffin of different hardness—re-embed the material and stir the melted paraffin.

3. Sections compressed, wrinkled and jammed together. (a) The knife may be too dull. (b) Or the room may be too warm; cool trimmed block and knife in very cold or ice water immediately before sectioning or re-embed in a harder paraffin. (c) Tilt the knife more; the knife tilt may be too slight so facet bevel rubs over block. (d) The knife edge may be gummed with paraffin; wipe with finger or cotton moistened with xylol. (e) Soak block in water from an hour or two to overnight before cutting. (f) If cutting is done too rapidly, thin tissues will wrinkle.

4. Sections crumble and specimen may tear out. (a) Material incompletely dehydrated or not properly cleared. (b) When soft and mushy, material incompletely infiltrated—reinfiltrate and embed. (Salvage rarely possible if material was incompletely dehydrated.) (c) Alcohol not completely removed by clearing fluid. (d) Object too long in paraffin bath or paraffin too hot. (e) Subject hard and brittle due to clearing fluid. Try toluene in place of xylol or a mixture of toluene and cedar oil. (f) Try celloidin embedding or a rubber or asphalt mixture with paraffin for fragile material. (g) Try dioxane method for dehydrating.

5. Split ribbon or lengthwise scratches in ribbon. (a) If there are nicks in knife, resharpen or use another knife. (b) Use less tilt of knife so it will cut rather than scrape. (c) Knife edge may be dirty. (d) Object may be too large for paraffin method—use celloidin. (e) Hard particles in block may cause scratching. If there is dirt in the paraffin, filter or decant melted paraffin. There may be crystals from killing fluid (mercuric chloride); washing was insufficient. If calcareous or silicious particles are present, decalcify or desilicify.

6. Knife rings on upstroke and sections are scratched. (a) Change knife tilt to greater or lesser degree—tilt must be sufficient to clear facet bevel but not enough to scrape instead of cut. (b) Material is too hard. Soak in water to soften; clearing may be at fault. (c) A thicker or wedge-shaped knife may prevent springing of the edge when cutting. (d) Material may be too tough for paraffin method—try celloidin.

7. Sections lifted from knife on upstroke. (a) Increase knife tilt. (b) Room too warm or paraffin too soft—try harder paraffin or cooler room; or cool the block. (c) Knife may be dull—resharpen.

8. Sections stick to knife. (a) Knife edge dirty. (b) Increase knife tilt. (c) Try a sharper knife.

9. Undulations in the surface of the section. (a) Tighten all screws on knife and block holders and see that knife holder is clamped fast to microtome base. (b) Lessen excessive knife tilt to prevent vibration.

10. Scratching noise during cutting. (a) Material may be too hard or small regions of material may be hard.

11. Sections fly and stick to parts of microtome or other nearby objects because of static electricity formed from the friction of cutting. This usually occurs only in winter when the air is very dry. (a) Increase humidity of room by boiling water in an open pan or burn a Bunsen burner in the room. (b) Ground microtome to a water pipe with a wire or a chain. (c) Ionize the air by an electrical method.

12. Sections vary in thickness or are skipped. (a) Knife not tilted enough to clear facet or bevel, or tilted too much, and tissue is compressed until the inevitable expansion gives a thick section. (b) Some of the clamping set screws on the block or knife holder are not tight or knife holder block is not clamped firmly. (c) Microtome worn through lack of lubrication or is not in adjustment. (d) Very large blocks or blocks with hard regions may spring knife edge while sectioning—soak block in water to soften, use other methods for softening the material, or embed in celloidin. The block will soak quicker if the paraffin is trimmed off one side to expose the tissue. Very little water is absorbed, but this process sometimes makes possible the cutting of hard or tough material.

Serial sections

To obtain serial sections by any of the 3 methods, it is only necessary to avoid losing any of the sections cut. The paraffin method is preferable to the others because by this method long ribbons are cut and placed on a sheet of paper in proper order. These can then be divided with a teasing needle into short series of any desired number of sections and fastened to numbered slides by means of egg albumin-glycerin fixative.

Vacuum embedding

Vacuum embedding or embedding under reduced pressure is used for certain purposes. A special type of apparatus is necessary, in which the embedding chamber is so arranged as to be airtight. The procedure consists in partially reducing the pressure during impregnation with paraffin. The necessary reduction in pressure is effected by a hand exhaust pump or by a water aspirator.

The advantages of the method are (1) the time required for embedding is considerably reduced, the clearing reagent being more rapidly replaced by the paraffin (this reduction in time is important in tissues that become unduly hard during the process of embedding) and (2) any air present in the tissue is extracted.

For the vacuum thermostat the embedding chamber is a circular brass well, closed at the upper end by a thick glass lying upon a rubber ring. The chamber is kept at the proper temperature by a water jacket, while a small tube connects it with the exhausting apparatus (vacuum pump or aspirator). There is also an arrangement in the shape of a small screw plug, fitted into the wall of the chamber for the admission of air. When the apparatus is used in conjunction with water aspirator, a glass bottle or a thick-walled flask of at least 500 ml. capacity should be placed between aspirator and thermostat. This prevents water from being sucked directly into the embedding chamber should the water supply to the aspirator be inadvertently turned off before opening the air valve. It is advantageous to attach a mercury manometer to the apparatus.

Procedure:

1. Place the cleared tissue in pure paraffin within the apparatus.
2. Reduce the pressure very slowly. A reduction to 400 or 500 mm. Hg is usually sufficient. The time required for impregnation varies from ¼ to ½ of that required for the same objects at atmospheric pressure.
3. Slowly admit air through the air valve until the pressure within the apparatus is in equilibrium with that of the atmosphere. For large objects repeat the process of exhaustion 2 or 3 times, changing the paraffin each time. To ensure success the exhaustion and the readmission of the air must be very gradual. Delicate air-containing tissues are damaged by too rapid a change.

The vacuum method is indicated for air-containing tissues, especially lung tissue; for large and dense objects, e.g., whole embryos or large pieces of brain; for tissues that become unduly hard if the embedding bath is prolonged, e.g., fibrous tissue and muscle; and for any work in which speed is important.

Technic for small pieces of tissue, skin, etc., using Bouin fixative

Fix tissue overnight in Bouin solution (p. 1641); 24 hr. is the maximum.

First day:

9:00 A.M.	Wash in 50% alcohol.
10:00 A.M.	Wash in 70% alcohol containing about 3 drops of a saturated solution of lithium carbonate.
12:00 noon	Place in 70% alcohol (may be left over the week end in this solution).
3:00 P.M.	Place in 80% alcohol.
5:00 P.M.	Place in 95% alcohol.

Second day:

9:00 A.M.	Place in absolute alcohol.
10:30 A.M.	Place in amyl acetate.
4:00 P.M.	Place in paraffin in a paraffin oven.
5:00 P.M.	Pour off paraffin and leave tissue outside of paraffin oven. Never leave tissue in oven overnight. Never re-use any paraffin.

Third day:

9:00 A.M.	Place in second paraffin.
12:00 noon	Place in third paraffin.
2:00 P.M.	Embed. Cut and stain with routine hematoxylin and eosin stain.

Amyl acetate can be used for clearing formalin-fixed tissues as well as those fixed in Bouin solution.

If tissue is fixed in formalin, first wash in water from 9 A.M. until 10:30 A.M.

Then place in 50% alcohol and then in 70% alcohol until 12 noon. The technic for Bouin-fixed tissue is followed from this point. Staining is with hematoxylin, eosinol, etc., p. 1691.

ROUTINE METHODS OF EMBEDDING AND CUTTING PARAFFIN SECTIONS

Alcohol dehydration method for paraffin embedding

Reagents:

1. Formalin, 10%. Described on p. 1641.
2. Alcohol, 70%.
   Dilute 70 ml. 95% ethyl alcohol or isopropanol to 95 ml. with distilled water. Wait for the bubbles to stop rising and then dilute again to 95 ml.
3. Alcohol, 80%.
   Dilute 80 ml. 95% ethyl alcohol or isopropanol to 95 ml. with distilled water, carrying out the same technic.
4. Alcohol, 100%.
   Absolute alcohol can be kept at 100% concentration by mixing it with pulverized copper sulfate that has been previously dehydrated. The copper sulfate falls to the bottom of the bottle, the 100% alcohol remaining above.
5. Xylol.
   Purchase chemically pure or U.S.P. xylol (xylene, water- and acid-free).
6. Paraffin. See pp. 1674 and 1675.

7. Mayer albumin fixative. Refer to p. 1652.

Procedure:

1. Fix tissue blocks in 10% formalin at least 2 hr. (After a month in formalin it is difficult to treat the section.)
2. Wash 1 hr. in tap water or a shorter time in running water to remove the formalin. The tissue may be kept in the same bottle throughout the dehydrating and clarifying processes.
3. Dehydrate in
   70% alcohol* 1 hr. (longer, if necessary; stopping point, 1 hr.)
   80% alcohol 1 hr. (longer, if necessary; stopping point, 1 hr.)
   95% alcohol 1 hr. (longer, if necessary; stopping point, 1 hr.)
   100% alcohol not more than 1 hr.
   These solutions may be used repeatedly until a sediment appears.
4. Place in xylol 1 hr. to clear. If not clear, immerse for a longer period. It is opaque until placed in xylol, when the edges become clear. If there are milky or chalky spots in the tissue, put it back in 95% alcohol, then absolute alcohol, and then xylol.
5. Place in xylol-paraffin (equal parts) all night with just enough heat to keep liquid. **Do not put in the paraffin oven.**
6. The following morning place in pure paraffin for 2-2½ hr. in an oven at 58°-60° C.
7. Transfer to pure paraffin again. Tissues may be left here a day if necessary, but 4-5 hr. is sufficient. The oven must not be hotter than 58°-60° C. or 2° above the melting point of the paraffin.
8. Embed or orient, using the paper box or "boat" (p. 1674) or other devices for the purpose.
9. Trim the blocks when hardened, attach to a wooden block or pivot (p. 1675), and label the back of the block. Retain the label throughout the process.
10. Cut the tissue according to directions on p. 1676 and float in warm water.
11. Mount with Mayer albumin fixative (p. 1652 for fixative and p. 1678 for affixing sections to the slide) on a glass slide.
12. Allow to stand in an upright position until dry.
13. Stain, mount, and label.

Acetone-benzine method for routine paraffin embedding (Krajian)—preferred method

1. Fix thin blocks of tissue in 10% formalin for 16-24 hr. In emergencies fix for 30 min. in a paraffin oven at 56° C.
2. Place in acetone for 1 hr. using at least 20 times as much acetone as tissue.
3. Place in a second acetone for 1 hr., using the same quantity of acetone.
4. Place in benzine for 30 min.
5. Place in second benzine for 30 min.
6. Place in paraffin No. 1 in the paraffin oven for 1 hr.
7. Place in paraffin No. 2 in the paraffin oven for 1 hr.
8. Embed in the usual manner.

This method is useful for surgical tissues.

Alcohol-chloroform method for routine paraffin embedding

1. Dehydrate tissues in 70% alcohol for 2-3 hr.
2. Dehydrate in 80% alcohol for 2-3 hr.
3. Dehydrate in 95% alcohol for 2-3 hr.
4. Dehydrate in 95% alcohol (second time) for 2-3 hr.
5. Dehydrate in absolute alcohol for 2-3 hr.
6. Place in chloroform for 2 hr.
7. Place in a paraffin oven at 55° C. in a mixture of equal parts of chloroform and melted paraffin for 2-3 hr.
8. Place in pure paraffin in a paraffin oven at 55° C. for 2-3 hr.
9. Embed in the usual manner.

This method is excellent for autopsy specimens.

Benzine method for routine paraffin embedding

1. Dehydrate tissues in 70% alcohol for 2-3 hr.
2. Dehydrate tissues in 80% alcohol for 2-3 hr.
3. Dehydrate tissues in 95% alcohol for 2-3 hr.
4. Dehydrate tissues in 95% alcohol for 2-3 hr.
5. Dehydrate tissues in absolute alcohol for 2-3 hr.
6. Place in benzine for 2-3 hr.
7. Place in benzine and melted paraffin, equal parts, in a paraffin oven at 55° C. for 2-3 hr. For the evaporation of benzine leave the corks out of the bottle; otherwise the fumes may cause an explosion.
8. Place in pure melted paraffin in the paraffin oven at 55° C. for 2-3 hr.
9. Place in second paraffin bath in paraffin oven at 55° C. for 2-3 hr.

Dioxane or isopropanol in the process of embedding tissues

Dioxane*: Using graded alcohols, as described above, in the preparation of tissues requires time and necessitates constant attention. One of the bugbears in paraffin work is over-hardening of the object, making it difficult or impossible to cut sections without tearing or cracking.

Dioxane (diethylene dioxide) has been suggested as a dehydrating agent, and it has proved remarkably efficient. It is miscible in all proportions with water and gives up water and methyl or ethyl alcohol to anhydrous calcium chloride; it is also miscible with melted paraffin. If the tissue is put into an

---

*Isopropanol of appropriate strength may be substituted for ethyl alcohol in all dehydrating processes but **not** in the staining solution formulas.

*Union Carbide Chemicals Co., South Charleston, W. Va.

alcoholic solution of dioxane containing calcium chloride, the water is removed and the tissue is permeated with dioxane. Upon transfer of such a specimen to melted paraffin the dioxane is removed and the tissue is infiltrated with paraffin ready for sectioning when cool.

Isopropanol*: The use of isopropanol to replace graded alcohols, absolute alcohol, and xylol, except when reference is made to acid alcohol, is also recommended. It is economical, being less expensive than ethyl alcohol.

Method 1:

1. Cover the bottom of a vessel with calcium chloride and put a fine wire net over it, on which the objects are placed.
2. Cover the vessel to prevent evaporation of the dioxane and absorption of water from the atmosphere.
3. After fixation take the specimen from the fluid (formalin) and place it directly into the dioxane and leave it there for 3-24 hr.
4. Transfer to a paraffin oven at 55°-60° C. in a mixture of ⅓ dioxane and ⅔ paraffin, and then put it into pure paraffin.
5. Keep the pure paraffin in a dish with gauze a short distance above the bottom since the dioxane tends to sink through it.

Method 2:

1. Fix tissues in any desired fixative in the usual manner. Zenker-fixed tissues must be washed 16 hr. before being subjected to dehydration.
2. Dehydrate in 25% dioxane for 1 hr.
3. Dehydrate in 50% dioxane for 2 hr.
4. Dehydrate in 100% dioxane for 3 hr.
5. Place in paraffin at 56° C. for 30 min.
6. Place in paraffin at 56° C. for 1 hr.
7. Place in paraffin at 56° C. for 3 hr.
8. Embed in paper boxes.

Dioxane is **highly flammable**, and the vapor is quite toxic. **Excessive exposure to the vapor might cause serious consequences.**

Butyl alcohol in paraffin embedding

1. Fix tissues in 10% formalin for 24 hr. or longer.
2. Dehydrate in 80% ethyl alcohol for 3 hr.
3. Dehydrate in 90% ethyl alcohol for 20 hr.
4. Place in butyl alcohol No. 1 for 3 hr.
5. Place in butyl alcohol No. 2 for 3 hr.
6. Place in butyl alcohol No. 3 for 15 hr.
7. Place in paraffin No. 1 in a paraffin oven at 56° C. for 1 hr.
8. Place in paraffin No. 2 in a paraffin oven at 56° C. for 1 hr.
9. Place in paraffin No. 3 in a paraffin oven at 56° C. for 1 hr.
10. Embed in paraffin in paper boxes.

EMBEDDING TISSUE WITH A WATER-SOLUBLE WAX

Blank and McCarthy[20] developed a method for embedding tissues which is suitable for skin, liver, kidney, spleen, lung, testis, muscle, spinal cord, pancreas, adrenal, gastrointestinal tract, etc. It is especially applicable to delicate specimens such as skin with vesicles, eyes, embryonic membranes, etc. This method eliminates time-consuming, deleterious, dehydrating chemicals.

Embedding mixture:

Carbowax 4000	9 parts
Carbowax 1500	1 part

1. Melt these substances together at 55° C.

Solution for floating and affixing sections to slides (optional):

Potassium dichromate . .	0.2 gm.
Gelatin	0.2 gm.
Distilled water	1000 ml.

1. Boil in daylight for 5 min. cool, and filter. Ready for use.

Procedure:

1. Cut blocks of tissues, fix, and wash in the routine manner. As with other methods, the thinner the specimen the more rapid the impregnation with wax.
2. Immerse in the melted embedding medium and agitate occasionally. The minimum time for impregnation is 30 min. for a 1 mm. section, 80 min. for a 2 mm. section, and proportionately longer for thicker sections. Specimens have been left in melted Carbowax for periods up to 4 days with little perceptible distortion. The routine time should be about 3 hr.
3. After impregnation, transfer to a mold and add fresh melted wax to form a block.
4. Transfer the mold to a cool dry place, such as a refrigerator, and allow to harden for 5-10 min. Avoid contact with ice and water because of the solubility of the wax.
5. Attach the hardened block to a microtome specimen holder, and it is ready for sectioning. The block may be cut at 2-10μ with the formation of satisfactory ribbons. The knife and block should not be moistened or chilled because best results are obtained at room temperature.

Sections may be hydrated and affixed to the slide either by water or gelatin-dichromate solution. The latter keeps the sections firmly in place on the slide during subsequent staining procedures.

AUTOTECHNICON SYSTEM FOR PARAFFIN SECTIONS*

The Autotechnicon is a method especially designed for fixation, dehydration, and embedding of specimens by use of a special automatic apparatus. It is adaptable to any technic and, once set, adheres to that technic, eliminating human error. It requires no supervision since it operates automatically. The apparatus consists of a timing clock, reagent beakers of Pyrex glass, beaker platform, mastershift carriage, beaker covers, displacer rotor, receptacle basket, receptacles, washer, and paraffin bath. Figs. 539 and 540 show the equipment.

---

*Union Carbide Chemicals Co., South Charleston, W. Va.

*We are indebted to the Technicon Co., Inc., Chauncey, N. Y., for permission to prepare the section on the Autotechnicon.

The Autotechnicon is especially recommended for overnight and week-end tissue routine. To use the instrument for staining, plug in a 1 hr. staining clock and replace the processing fluid beakers with others containing the staining fluids required by the prescribed technic.

Typical daily hospital routine for embedding paraffin sections with Autotechnicon system: At a convenient time, usually in the late afternoon, the pathologist receives the tissues that have been collected during the day. While preparing and examining the specimens, he dictates the gross aspects into a recording apparatus. It is convenient to have a permanent microphone set up at the cutting board, with a foot switch to start and stop the recorder so that both hands are free for processing. Such pieces should be no more than 4 mm. thick, regardless of the other dimension. As the pieces are cut they are placed in a tissue receptacle fitted with dividers that enable it to hold several specimens for simultaneous processing. During this procedure the receptacle bottoms should be stored on one tray, dividers on another, and tops on a third. The pathologist can then select the tissues, pick the proper dividers, place them in the receptacle, and finally snap on the cover in a continuous operation.

If the pieces are small, the receptacle may hold 3 pieces; if larger, 2; or if very large, only 1. Paper identification slips are placed in the receptacle along with the tissue. Slips should be no larger than 3 × 10 mm. so as not to impede penetration of the fluid. Notations made with an ordinary graphite pencil remain legible during the ensuing processing and immersion in paraffin. As each receptacle is filled it is placed in the receptacle basket, which is immersed in a beaker of fixative lying beside the cutting board. Receptacles should be placed vertically in the basket rather than horizontally, for better penetration and draining during processing.

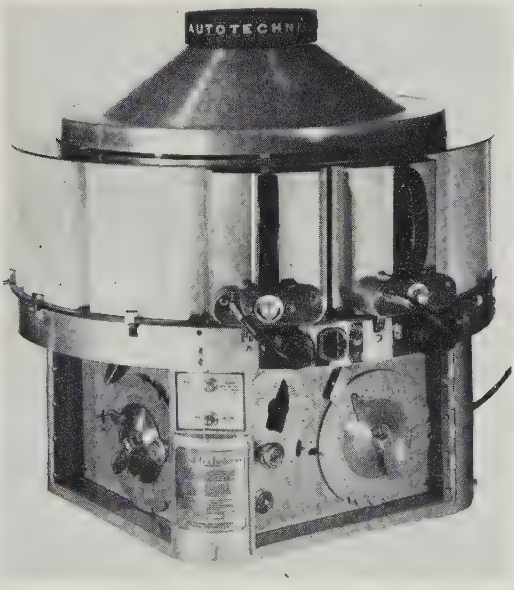

Fig. 539. Mono Autotechnicon. (Courtesy The Technicon Co., Inc., Chauncey, N. Y.)

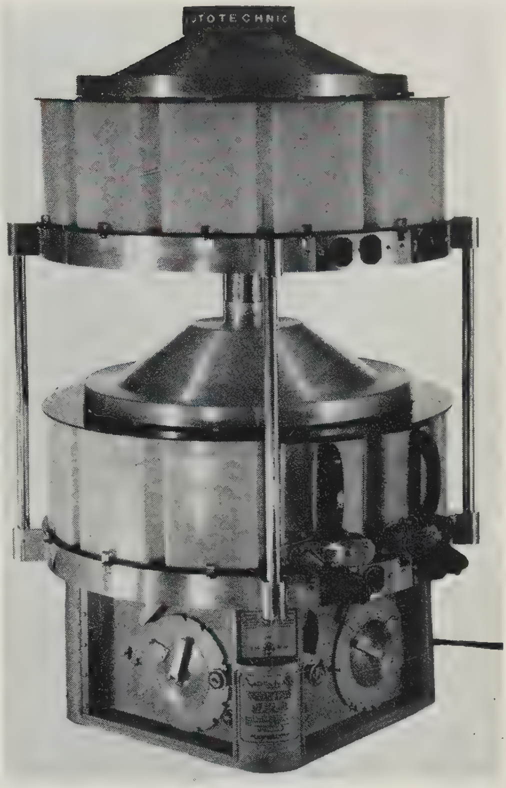

Fig. 540. Duo Autotechnicon. (Courtesy The Technicon Co., Inc., Chauncey, N. Y.)

When the receptacle basket has been filled, the displacer rotor is attached to it, and the whole assembly, including the beaker of fixative in which it has been lying, is mounted on the Autotechnicon. Then a check is made to see that no paraffin adheres to any of the beaker covers, since it might solidify and cause the beaker to tip and spill when the carriage rises.

The machine is now started and, from this point on, takes over. Precise time periods for each step in the desired procedure have already been cut into the timing dial.

Assume that the machine has been started at 5 P.M. In a typical routine, the tissues will remain in the fixative for 4½ hr., until 9:30 P.M. A stable solution, Technicon fixative, with all the properties of Zenker fluid but with none of its disadvantages, is recommended. It is chemically balanced to preserve the selectivity of the ensuing stain. Although it is a potassium dichromate formula, tissues fixed in it need not be washed since it produces no appreciable precipitate. It does not harden tissues, and they may remain in it for prolonged periods without harmful effects. Subsequent immersion in a

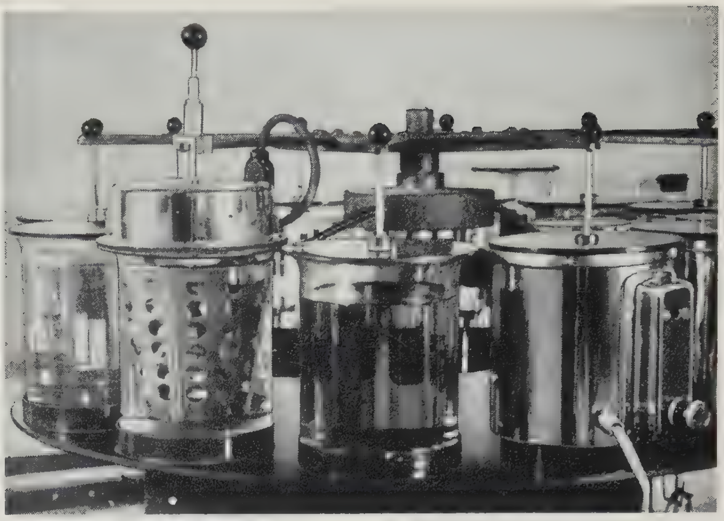

Fig. 541. Displacer rotor is attached to receptacle basket and the whole assembly mounted on Autotechnicon. (From Krajian, A. A., and Gradwohl, R. B. H.: Histopathological technic, St. Louis, 1952, The C. V. Mosby Co.)

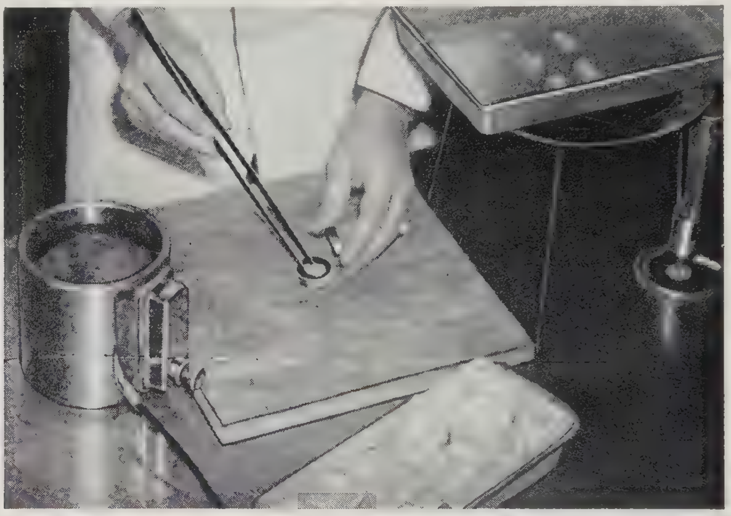

Fig. 542. Tissues are removed from their receptacles with forceps and placed in a flat pan of melted paraffin. (From Krajian, A. A., and Gradwohl, R. B. H.: Histopathological technic, St. Louis, 1952, The C. V. Mosby Co.)

beaker of water or the tissue washer for a period of 30 min. is recommended in order to wash off excess fixative and avoid contamination of the reagents that follow.

From 10 P.M. to 4 A.M. the tissues go through 6 changes of dehydrants, 1 hr. for each change. Technicon Dehydrant is neither hygroscopic nor highly volatile, does not take up atmospheric moisture, and is practically without loss from evaporation. It does not cause tissue shrinkage, nor does it harden. The tissues may be left for prolonged immersion without damage. Its physical properties materially lessen fire hazard.

From 4 to 6 A.M. tissues go through 2 stages of 1 hr. each of clearing. The Technicon clearing agent is an excellent medium for clearing. It manifests somewhat the same qualities as the dehyrant, i.e., is not volatile, hygroscopic, or markedly flammable and produces no shrinking, distortion, or hardening of the tissues. It is excellent for clearing fatty tissues. It removes all the dehydrant and at the same time conditions the tissues so that they will cut easily. It is highly soluble in paraffin, renders the tissues translucent, and increases their refractive index.

From 6 to 7 A.M. the cleared tissues enter and remain in the first paraffin bath. From 7 to 9 A.M. they undergo a second paraffin treatment. Although the first bath becomes contaminated, the second remains reasonably free of contaminants. Paraffin used in infiltrating the tissues should have a relatively low melting point, 54°-58° C., so that tissues are not subjected to too high a temperature for prolonged periods.

At 9 A.M., or whenever the working day starts, the paraffin bath is lifted with its contained load of

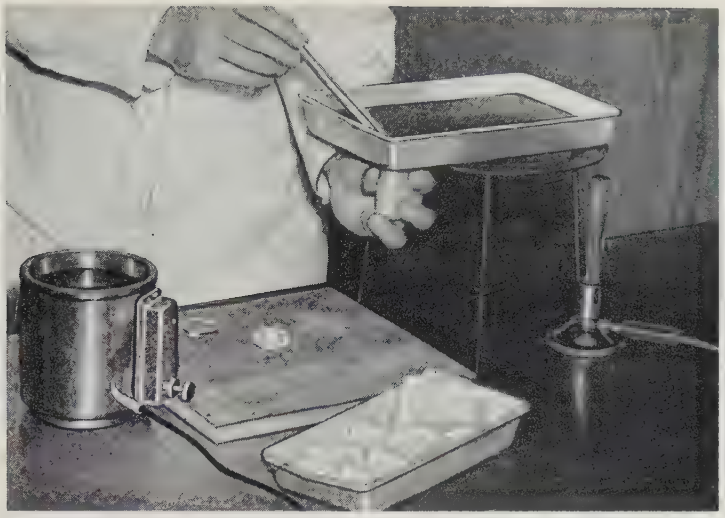

Fig. 543. Rubbing ice along bottom of pan causes the paraffin to solidify locally, anchoring tissues securely in place. (From Krajian, A. A., and Gradwohl, R. B. H.: Histopathological technic, St. Louis, 1952, The C. V. Mosby Co.)

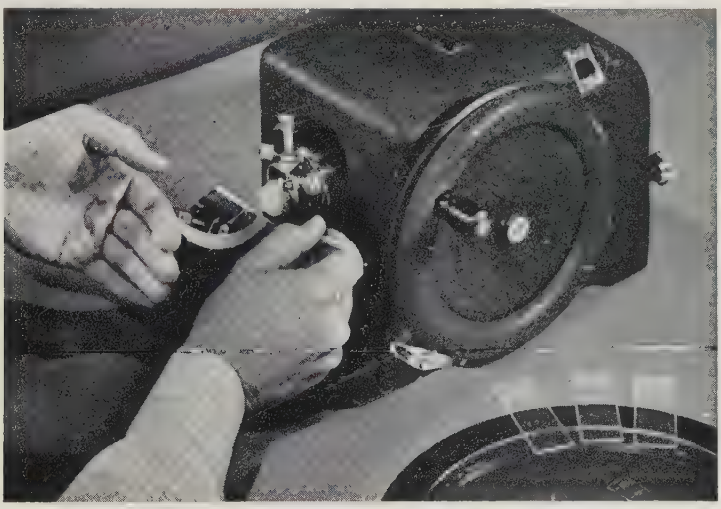

Fig. 544. Cut tissues are lifted carefully from microtome and spread face up on Technicon constant temperature water bath. (From Krajian, A. A., and Gradwohl, R. B. H.: Histopathological technic, St. Louis, 1952, The C. V. Mosby Co.)

tissues in the receptacle basket and carried to the embedding bench; then the bath is plugged into an electric outlet to maintain the paraffin at the desired fluidity.

Preparing the tissue blocks: Remove the tissue receptacles one by one from the paraffin and lay them on the table, bottom down. With the handle of the forceps strike the top lightly, which causes the clamping lugs to spring open with a snap that breaks loose any adhering paraffin.

Using the same forceps remove the tissues from the receptacle, each with its identifying label, and place in a flat pan of melted paraffin. For embedding purposes use a paraffin with a melting point of 60°-62° C.

Place a Bunsen burner or similar heating device beneath the pan to keep the paraffin fluid during embedding. Set the pan on a fairly high stand so that ice may be rubbed along the bottom. This causes the paraffin to solidify locally, anchoring the tissues securely in place. The pan should contain about ½ in. of paraffin, and the tissues should be embedded with the side to be cut facing down.

Before pouring in the paraffin, lightly coat the pan with glycerin so that the final paraffin slab can be easily removed when embedding is completed.

Place the tissues in straight rows so that neatly squared blocks can be cut when the paraffin slab is divided for sectioning. Cool the slab slowly to prevent crystal formation. It is best to let it stand at room temperature until the paraffin congeals. Once congealed, the paraffin slab should be cooled in water for hardening. Do not use too low a temperature since this will probably cause the paraffin to form crystals, making the tissues difficult to cut.

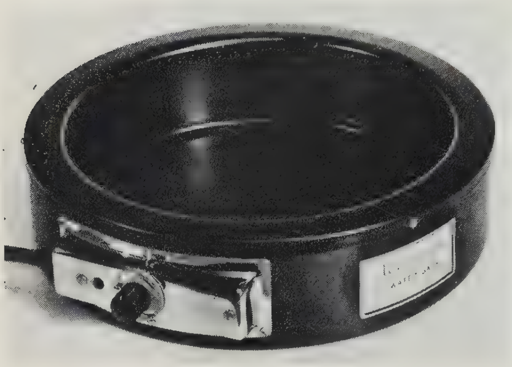

Fig. 545. Constant temperature water bath for tissue flotation. (Courtesy The Technicon Co., Inc., Chauncey, N. Y.)

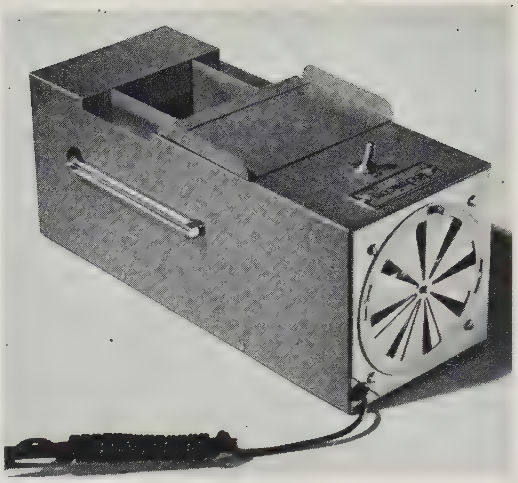

Fig. 546. Technicon microslide dryer. (Courtesy The Technicon Co., Inc., Chauncey, N. Y.)

When the hardened slab is freed from the pan, cut it into individual blocks, each containing a piece of tissue with its accompanying label.

From this point proceed to mount the block, cut the sections, affix them to slides, and stain in the usual manner.

Staining with the Autotechnicon: Insert the slides containing the tissue into a Technicon microslide dryer, where a current of warm, filtered air at 56° C. passes over them, completely drying the slides in about 7 min.

Take the dried slides, still in the rack, from the drier and mount the rack on the Autotechnicon for staining. Operation from this point is completely automatic. The tissues move into a beaker of xylol for 2 min. and then into 0.25% iodine dissolved in the dehydrant to remove any mercuric chloride crystals persisting in the tissue. They remain in the iodine for 2 min. and then go for 2 min. into a bath of Technicon dehydrant to remove any excess iodine. The next step is distilled water for 2 min. and then hematoxylin for 10 min., more or less, depending on the intensity of color required. The Technicon hematoxylin needs no subsequent decolorization. The next step is a rinse of distilled water for 4 min. then 0.01N lithium carbonate solution for 2 min., followed by distilled water for 2 min. Next, the tissues go for 5 min. into eosin solution. (The Technicon eosin solution will remain active under steady use for approximately 6 mo. No subsequent decolorization is required with this solution.)

The tissues pass into distilled water, then for 5 min. each in the dehydrant for 2 baths, and then into xylol. With the use of tongs lift the staining rack with its load of stained slides and place upside down in a beaker of xylol.

Remove the slides from the rack singly, clean, and mount with a cover glass. The slides, once labeled, are ready for microscopic examination.

Chapter 90

Celloidin sections*

ARAM A. KRAJIAN

Celloïdin methods are used for large tissues and organs and for hard or delicate materials. The celloidin is not removed from the tissues and holds the delicate structures permanently together.

The material to be cut is embedded in one of the commercial celloidins (cellulose nitrate), the slow burning kinds being preferred. The disadvantages of the method are that a longer embedding time is necessary, serial sections cannot be cut, so that each section has to be handled individually, and only dyes that do not stain celloidin may be used.

For materials not injured by moderate amounts of heat, the rapid process facilitates impregnation and preparation of the tissue. The slower, cold process takes more time and does not damage the tissue. It may not be possible to embed a hemisphere of a brain or a whole lung and harden it sufficiently for cutting in less than 6 mo.-1 yr.

The chief difficulty in celloidin sectioning arises from trying to cut improperly prepared material. Inadequately hardened blocks cannot be sectioned successfully. The blocks should be dense enough to cut at the required thickness. Unless the block is sufficiently hardened, the sections are uneven and distorted. If the block is too hard, irregularities are likely to occur. The surface of the block and the surface of the knife should be kept wet with 70% alcohol, and as soon as the sections are removed they should be placed in alcohol.

The sliding microtome is the instrument of choice for cutting celloidin material, using a slice angle of 10-40°.

Tilt the knife a little more than for cutting with paraffin, though the actual tilt will depend upon the hardness of the tissue. It is convenient to let large sections roll up on the knife. Then lift off of the knife and unroll into 70% alcohol. Or remove the sections from the knife and lay a piece of filter paper on top of the section. It usually adheres to the filter paper and then both may be placed in a Stender dish. If the filter papers are numbered, they may be kept in order. Or stamp a number on the margin of the section with a commercial numbering machine as each one is cut.

The knife for sectioning celloidin-embedded tissue must be very sharp. Any irregularities in the edge will leave marks on the section. Keep the section and materials for embedding free from dust. Dust particles catching on the edge of the knife spoil the section, particularly when very thin sections are required. Remove silicious or calcareous material before sectioning. Do not allow the surface to dry. If it is necessary to stop sectioning for even a short time, cover the block with absorbent cotton and saturate with alcohol or remove the block and place in 70% alcohol or other storage liquid.

The so-called dry process has been developed to replace the method which requires keeping the block and knife wet with alcohol. After the tissue is embedded and hardened, soak the block in an oil (cedar oil) which lubricates the block during cutting. As the sections are removed from the knife, place them in the same oil. The oil-soaked block may be cut on a rotary microtome, since no slicing cut is required. This method is exceptionally good for making sections of difficult organs, such as the entire mammalian eye.

---

*We are indebted to Dr. O. W. Richards for this material from his pamphlet "The effective use and proper care of the microtome," American Optical Co., Scientific Instruments Division, Buffalo, N. Y.

Special knife holders are available so that the knife can be turned to give a slicing stroke and may be used for cutting small celloidin blocks on a rotary microtome. The position of the block and knife is such, however, that it is difficult to keep the surfaces properly lubricated with alcohol so that the rotary microtome is not very satisfactory for this type of sectioning. If much sectioning in celloidin must be done on a rotary microtome, it is advisable to use the dry method which does not require a slicing stroke.

Celloidin-embedded blocks are sometimes embedded in paraffin to hold them for sectioning. The size of the section that may be cut depends on the size of the microtome and the knife and the skill of the operator.

Celloidin sections are usually stained in Stender dishes or watch glasses. They are not affixed to the slides until ready for mounting. At times it is more convenient to stain them on the slide by the following method.

1. Transfer the sections from water to the slide and dry by blotting in fine filter paper.
2. Cover with absolute alcohol for ½ min. and again blot.
3. Dip in thin celloidin (p. 1666) and drain off the excess quickly. Blow the breath briskly over them and immerse in water.

Celloidin sections can be stained by almost all methods without removing the celloidin. When it is necessary to remove the celloidin, place the sections in oil of cloves or ether-alcohol mixture for 5-10 min. and then pass through absolute alcohol into 95% alcohol.

During the process of staining, most celloidin sections swell and shrink. To flatten them, treat in equal parts of absolute alcohol and oil of cloves for 2 or 3 min. before placing in xylol.

Difficulties encountered in handling celloidin-embedded material

1. The chief difficulty comes from trying to cut improperly prepared material. Adequate impregnation of a large organ, such as a hemisphere of a brain, may take a year. Improperly hardened blocks cannot be sectioned successfully. Pressure methods involving heat speed up the process and are available when warming will not injure the material.

2. Lengthwise scratches or splits in the section may be due to the following: (a) Nicks in the knife. Use a different part of the knife or resharpen. (b) Particles of hard material in the block. Dust or dirt in the celloidin stock solution—let stand and use only upper portion after the particles have settled or filter the stock solution. If calcareous or silicious deposits are present, decalcify or desilicify.

3. Specimen falls out of section, is mushy and soft. (a) Dehydration was incomplete. (b) Infiltration was incomplete—refilter, reembed, and harden. (c) Harden block, if too soft, in chloroform or a mixture of equal parts of 95% alcohol and glycerin.

4. Variation in thickness of sections. (a) Loose screws on knife or block holders—tighten all set screws. (b) Knife holder depressed or raised by the hand while sectioning—hold knife block so as not to move it vertically while cutting. (c) Knife not tilted enough to clear facet of cutting bevel. (d) Knife too dull. (e) Microtome worn and out of adjustment. (f) Material not hardened properly. (g) Slight drying of block between sections.

Celloidin embedding and sectioning methods

After they are properly fixed in any given fixative, tissues are subjected to 1 of the 3 celloidin-embedding processes described below.

Wet celloidin embedding:

1. Prepare tissue blocks not more than 2-3 mm. thick.
2. Harden and dehydrate in 80% alcohol for 24 hr.
3. Repeat in 95% alcohol for 24 hr.
4. Repeat in absolute alcohol for 24 hr.
5. Soak in a mixture of equal parts of absolute alcohol and ether for 24-27 hr.
6. Impregnate in medium celloidin (p. 1666) for 2-4 days or longer, depending on the thickness and consistency of the tissue.
7. Soak in thick celloidin (p. 1666) for 3-6 days.
8. Embed in a paper box or mount on vulcanized fiber.
9. Harden in a desiccator with chloroform vapor. To harden the celloidin lift the cover of the desiccator jar once or twice a day for a moment to allow evaporation and thickening of the celloidin. When the celloidin attains the right consistency, add several drops of chloroform to the bottom of the desiccator. The vapor hardens the celloidin in several hours for small objects or several days for large ones. When the celloidin is hardened, place the blocks in 80% alcohol.
10. To mount, trim the block to proper size, dip the base in thick celloidin, press it firmly on vulcanized fiber, and treat with chloroform vapor as described above.
11. Keep the block in 80% alcohol until it is sectioned.

Celloidin is a purified form of colloidon or nitrocellulose. For histologic work it is supplied in small quantities (ounce) in brown bottles.*

Dry celloidin embedding:

1. Follow the wet celloidin embedding process and mount the tissue blocks on vulcanized fiber.
2. Expose them to the air until the celloidin mass attains the right consistency.
3. Then instead of hardening in chloroform, place them in **Gilson mixture,** made of equal parts of chloroform and cedar oil. Add cedar oil at intervals of 1 hr. for small blocks and 10 hr. or longer for larger blocks, until the mixture is about 90% cedar oil. By this time the celloidin becomes quite transparent.
4. Then expose the blocks to the air until dry.
5. Keep the blocks in stoppered bottles and cut dry.

Celloidin-paraffin embedding: The following technic enables one to obtain serial sections by embedding celloidin blocks in paraffin mass.

1. Embed blocks in celloidin by the dry process.
2. Trim the celloidin blocks and transfer them from cedar oil into melted paraffin in an oven at 55° C. for about 2 hr.
3. Place the blocks in paper boxes containing fresh paraffin and harden by placing on a wet towel.
4. For cutting, follow the paraffin sectioning method.

Advantages and disadvantages of celloidin method

Advantages: For large tissues, long period of immersion in celloidin does not affect the consistency. Such objects treated by the paraffin method become very hard since prolonged infiltration is necessary to ensure complete penetration.

For hard objects, such as eye and bone tissue, celloidin provides better support than paraffin and does not crumble in sectioning.

Disadvantages: The disadvantages are (1) very thin sections cannot be obtained, (2) embedding process is very slow, and (3) serial sections are difficult to prepare.

---

*Parlodion (Mallinckrodt) is recommended.

Chapter 91

Tissue staining methods

ARAM A. KRAJIAN

The use of dyes in histologic microscopy began about 1850. Carmine, indigo, iodine, fuchsin, aniline red, aniline violet, and other dyes were used in simple solutions. Hematoxylin was first introduced by Waldeyer[22] to stain axis cylinders in an aqueous solution. In 1865 Boehmer[23] combined hematoxylin with alum and thereby made it a valuable histologic stain, opening the way for more combination stains. The differential stains were introduced around 1890, with the use of various chemical reagents. Progress continued, and many new staining methods of considerable importance were introduced. Mallory[24] developed his famous aniline blue stain for connective tissue, Heidenhain,[25] developed his iron hematoxylin stain for protozoologic work, Levaditi[26] discovered a stain for *Treponema pallidum* in tissue, and Cajal[27] revolutionized the subject of neuropathology by his investigations and discovery of various staining methods for nerve fibers. Other investigators and authors have developed important methods for identifying such elements as glycogen, amyloid, fat, etc. in tissue.

The purpose of staining is to recognize different tissue elements by their color reactions. Because the physical chemistry of the cell and tissue elements is not well understood, it is not clear why certain tissues have an affinity for one dye and not for another.

Staining methods may be classified as (1) routine staining, (2) special or differential staining methods, and (3) vital staining.

ROUTINE AND SPECIAL STAINING

A routine method is one which stains various types of protoplasm generally, with little differentiation except between nucleus and cytoplasm. It demonstrates the cells and the general cellular arrangement of the tissue. Special staining methods are those of more limited scope, which demonstrate or differentiate special features of the tissue, such as the minute intracellular or intercellular structure, foreign materials, organisms, etc.

VITAL STAINING

Vital staining is employed to stain living cells by injecting the staining solution into any part of the animal body. It causes a specific coloration of the cytoplasm of certain cells, chiefly those of the reticuloendothelial system.

In employing vital stains a sterile syringe and needle are used. The staining solution to be injected should be free from particles or clumps which might cause emboli in the capillary vessels.

The vital dyes are usually injected intravenously, intraperitoneally, or subcutaneously. Smaller doses are needed for intravenous administrations, but large doses are necessary for subcutaneous and intraperitoneal injections.

Technic:

Lithium carmine:

1. Prepare a concentrated suspension of carmine, about 5 gm./100 ml., in cold saturated lithium carbonate. Filter and sterilize.
2. Inject 5-10 ml. intravenously into rabbits.

India ink (Higgins):

1. Dilute the India ink with an equal volume of sterile distilled water in a sterile test tube. Warm to body temperature before injecting.
2. The average intravenous dose is about 5 ml. for rabbits, repeated daily for 3-4 days, and then every 3 days thereafter.

Combination of vital stains: If desired, combine 2 or more types of vital stains; for example, one may inject India ink intravenously, trypan blue intraperitoneally, and lithium carmine intrapleurally. Some cells will ingest one dye, others may take up all the dyes.

SUPRAVITAL STAINING

Supravital stains are used to stain living cells immediately after removal from the living body.

Place thin slices of tissue in small staining dishes and add enough staining solution to cover the tissue. Several dyes are in general use.

Neutral red: This is a basic dye used for observing cell granules and vacuoles of phagocytic cells. It is employed on tissue slices in a concentration of 1:10,000 to 1:100,000.

Another method is to exsanguinate the animal and inject a 1:15,000 solution of dye in physiologic saline.

Janus green: This is regarded as a specific stain for mitochondria. Stain thin slices of tissue in 1:10,000 Janus green B in physiologic saline. Specific mitochondria stain may be given with a weaker solution, 1:500,000. Janus green B, 1:10,000 in physiologic saline, can be injected into animals previously bled to the point of exsanguination.

Trypan blue: For use, suspend 1 gm. of the dye in 100 ml. sterile distilled water and use immediately. It is dangerous to allow the suspension to stand more than 1 hr. because it is likely to become toxic.

Isamine blue and *Niagara blue* give similar results and are used in the same manner as is trypan blue.

ROUTINE STAINING OF SECTIONS

The method of staining frozen sections is given on pp. 1666 and 1668.

Routine hematoxylin-eosin staining of paraffin sections

Method 1—Recommended procedure[28]

This method is an adaptation of the staining technic devised by Krajian[29] for staining frozen sections. It gives excellent results. With this method sections are seldom lost during the staining process

1. Prepare paraffin sections in the usual manner. Cut them as thin as possible and mount on a glass slide without fixative. If a fixative is considered necessary, use Mayer albumin fixative. Allow the tissues to dry on the slide. Carry out the process from here in staining jars. (Fig. 528.)
2. Place slides in xylol No. 1 in a Coplin jar for 5 min.
3. Transfer to xylol No. 2 in a staining jar for another 5 min. to ensure removal of paraffin from sections. If necessary, use a third xylol bath.
4. Place slides in anhydrous isopropanol or absolute alcohol to remove the xylol. This usually requires 2 to 5 min.
5. Blot twice with several thicknesses of Whatman No. 1 filter paper.
6. Immediately dip twice in thin celloidin (p. 1666). Keep the slide perpendicular while dipping and dip quickly but not suddenly. Do not turn the slide while dipping in and out. Blow gently over the slide while holding it in a perpendicular position. Continue the gentle blowing until the celloidin is dry. Wipe the celloidin off the back of the slide. The slide is now ready to be stained, following the method for routine staining of frozen sections (pp. 1666 and 1668).

Method 2—Routine procedure

1. Flood the slide containing the cut section, previously affixed to the slide with Mayer albumin fixative, with pure xylol from a dropping bottle, placing sections on staining dishes for 5 min. Repeat the process.
2. Pour off the second xylol and flood the slide with absolute alcohol or anhydrous isopropanol twice, 5 min. each.
3. If the tissue is fixed in Zenker fluid or other fluid containing mercuric chloride, treat first in tincture of iodine 5 min. to remove the mercury precipitate, followed by **sodium thiosulfate (hypo) solution** until the natural color of the section reappears.

Sodium thiosulfate	0.75	gm.
Alcohol, 95%	10	ml.
Water	90	ml.

4. Wash in tap water.
5. Stain in Harris hematoxylin (p. 1658) 7-10 min.
6. Wash in a beaker of water until blue.
7. Destain in 1% acid alcohol until the reddish color of hematoxylin ceases to come off.
8. Wash in a large basin of tap water.
9. Blue the sections by dipping in 2% ammonia water (2 ml. ammonium hydroxide in 98 ml. tap water).
10. Rinse in tap water.
11. Stain in 1% aqueous eosin 5-10 min. or follow eosinol technic after dehydrating in isopropanol (p. 1668). When eosinol is used, omit the subsequent dehydrating steps.
12. Wash in 2 changes of tap water.
13. Dehydrate thoroughly in 2 changes of absolute or butyl alcohol or anhydrous isopropanol, 2 min. each.
14. Place in 2 changes of carbolxylol for 5 min.
15. Clear in pure xylol for 5 min.
16. Clear in a second pure xylol for 5 min. or longer.
17. Mount in gum damar.

Method 3—Routine procedure

Reagents:

1. Alcohols. The various strengths are described on p. 1680.
2. Hematoxylins. Harris, Delafield, Boehmer,

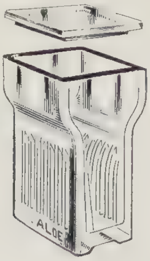

Fig. 547. Wide top staining jar. (Courtesy Aloe Scientific, St. Louis, Mo.)

Ehrlich, or Mallory phosphotungstic acid hematoxylin may be used.

3. Acid alcohol. 1% hydrochloric acid in 70% ethyl alcohol.
4. Alkaline alcohol.
    (a) Dissolve 2 gm. sodium bicarbonate in 100 ml. 70% ethyl alcohol
    or
    (b) Add 1 ml. concentrated ammonium hydroxide to enough 70% alcohol to make 100 ml. total.
5. Alcohol eosin, 0.5%.

Procedure: Prepare paraffin sections and mount on slides in the usual manner.

1. Put all solutions in Coplin jars or large staining jars (Fig. 547) and arrange the jars in the proper sequence. When transferring slides from one solution to another, catch the excess solution on a cloth as it drains off and dry the back of the slide with a towel. **Never let the section dry during the staining process.**
2. Immerse in xylol for 5 min. to dissolve the paraffin.
3. Place in absolute alcohol for 1 min.
    95% alcohol for 1 min.
    80% alcohol for 1 min.
    70% alcohol for 1 min.
    50% alcohol for 1 min.
    Do not make changes too rapidly or the section may fall off the slide.
4. Place in tap water for 1 min.
5. Stain in hematoxylin for 5 min. or longer. If the tissue has not stained the correct shade of purplish blue, replace the slide in the hematoxylin.
6. Rinse in tap water until no more color comes off.
7. Place in 50% alcohol. Then wash, just dipping the slide in and out.
8. Decolorize in acid alcohol. Dip the slide in the jar; then hold it above until the tissue is salmon pink. **Do not decolorize too long.**
9. Place in alkaline alcohol until blue.
10. Look at the tissue under a microscope to ascertain whether the nuclei are sufficiently blue. If not, replace the slide in acid alcohol, then 50% alcohol, then water, then hematoxylin, and then continue on from this point.
11. Place in 80% alcohol for 1 min.
12. Place in 95% alcohol for 1 min.
13. Dip in 0.5% alcoholic eosin Y about ½ min. or longer.
14. Wash in 95% alcohol but not too long since the eosin decolorizes.
15. Dehydrate in 100% alcohol but not too long; otherwise the eosin may disappear.
16. Finally place in xylol until clear, usually about 3-10 or 15 min. Look at the tissue under a microscope. If it is not red enough, pass the slide through the alcohols back to the eosin; if not blue enough, pass the slide back through the process to the hematoxylin.
17. Place 1-2 drops of gum damar over the tissue and mount with a cover glass without admitting any air bubbles.
18. Label.

Difficulties encountered in staining

If objects do not remain on the slide:

1. Slide may have been dirty or oily.

2. Albumin fixative is too old. (If too old, it loses its clear color. Or it may have an odor. Make it in 1 oz. quantities. This will last 2 or 3 mo.)

3. Slides might have been carried through the first alcohol baths too fast.

4. Dehydration of the tissue through alcohol may have been too rapid. (If tissue is too small, use 60% alcohol after the 50%.)

5. Paraffin section not thoroughly spread on slide when mounted.

If objects do not stain:

1. Stain is at fault. Hematoxylin must ripen. Do not use it too soon after preparation.

2. Stain has deteriorated.

3. Paraffin had not been thoroughly removed from the slide. Leave longer in xylol. The slide can be run back through the solutions to the first xylol.

4. Early fixation in alcohols before paraffin embedding was not correct; nothing can be done to remedy this.

5. Fixing agent not thoroughly washed out of tissue before immersing in alcohols.

If section is not clear under microscope:

1. Xylol should be replenished.
2. There was water in the absolute alcohol.
3. Moisture on the cover slip.
4. Too much egg albumin on slide.

5. All the acid after acid alcohol decolorization was not removed.

6. A film from the alkaline alcohol was carried along.

To remedy:

1. Put in Coplin jar of xylol to dissolve gum damar. Run back through the processes to the jar where the fault lay and use fresh solutions. Then restain.

2. If the tissue is thoroughly adherent to the slide, it can be taken back several times without danger.

Miscellaneous pointers

1. When mounting tissues on slides, make several at once.

2. Thick sections come off the slide.

3. Occasionally a tissue cannot be cut less than 10μ thick.

4. If the tissue is likely to come off (a) put slide in xylol to dissolve paraffin (b) dip in solution of ¾ gm. celloidin in 100 ml. ether-alcohol (equal parts). This places a slight film over the slide and does not interfere with the penetration of stain (except carmine).

5. After cover glass is on, if gum damar creeps out, rub off with xylol cloth.

6. Keep knives sharp.

7. If tissue is not embedded well, melt the paraffin in oven and re-embed it.

Eosin-methylene blue stain

Zenker and mercuric chloride-fixed tissue sections give the best results.

1. Deparaffinize sections by 2 applications of xylol, 2 min. each.
2. Remove xylol with 2 applications of absolute alcohol, 2 min. each.
3. Wash thoroughly in tap water.
4. Place the section in a jar containing 5% eosin Y and leave it in a paraffin oven for 30 min. at 52° C.
5. Rinse rapidly in tap water and immediately place in Borrel methylene blue; then leave it in a paraffin oven 30 min. at 52° C.
6. Wash in tap water. The section should be blue-black.
7. Differentiate in **colophonium-alcohol** (0.5 ml. colophonium in 100 ml. alcohol), agitating the slide constantly and examining every few seconds under a microscope.
8. Dehydrate rapidly in absolute alcohol.
9. Clear in xylol 5 min. and mount in gum damar.

Cell nuclei stain blue; cytoplasm, collagen fibers, and muscle stain pink; and erythrocytes and eosinophils stain bright pink.

Routine staining of celloidin sections

1. Stain loose sections in a Stender dish containing Harris hematoxylin for 2-5 min.
2. Wash in tap water until blue.
3. Destain in acid alcohol until the reddish color of hematoxylin ceases to come off.
4. Dip in ammonia water until blue.
5. Stain in 1% aqueous eosin 5-10 min. (or in eosinol 10-20 sec., after dehydrating in isopropanol).

Omit the next 3 steps if eosinol is used.

6. Wash in 2 changes of tap water.
7. Place in graded alcohols, 70%, 80%, and 90%, for a few minutes each.
8. Place in 90% alcohol for a few minutes.
9. Place in the following mixture not more than 5 min.: xylol, 1 part; chloroform, 1 part; absolute alcohol, 1 part.
10. Transfer to a dish of pure beechwood creosote. If wrinkled, the sections will immediately flatten out. Do not leave in the creosote more than 10 min. since celloidin is slightly soluble in creosote and alcohol.
11. Transfer the sections to glass slides.
12. Blot in filter paper.
13. Pour pure xylol on the slide, drain it off, and repeat the process once or twice. Do this as rapidly as possible since prolonged treatment with xylol will cause the sections to crease.
14. Blot rapidly with filter paper.
15. Mount in gum damar or Permount.

Chapter 92

Special or differential staining methods

ARAM A. KRAJIAN

STAINING COLLAGEN FIBRILS AND RETICULUM OF CONNECTIVE TISSUE

Mallory aniline blue stain, modified

Mallory aniline blue stain is not absolutely differential because in addition to collagen fibrils and reticulum it also stains hyalin, fibrin, fibroglia fibrils, smooth and striated muscle fibers, and amyloid.

1. Fix tissues in Zenker fluid.
2. Embed in celloidin or paraffin.
3. Cut thin sections.
4. Flood the slides with xylol for 5 min. Repeat.
5. Then flood slides with absolute alcohol or anhydrous isopropanol for 3 min. Repeat.
6. Rinse in water and place in tincture of iodine for 5 min.
7. Rinse in alcohol; then water.
8. Bleach with 5% sodium thiosulfate for 5 min. Rinse thoroughly in water.
9. Place in 1% acid fuchsin 5-10 min.
10. Rinse quickly in tap water.
11. Place in 1% aqueous phosphomolybdic acid solution for 1 min.
12. Rinse in water.
13. Stain for 5 min. in modified Mallory aniline blue (p. 1660).
14. Rinse in tap water and blot.
15. Dehydrate thoroughly with absolute alcohol or anhydrous isopropanol.
16. Clear in xylol for 5 min. Repeat in fresh xylol.
17. Mount in gum damar.

For celloidin sections use 95% alcohol and clear in xylol by the blotting method.

The collagen fibrils, reticulum, connective tissue, amyloid, mucus, and hyaline stain blue; nuclei, cytoplasm, fibroglia fibrils, axis cylinders, neuroglia fibers, and fibrin stain red; red blood corpuscles and myelin sheaths stain yellow; and elastic fibers stain pale pink or yellow.

If it is desired to bring out the collagen fibrils as sharply as possible, omit the staining with acid fuchsin. Then the nuclei and cytoplasm stain yellow, and the blue fibrilla and reticulum stand out more prominently.

This is an excellent and colorful method to demonstrate connective tissue fibers.

Azocarmine stain—Heidenhain modification of Mallory aniline blue

1. Fix tissue in Zenker solution 16 hr. Wash overnight. Pass through graded alcohols:
    - 80% alcohol overnight
    - 95% alcohol the next day
    - absolute alcohol overnight
2. Place in xylol for 2 hr. or more until tissue is clear.
3. Place in an oven at 56° C. for 30 min. Then change the paraffin.
4. Leave in oven for 3-4 hr. Embed.
5. Cut and mount sections and dry in an oven at 45° C. for 3-7 days. Pass slides through:
    - xylol for 5 min.
    - absolute alcohol for 3 min.
    - 95% alcohol for 3 min.
    - 80% alcohol for 3 min.
    - distilled water for 3 min.

NOTE: **Deformalinization**, if necessary, should be done at this stage, as follows:

Place sections in ammonia water (40 drops of ammonium hydroxide to 100 ml. distilled water). Leave in this solution for 7 hr.

(a) Wash in tap water for 1 hr.
(b) Place in Helly or Zenker fluid overnight.
(c) Wash in tap water for 1 hr.

This step is used only if tissues have been fixed in formalin.

6. Remove crystals with Lugol solution for 1 min. and then 2% sodium hyposulfite for 2 min. Wash in tap water for 5 min.
7. Stain sections in 1% acidified azocarmine (p. 1660) in an oven at 56° C. for 45-60 min. Allow to cool 5-10 min. at room temperature.
8. Wash in distilled water.

9. Differentiate in **aniline alcohol** 1-3 min.

Aniline oil	1 ml.
Alcohol, 95%	100 ml.

Nuclei stain red and cytoplasm stains pale pink (control under a microscope).

10. Remove aniline with alcohol acidified with 1% acetic acid for ½ min. If section is too red, put back in aniline-alcohol solution for a few seconds.
11. Place in phosphotungstic acid, 5%, for 2-3 hr.
12. Wash quickly in distilled water
13. Stain in Mallory aniline blue-orange G-acetic acid solution (p. 1660) for 3-6 hr.
14. Wash in distilled water.
15. Differentiate in absolute alcohol, controlling under the microscope.
16. Clear in xylol.
17. Mount in gum damar.

Amyloid, connective tissue, and mucous colloid take deep blue stain; nuclei are red.

This is a valuable stain to show minute details of connective tissue.

Krajian aniline blue stain for connective tissue and hyalin applicable to formalin-fixed frozen and paraffin sections

Frozen sections

Mordant:

Saturated aqueous solution of picric acid	25 ml.
Alcohol, 95%	25 ml.
Acetone	50 ml.
Thorium nitrate	4 gm.
Cadmium nitrate	5 gm.

1. Dissolve the thorium nitrate and cadmium nitrate in the picric acid solution; then add the alcohol and acetone.

Procedure:

1. Fix tissues in 10% neutral formalin as usual. In emergencies, fix in hot formalin in a paraffin oven at 56° C. for 15 min.
2. Cut thin frozen sections.
3. Place in the mordant for 5 min.
4. Rinse the tissue in tap water and transfer the sections to a glass slide.
5. Dehydrate with anhydrous isopropanol or absolute alcohol for 15 sec.
6. Blot and dip once in thin celloidin (p. 1666).
7. Dip in tap water and apply azocarmine fuchsin stain (p. 1660) for 5 min.
8. Rinse rapidly in tap water and treat with 10% aqueous phosphotungstic acid solution for 3 min.
9. Rinse in tap water and stain in Mallory aniline blue-orange G-acetic acid solution, p. 1660, for 5-8 min., using 2 vol. aniline blue solution and 1 part 10% aqueous citric acid.
10. Wash rapidly in tap water and control under a microscope. If a deeper shade of blue is desired, continue treatment with aniline blue until desired result is obtained.
11. Dehydrate rapidly with 3 applications of anhydrous isopropanol or absolute alcohol and follow with butyl alcohol for 2 min.
12. Clear in 2 changes of xylol, 1 min. each.
13. Mount in gum damar.

Collagen fibers stain deep blue; reticulum, light blue; hyalin, bright red; nuclei, red; erythrocytes, golden yellow; elastic fibers, dark red.

All the solutions should be kept in tightly stoppered bottles. They can all be used at least a dozen times, except aniline blue-citric acid combination, which should be discarded after it is used.

Paraffin sections

1. Fix tissues in 10% formalin in the usual manner and cut thin paraffin sections.
2. Mount on slides as usual.
3. Deparaffinize with 2 applications of xylol, 2 min. each, followed by 3 applications of anhydrous isopropanol or absolute ethyl alcohol.
4. Wash in tap water and place in the Krajian mordant (p. 1695) for 10 min.
5. Rinse in tap water and apply azocarmine-fuchsin (p. 1660) for 10 min., using 1 part stain with equal volume of 2% aqueous acid fuchsin solution.
6. Rinse in tap water and treat with 10% aqueous phosphotungstic acid solution for 5 min.
7. Rinse in tap water and stain in Mallory aniline blue-orange G-acetic acid solution (p. 1660) 8-12 min., using 2 vol. stain with 1 vol. 10% citric acid.
8. Wash rapidly in tap water and control under a microscope. If a deeper shade of blue is desired, continue staining with aniline blue until desired result is obtained.
9. Dehydrate rapidly with 3 applications of anhydrous isopropanol or absolute alcohol and follow with butyl alcohol 2 min.
10. Clear in 2 changes of xylol, 1 min. each, and mount in gum damar.

Van Gieson stain for connective tissue

The van Gieson stain is a selective method of demonstrating collagen fibers of connective tissue.

1. Stain frozen, paraffin, or celloidin sections rather deeply with alum hematoxylin, preferably the Harris formula.
2. Wash in water until blue.
3. Stain in van Gieson solution 5 min. (p. 1663).
4. Transfer directly to 95% alcohol, followed by absolute alcohol.
5. Clear in xylol and mount in gum damar or balsam.
6. For celloidin sections, clear in oil of origanum after 95% alcohol.

Cell nuclei stain dark brown; collagen fibers, bright red; muscle, erythrocytes, and other tissues, a transparent yellow.

Krajian modification of van Gieson stain

1. Prepare frozen, paraffin, or celloidin sections.
2. Stain for 5 min. in Krajian iron hematoxylin stain (p. 1658).
3. Wash in tap water.

4. Destain in 1% acid alcohol in 70% alcohol until no more color comes out.
5. Rinse in water.
6. Stain in van Gieson solution (p. 1663) for 5-10 min.
7. Rinse rapidly in water.
8. Blot dry.
9. Differentiate with equal parts of oil origanum and absolute alcohol or isopropanol for 5 min., changing the solution twice.
10. Clear in xylol and mount in gum damar.

The elastic tissue staining solution keeps well for long periods in well-stoppered bottles. It acts as a mordant in the van Gieson stain; it stains elastic tissue fibers, myelin sheath, and bacteria.

Cajal trichrome stain for connective tissue—Ramon Castreviejo modification

1. Fix tissue in 10% formalin.
2. Prepare frozen, paraffin, or celloidin sections.
3. Stain in acetic fuchsin formalin 2-5 min.:

Ziehl-Neelsen carbolfuchsin	15 drops
Glacial acetic acid	2 drops
Formaldehyde, 40%	2 drops

4. Wash in water.
5. Stain in the following solution 5-10 min.:

Indigo carmine	0.25 gm.
Saturated aqueous picric acid	100 ml.
Glacial acetic acid	5 ml.

6. Wash rapidly in water.
7. Dehydrate in 95% alcohol, followed by absolute alcohol.
8. Clear in carbolxylol, followed by xylol.
9. Mount in gum damar.

Nuclei stain deep red violet; cartilage, mucin, and mast cells, very intense bluish violet; cytoplasm, clear green or yellowish green; connective tissue, intense blue; and muscle fibers, clear green. This is a valuable connective tissue stain.

Perdrau-Bielschowsky method for reticulum

1. Fix tissue in 10% formalin.
2. Cut frozen sections 15-20μ thick.
3. Leave in distilled water 24 hr.
4. Treat sections for 10 min. in 0.25% potassium permanganate.
5. Wash and place in the following:

Oxalic acid	1 gm.
Potassium sulfite	1 gm.
Distilled water	200 ml.

6. Decolorize until white.
7. Wash thoroughly in several changes of distilled water overnight.
8. Place in 2% silver nitrate solution in the dark for 1-2 days.
9. Wash in distilled water for not more than 5 min.
10. Treat sections 40-60 min. in **Bielschowsky ammonium silver solution:**

Silver nitrate, 10%	5 ml.
Sodium hydroxide, 40%	5 drops
Distilled water	40 ml.

    Add strong ammonia drop by drop until precipitate is almost completely dissolved.
11. Wash quickly in distilled water.
12. Reduce in 20% formalin for 30 min.
13. Wash in distilled water. Tone in 0.2% yellow gold chloride solution.
14. Wash in distilled water. Fix in 5% aqueous sodium hyposulfite.
15. Wash, dehydrate, clear, and mount.

This is an excellent but slow method of demonstrating reticulum fibers.

Krajian rapid frozen section method for staining reticulum fibers

Ammoniacal silver solution: Place 20 ml. of 10% silver nitrate in a Stender dish. Add strong ammonium hydroxide drop by drop until the precipitate that is formed is almost completely dissolved.

Procedure:

1. Cut frozen sections 7-10μ thick.
2. Rinse in distilled water.
3. Place in the following potassium permanganate-ammonium hydroxide solution for 5 min.:

Potassium permanganate, 0.3% aqueous	15 ml.
Strong ammonium hydroxide	5 ml.

4. Rinse in distilled water for a few seconds.
5. Decolorize in 2% oxalic acid until all the brown color has disappeared (sections should not be left in this solution longer than necessary). Each section should be treated separately.
6. Wash in 2 changes of distilled water.
7. Place in warm ammoniacal silver solution, previously heated to 60° C. for 15 min., in a paraffin oven.
8. Wash in 2 changes of distilled water.
9. Reduce in warm 20% formalin for 2 min. (heated to 55° C.).
10. Rinse in distilled water.
11. Treat in 1:300 gold chloride solution for 2 min.
12. Rinse in distilled water.
13. Treat with 5% sodium thiosulfate solution for 2 min.
14. Wash and transfer to a glass slide.
15. When well drained off, mount in warm glycerin jelly.

This is a rapid and colorful method.

Foot method for staining reticulum

Silver ammonium carbonate solution:

1. Add 10 ml. saturated solution of lithium carbonate to 10 ml. 10% aqueous silver nitrate.
2. Allow the resulting heavy precipitate of silver carbonate to settle, and pour off the supernatant fluid.
3. Wash the precipitate several times in 25-50 ml. distilled water, allowing it to settle each time before decanting the supernatant fluid.
4. Add 25 ml. of fresh distilled water.
5. Dissolve the washed precipitate in strong ammonia water, adding it drop by drop while

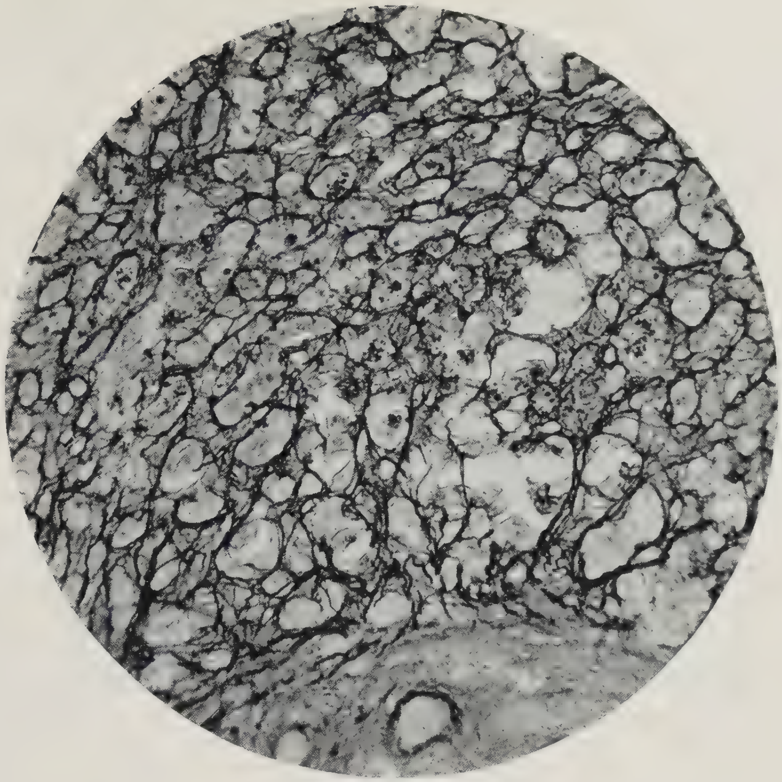

Fig. 548. Liver sections stained by Krajian rapid reticulum stain. Fibers of reticulum stain jet black. Frozen section. (From Krajian, A. A., and Gradwohl, R. B. H.: Histopathological technic, St. Louis, 1952, The C. V. Mosby Co.)

shaking the container continuously. The precipitate turns grayish brown as the ammonia is added. About 8-15 drops of ammonium hydroxide are needed, depending on the concentration.

6. Dilute the entire solution to 100 ml. with distilled water and heat to about 50° C.

Procedure:

1. Fix tissues in Zenker solution for 24 hr.
2. Wash under running tap water for 12-24 hr.
3. Dehydrate and embed in paraffin in the usual manner.
4. Cut thin sections, 5-7μ thick, affix to slides, and dry thoroughly in a paraffin oven for 12 hr. or longer.
5. Dissolve the paraffin in 2 changes of xylol.
6. Wash in alcohol, followed by tincture of iodine for 5 min.
7. Wash in alcohol and bleach in 5% sodium thiosulfate.
8. Place in 0.25% potassium permanganate 5 min.
9. Place in 5% oxalic acid for 10 min.; then wash in tap water and then in distilled water.
10. Treat with silver ammonium carbonate solution, made fresh each time, by immersing the slides in the silver ammonium carbonate solution in an incubator at 37° C. for 10-15 min.
11. Wash quickly in distilled water and place the sections in 20% neutral formalin for 2 min., until they become dark brown.
12. Wash in tap water and transfer sections to 1:500 gold chloride solution for 2 min.
13. Wash in water and fix in 5% sodium thiosulfate for a few minutes.
14. Wash in water. If desired, use a counterstain.
15. Dehydrate the sections, clear in xylol, and mount in gum damar.

This is a rapid and useful method to demonstrate reticulum in paraffin sections.

Tumor reticulum*

The cells of the body are bound together by a stroma or network of connective tissue fibers of which 3 varieties are universally recognized: elastin, collagen, and reticulin. Collagen and reticulin appear to be closely related physically and chemically. Evidence is accumulating which may indicate that reticulin is a distinct substance formed by a precipitation-enzyme reaction in the secretions of certain cells such as reticulocytes, histiocytes, monocytes, lymphocytes, fibroblasts, smooth and striated muscle cells, and vascular endothelium. Reticulin is apparently a precollagen since typical collagenous fibers may be formed by the impregnation of reticulin fibers with collagen.

---

*Much of the information regarding tumor reticulum is from Morhardt, R. P., and Krajian, A. A.: Atlas of tumor reticulum, Los Angeles, 1947, Mac Printing Co. Permission of authors and publisher has been granted to abstract this material.

Reticulum was first observed by Kupffer in 1876 during his histologic investigation of the liver. There is an increase in the sarcoma group of neoplasms rather than in the carcinomas. The reticulum stain as developed by Morhardt and Krajian impregnates epithelial cells, whereas those neoplasms of connective tissue origin exhibit fibers only. These authors are convinced that any undifferentiated cellular tumor that is without obvious characteristics is incompletely examined unless a reticulum stain is performed. They believe that carcinoma is never productive of an increase in reticulum and that sarcomas provoke an increase in reticulum; therefore, the use of reticulum stain offers a means of differentiating between sarcomas and carcinoma.

Morhardt and Krajian give a partial list of tumors, based on the amount of reticulum found, as follows:

Increased reticulum

Testicular seminoma
Pleural mesothelioma
Periphery of glioblastoma
Spinobasilar chordoma
Periphery of astrocytoma
Plasma cell myeloma
Retroperitoneal sarcoma, neurogenic
Giant cell tumor, osteoclastoma
Neurofibrosarcoma
Testicular lymphosarcoma
Periphery of metastatic melanoblastoma in brain
Leiomyosarcoma
Leiomyoblastoma
Reticulum cell sarcoma
Osteosarcoma
Lymphosarcoma
Monocytic leukemia (liver)
Plasma cell leukemia (liver)
Wilms' tumor (sarcomatous component)
Malignant lymphoma

Normal reticulum

Carcinoma of lung, primary
Fibroadenoma of breast
Neuroma
Uterine adenomyosis
Hemangioma
Lipoma
Neurilemoma
Dysgerminoma (ovarian seminoma)
Carcinoma of thyroid gland
Adamantinoma
Carotid body tumor

Diminished reticulum
(Displacement of normal tissue)

Hepatoma
Carcinoma of ovary
Carcinoma of testis
Neuroepithelioma
Glioblastoma, central portion
Glioma, central portion
Chorioepithelioma
Carcinoma, adrenal, metastatic
Medulloblastoma (center area)
Malignant melanoma, lymph node
Adrenal cortical adenoma
Ewing's tumor, lymph node
Carcinoma, pituitary, metastatic
Cystic disease of breast
Carcinoid in liver
Carcinoma of stomach

Staining tumor reticulum: A rapid and reliable method for the demonstration of reticulin fibers in frozen sections follows:

1. Fix blocks in 10% formalin.
2. Cut frozen section 7-10μ thick.
3. Place in a warm 10% ammonium hydroxide

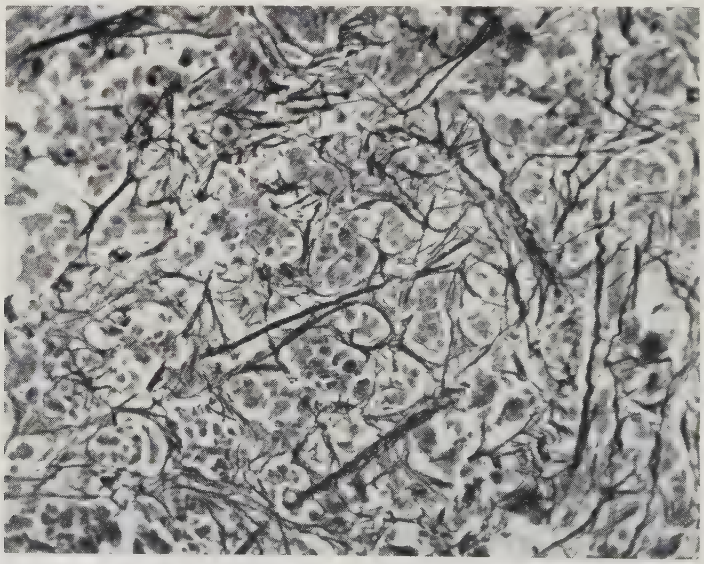

Fig. 549. Carcinoma of stomach. Note staining of carcinoma cells and absence of reticulum. (From Krajian, A. A., and Gradwohl, R. B. H.: Histopathological technic, St. Louis, 1952, The C. V. Mosby Co.)

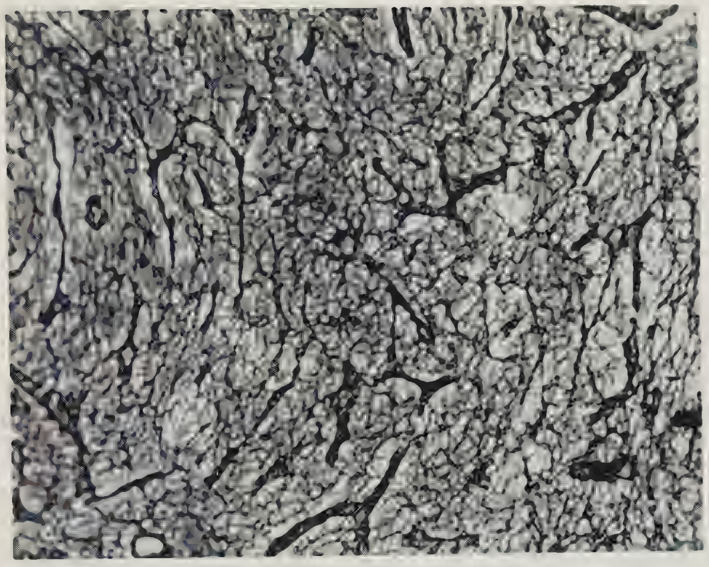

Fig. 550. Lymphosarcoma, showing great abundance of reticulum and absence of cellular staining. (From Krajian, A. A., and Gradwohl, R. B. H.: Histopathological technic, St. Louis, 1952, The C. V. Mosby Co.)

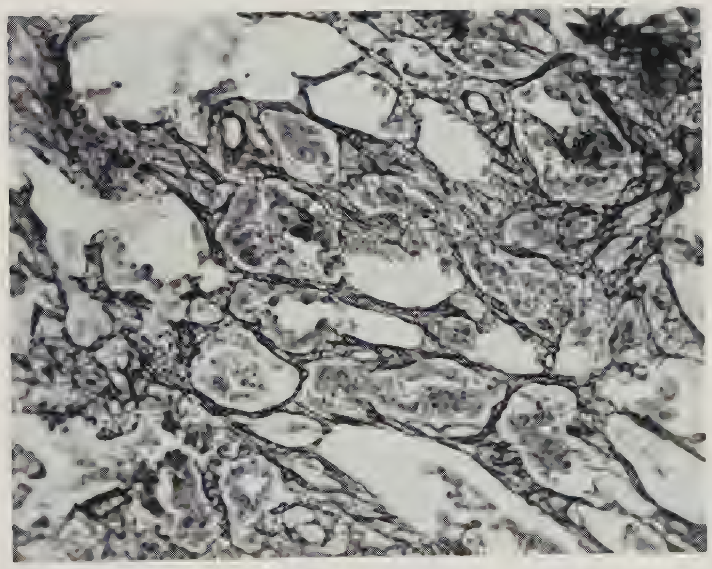

Fig. 551. Carcinoma of lung. Note staining of cells and absence of reticulum. (From Krajian, A. A., and Gradwohl, R. B. H.: Histopathological technic, St. Louis, 1952, The C. V. Mosby Co.)

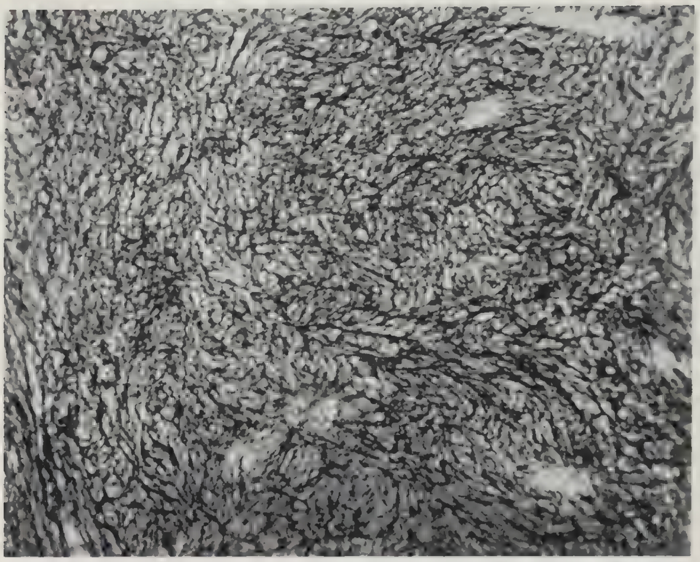

Fig. 552. Leiomyosarcoma showing great abundance of reticulum and absence of cellular staining. (From Krajian, A. A., and Gradwohl, R. B. H.: Histopathological technic, St. Louis, 1952, The C. V. Mosby Co.)

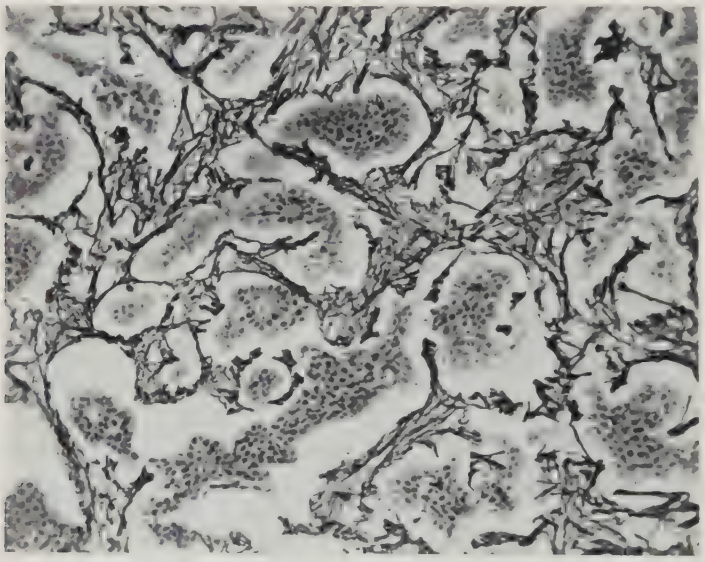

Fig. 553. Carcinoid of liver. Note deep stain of carcinoid cells and complete absence of reticulum. (From Krajian, A. A., and Gradwohl, R. B. H.: Histopathological technic, St. Louis, 1952, The C. V. Mosby Co.)

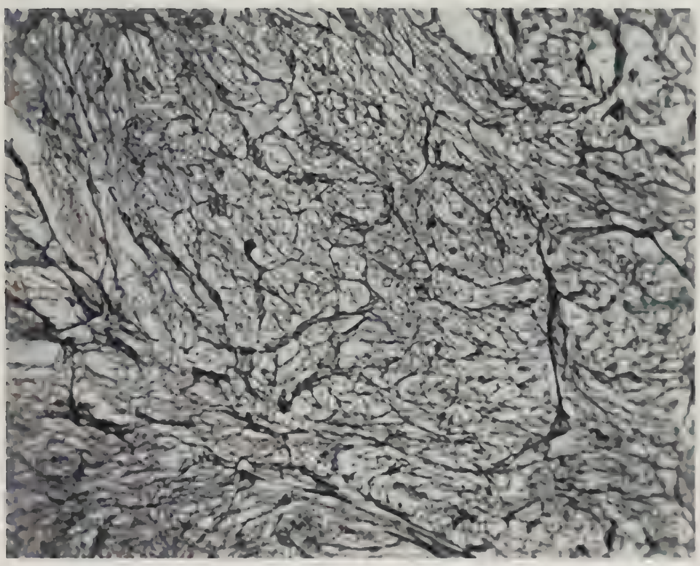

Fig. 554. Retroperitoneal sarcoma, showing great abundance of reticulum and absence of cellular staining. (From Krajian, A. A., and Gradwohl, R. B. H.: Histopathological technic, St. Louis, 1952, The C. V. Mosby Co.)

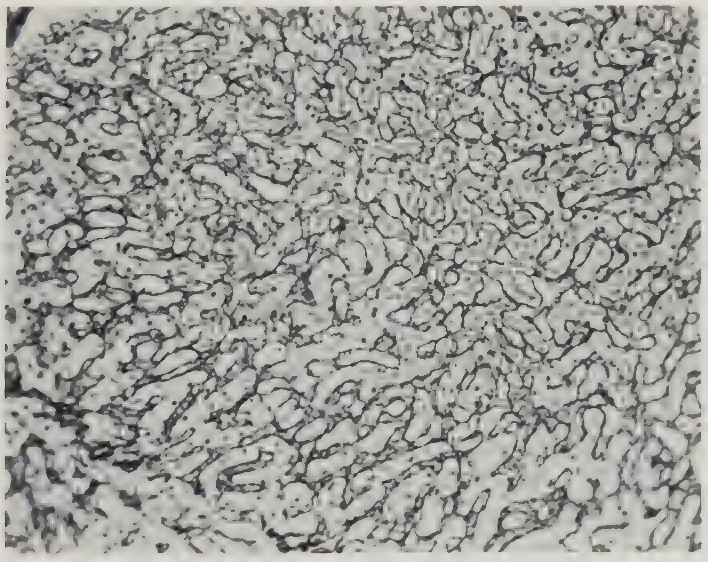

Fig. 555. Liver section showing normal reticulum. (From Krajian, A. A., and Gradwohl, R. B. H.: Histopathological technic, St. Louis, 1952, The C. V. Mosby Co.)

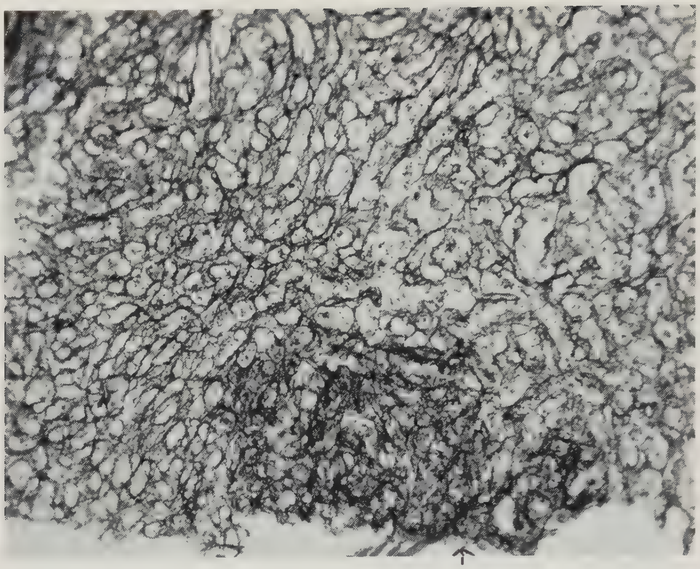

Fig. 556. Leukemia of liver, showing abnormal amount of reticulum (arrow). (From Krajian, A. A., and Gradwohl, R. B. H.: Histopathological technic, St. Louis, 1952, The C. V. Mosby Co.)

solution in a paraffin oven at 56° C. for 10 min.

4. Wash rapidly in distilled water
5. Place sections in 0.25% potassium permanganate for 10 min.
6. Wash in distilled water and decolorize in 3% oxalic acid until most of the brown color is removed.
7. Wash in distilled water.
8. Place in a warm ammoniacal silver solution (p. 1696) and put in a paraffin oven for 40 min. at 56° C.
9. Wash in distilled water and place in warm 20% formalin for 3 min. (for reducing).
10. Wash in distilled water and place in 0.5% gold chloride solution for 3 min.
11. Wash in distilled water and place in 5% sodium thiosulfate solution for 5 min.
12. Transfer to a glass slide and dehydrate with 2 applications of anhydrous isopropanol or absolute ethyl alcohol, blot twice, and dip in thin celloidin, blow over the surface to dry section, and blot again.
13. Dehydrate twice with anhydrous isopropanol or absolute ethyl alcohol and apply creosote-xylol mixture for 3 min. (creosote, 1 part; xylol, 2 parts).
14. Clear in xylol for 3 min. and mount in Permount or gum damar.

Numerous methods have been devised for demonstrating reticulum and collagen fibers, but unfortunately most of the methods require paraffin embedding. The paraffin method not only delays the results but may in some way obscure some of the reticulin fibers which might be demonstrated if the frozen technic were used.

ELASTIC FIBER STAINS

Weigert elastic fiber stain

1. Fix tissues in formalin or alcohol. Zenker-fixed tissues stain slowly, and there is greater tendency to diffuse coloring of collagen fibrils. Embed tissues in paraffin or celloidin or cut frozen sections from formaldehyde-fixed tissues.
2. Stain sections for 20 min.-1 hr. with Weigert elastic tissue stain (p. 1661).
3. Wash in 95% alcohol.
4. Blot with filter paper and add xylol quickly.
5. Repeat the blotting, followed by xylol, 2 or 3 times, until the section is cleared.
6. Mount in gum damar.

The elastic fibers appear dark blue, almost black, on a clear background. The nuclei can be stained red with carmine before or after staining of the fibers. Carmine stain is hard to obtain after Zenker fixation. A light nuclear stain with some alum hematoxylin after the fibers have been colored is preferable. This is a useful and permanent stain.

Krajian method for staining elastic fibers[30]

This is a rapid method for elastic tissue, connective tissue, fibrin, and amyloid, employing Congo red.

1. Fix tissues in 10% formalin for 24 hr. or longer.
2. Cut frozen sections about 10μ thick.
3. Place in 2% aluminum chloride solution for 5 min.
4. Wash thoroughly in tap water.

5. Place in Krajian Congo red (p. 1662) for 10 min.
6. Wash quickly in tap water.
7. Transfer to 1% aqueous potassium iodide solution for 10 sec., rotating the section in the solution.
8. Wash thoroughly in tap water.
9. Place sections in Krajian aniline blue for elastic fibers (p. 1660) for 5-10 min.
10. Wash thoroughly in tap water in a large basin. Float sections onto slides and blot with filter paper.
11. Dehydrate in absolute alcohol for 2 min., changing the alcohol twice using the dropping bottle method.
12. Clear for 2 min. in oil of origanum.
13. Clear in pure xylol.
14. Mount in gum damar.

This method gives a colorful, well-differentiated preparation that keeps well when protected from direct exposure to light.

Elastic fibers appear bright red; fibrin and connective tissue, dark blue. Red blood cells are colored orange yellow.

Sections embedded in paraffin may be used satisfactorily, but they require longer staining periods. The staining technic is the same as that for frozen sections, except that it requires 30 min. staining in Congo red solution and 30 min. in the aniline blue solution.

If nuclear staining is desired in addition to differentiation of elastic tissue, stain sections in Harris hematoxylin for 2 min. after washing in tap water following the Congo red step. Wash, dehydrate, and clear in oil of origanum and xylol.

MacCallum modification of Verhoeff elastic tissue stain

1. Fix tissues in 10% formalin for 24 hr. or longer.
2. Cut frozen or paraffin sections.
3. Stain in MacCallum hematoxylin (p. 1658) for 30-60 min.
4. Wash in tap water.
5. Differentiate for a few seconds in 1% ferric chloride solution.
6. Wash in water.
7. Dehydrate completely in absolute alcohol.
8. Clear in xylol.
9. Mount in gum damar.

Elastic fibers assume a black color.

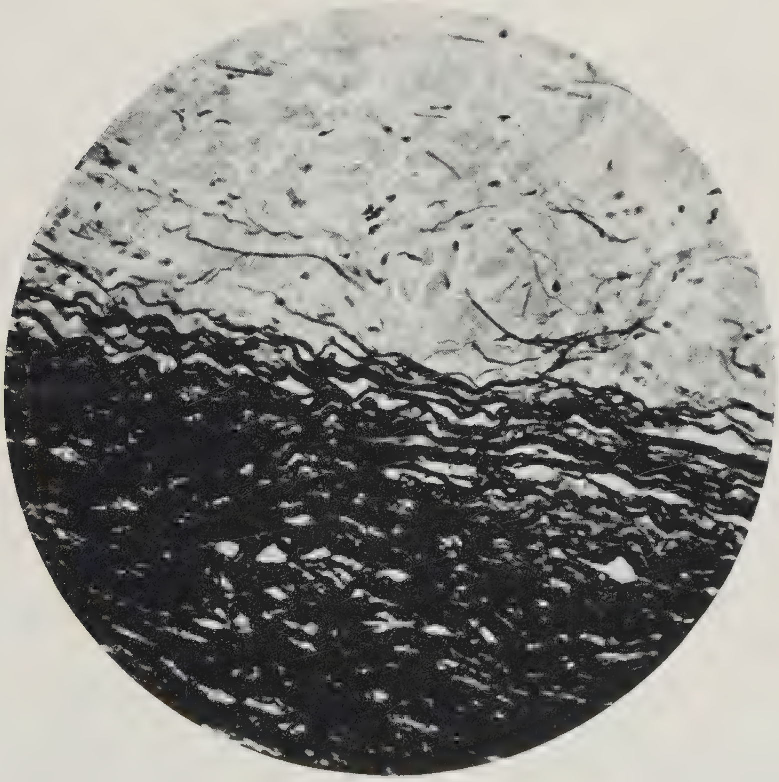

Fig. 557. Section of aorta from a case of syphilitic aortitis, stained with Krajian elastic tissue stain. Elastic fibers stain bright red; degenerated area remains unstained. Frozen section. (From Krajian, A. A., and Gradwohl, R. B. H.: Histopathological technic, St. Louis, 1952, The C. V. Mosby Co.)

Krajian modification of MacCallum elastic tissue stain

1. Fix tissues in 10% formalin for 24 hr. or longer. In emergency, fix in paraffin oven at 56° C. for 15-30 min.
2. Cut frozen or paraffin sections in the usual manner.
3. Stain frozen sections 3-5 min. and paraffin sections 7-10 min. in the Krajian modification of MacCallum hematoxylin (p. 1658).
4. Wash in tap water.
5. Differentiate for a few seconds in 1% acid alcohol until the background begins to clear. Examine under the low power of a microscope.
6. Wash in tap water.
7. Treat with 2% aqueous zinc sulfate for 2 min.
8. Wash in water.
9. Dehydrate completely in absolute alcohol or isopropanol.
10. Blot and clear in xylol.
11. Mount in gum damar.

Treatment with van Gieson solution for a few seconds following washing after hematoxylin gives a combination of elastic and connective tissue stains. Prolonging the treatment in van Gieson solution will affect the elastic fibers. For this reason sections should be examined under a microscope for desired resuls.

FIBRIN STAINS

In fresh specimens fibrin swells and dissolves rapidly on treatment with 1% acetic acid.

Weigert fibrin stain

The Weigert fibrin stain is a modified Gram-Weigert method. It is by no means specific for fibrin, for it sometimes stains hyalin and coarse muscle fibers also.

1. Fix tissues in alcohol or formalin.
2. Stain sections on slides in 1% aqueous eosin solution or lithium carmine for 5 min.
3. Wash in water and stain in Sterling gentian violet 10 min. for paraffin sections and 3 min. for frozen sections.
4. Wash with physiologic saline.
5. Place in Gram's iodine solution for 3 min.
6. Wash with water.
7. Blot and destain in aniline oil-xylol mixture (equal parts) until the section is free from excess violet color.
8. Clear in 2 changes of pure xylol, blotting between changes.
9. Mount in gum damar.

The fibrin, gram-positive bacteria, and fungi are stained blue. The nuclei take a red stain.

This is a rapid and useful method to demonstrate fibrin in tissue.

Krajian stain for fibrin

This is a combination stain to demonstrate elastic tissue, connective tissue, fibrin, and amyloid, employing Congo red. It has been found especially useful to demonstrate fibrin in lungs from unresolved pneumonia. (See elastic tissue stain, p. 1702.)

Mallory iron chloride–hematoxylin for fibrin

1. Prepare frozen or paraffin sections. Stain sections on the slide for 5 min. in 10% aqueous ferric chloride solution.
2. Drain and blot; then pour on a few drops of freshly prepared 1% aqueous solution of hematoxylin. If all the hematoxylin is precipitated by the excess ferric chloride, pour off the solution and add a fresh supply. In 3-5 min. the sections will be colored bluish black.
3. Wash in water.
4. Decolorize and differentiate in 0.25% aqueous ferric chloride. The sections should be kept constantly moving in the solution. Differentiation will be complete within a few seconds to 1 min. or more.
5. Wash in water.
6. Dehydrate in 95% alcohol, followed by absolute alcohol.
7. Clear in oil of origanum for 3-5 min.
8. Clear in 2 changes of xylol, 3 min. each.
9. Mount in gum damar.

Nuclei take a sharp, permanent, dark blue stain; fibrin, grayish to dark blue stain.

AMYLOID STAINS

Amyloid is a firm translucent albuminous substance. In fresh material, Gram's iodine turns amyloid a deep blue. Add a little dilute acetic acid to the preparation before treating with the iodine solution. Treated first with iodine and then with concentrated sulfuric acid, the color of amyloid material will change from brown to blue.

Krajian amyloid stain (modified Bennhold method)

1. Stain unmounted frozen sections in Harris hematoxylin about 15 sec. and wash thoroughly in tap water until they are light blue.
2. Transfer to Krajian Congo red (p. 1662) for 15 min.
3. Wash in tap water.
4. Differentiate in 2% aqueous sodium cyanide solution for a few seconds and wash thoroughly in tap water.
5. Float sections onto slides and allow to drain thoroughly (not dry).
6. Mount in warm glycerin jelly.

Amyloid is stained red and is beautifully differentiated from surrounding tissue. The clearing of the tissue does not in any way interfere with the amyloid stain, and the picture is further enhanced by the hematoxylin nuclear stain. The elastic fibers also are stained red but are of a darker hue and may be easily differentiated from amyloid.

Of the number of staining methods for amyloid, this one is best for brilliant staining and permanent keeping without fading.

Iodine and sulfuric acid reaction

1. Stain sections quickly in dilute Lugol solution.
2. Treat with dilute sulfuric acid (5%) on the slide.

The change of color from red to blue usually occurs within a few minutes but occasionally does not take place at all.

This is not a dependable method for staining amyloid.

Reaction with methyl violet

1. Stain frozen sections in 1% aqueous methyl violet 3-5 min. Rinse in water.
2. Differentiate in 1% aqueous acetic acid.
3. Wash thoroughly in tap water to remove all traces of acid.
4. Mount in glycerin jelly.

The amyloid is stained violet red and the tissue blue. The stain will keep only a few hours and soon fades.

HYALIN STAINS

Hyalin degeneration takes place in the liver, in renal epithelium, in lymph nodes, and in some malignant tumors. Chemically, very little is known about it other than that it is protein in nature.

In fresh specimens it resists dilute acids, alkalies, and alcohol and is not affected by water. It does not give a brown reaction when treated with iodine, nor does it turn blue after treatment with sulfuric acid. In sections it takes an uneven blue color when stained with Krajian elastic and connective tissue stain.

Kuhne modified technic for hyalin

1. Fix tissues in formalin, Zenker fluid, or alcohol.
2. Stain frozen, paraffin, or celloidin sections on the slide for 3 min. in freshly mixed Kuhne crystal violet (p. 1662).
3. Wash in tap water.
4. Treat with Lugol solution for 2 min.
5. Rinse rapidly in tap water.
6. Differentiate in saturated solution of fluorescein in absolute alcohol until the hyaline material stains in various shades of blue and the other constituents decolorize.
7. Rinse in tap water.
8. Counterstain for 2 min. in 1% aqueous neutral red.
9. Rinse in tap water.
10. Dehydrate rapidly in 90% alcohol and then absolute alcohol, controlling the degree of differentiation of the neutral red under a microscope.
11. Clear in xylol and mount in gum damar.

The introduction of neutral red into this method gives an extremely transparent nuclear stain. The hyaline substance stains in shades of blue; the older the hyalin, the darker the blue. This is a rapid and useful stain.

Russell carbolfuchsin method for hyalin

1. Fix tissues by one of the standard fixatives.
2. Cut frozen, paraffin, or celloidin sections and treat them on the slide as follows:
3. Stain in carbolfuchsin for 10-30 min.
4. Rinse in tap water.
5. Pass rapidly through absolute alcohol (½-1 min.).
6. Differentiate and counterstain for a few minutes in the following solution:
   Iodine green . . . . . . 1 gm.
   Phenol, 5% aqueous solution . 100 ml.
7. Rinse rapidly in absolute alcohol.
8. Clear in xylol and mount in gum damar.

Hyaline substance stains bright red; nuclei, light green.

This is a very useful stain.

Weigert fibrin stain for hyalin (Gram-Weigert method)

The Weigert fibrin method stains hyaline material blue black (see Gram-Weigert method, p. 1712). Krajian's connective tissue and hyalin stain, applicable to frozen and paraffin sections of formalin-fixed tissue, stains hyalin bright red (p. 1695).

GLYCOGEN STAINS

Glycogen is a carbohydrate occurring in cells and nuclei, either diffusely or more commonly in large or small granules. It is transparent in appearance and is water-soluble, but it can be precipitated by absolute alcohol.

Tissues to be examined for glycogen should be as fresh as possible since glycogen may be transformed into sugar after death. Tissues removed from the body should first be dried with a towel and then immediately placed in absolute alcohol. After fixation for 1 hr. they should be transferred into fresh absolute alcohol.

There are 2 good methods for staining glycogen: Langhan iodine method and Best carmine method.

Langhan iodine stain for glycogen

1. Fix thin blocks of tissue in absolute alcohol, clear in xylol, and embed in paraffin.
2. Cut paraffin sections; dissolve paraffin in pure xylol and then in absolute alcohol.
3. Stain sections in Lugol solution for 5-10 min.

4. Dehydrate in 1 part tincture of iodine to 4 parts absolute alcohol. Wipe around section rapidly.
5. Clear and differentiate in oil of origanum.
6. Wash in xylol to stop overdifferentiation.
7. Mount in gum damar.

The standard method is to mount the section in oil of origanum or gum damar, but no matter how the sections are mounted the stain tends to fade. Glycogen is stained brownish red; the nuclei, if stained in hematoxylin, are greenish. This is a rapid stain, but it is not permanent.

Best carmine method for glycogen—Krajian modification

1. Fix tissues in absolute alcohol. Embed in either paraffin or celloidin. Celloidin is preferable, since it prevents the glycogen from dissolving in water. If paraffin sections are used they must be dipped twice in a thin celloidin (commonly used for attaching frozen sections) after deparaffinization. The celloidin or modified paraffin sections are then stained in the following manner:
2. Stain sections deeply in Harris or Delafield hematoxylin.
3. Destain if necessary and wash thoroughly in tap water until blue.
4. Mordant in 5% alcoholic benzoic acid for 5 min.
5. Without washing, add an equal volume of Best carmine stain (p. 1659), mix well, and let stand for 5 min.
6. Differentiate in Best differentiator (p. 1659) for 1 min. or more, dipping section in and out until no more pink color is seen.
7. Dehydrate in absolute alcohol or anhydrous isopropanol and then in xylol-acetone solution (1 part acetone to 4 parts xylol).
8. Clear in xylol and mount in gum damar.

Glycogen stains red; nuclei, blue.

This is an excellent and permanent stain for glycogen.

Treatment of pale-staining sections with 1% aqueous basic fuchsin acidified with 0.5% hydrochloric acid will brighten the glycogen stain.

MUCIN STAINS

Mucin is an intercellular secretory product, having some proteid substance. It is soluble in weak alkalies and is precipitated by 1% acetic acid, forming threads or granules.

Hoyer thionine stain for mucin

Tissues may be fixed in one of the standard fixatives, but saturated aqueous solution of mercuric chloride gives the best results.

1. Stain paraffin sections, after freeing them from paraffin, for 10-15 min. in the following solution:

Thionine, saturated aqueous solution	2 drops
Distilled water	5 ml.

2. Dehydrate rapidly in absolute alcohol.
3. Clear in xylol.
4. Mount in gum damar.

Mucin stains purple to red; other constituents, shades of blue. However, mast cell granules, ground substance of cartilage, and jelly of umbilical cord also stain purple by this method. Do not treat the mercury-fixed sections in iodine. This is a useful and permanent method.

Mayer mucicarmine stain—Krajian modification

1. Tissues may be fixed in 10% formalin or Zenker fluid, and frozen or paraffin sections made.
2. Stain sections deeply in Harris or Delafield hematoxylin for about 3 min.
3. Wash in tap water until blue.
4. Stain for 10-15 min. in Krajian modification of Mayer mucicarmine (p. 1660).
5. Rinse and treat with martius yellow for 1 min.
6. Dehydrate in several changes of absolute alcohol or isopropanol and blot in filter paper.
7. Clear in pure xylol and mount in gum damar.

Mucin is stained pink. Cartilage cells also are stained pink, though some claim that this is a specific stain for mucin.

This method is applicable to frozen sections, is easy to perform, and gives brilliant results.

Mucin stain—Krajian carbolfuchsin method

1. Fix tissues in 10% formalin.
2. Prepare frozen or paraffin sections in usual manner.
3. Stain in Krajian carbolfuchsin (p. 1661) for 5 min.
4. Wash in tap water.
5. Differentiate with picric acid-alcohol mixture (equal volumes of saturated aqueous picric acid and 95% alcohol) for 5-10 sec., agitating the slide during this period.
6. Wash thoroughly in tap water.
7. Dehydrate in isopropanol or 95% alcohol for 1 min. and follow with anhydrous isopropanol or absolute alcohol.
8. Blot dry and clear in xylol for 2 min.
9. Mount in gum damar.

Mucin assumes a magenta color and sometimes is pale lilac; nuclei are reddish brown.

The differentiation is very important and should be controlled under a microscope for uniform results.

The staining solution is not permanent. It should be freshly prepared before use.

Pseudomucin

Pseudomucin is dissolved in water, and when treated with 95% alcohol, it is precipitated in threadlike masses, which are again soluble in water.

Pseudomucin is not affected by acetic acid. It is found in certain ovarian tumors.

FAT AND LIPOID STAINS

Fats and lipoids are chemically related substances. They occur in the human body under normal and diseased conditions, generally in mixtures, rarely in pure form. The different fats and lipoids are detected by chemical methods, and large numbers of them may be recognized in color reactions by some staining methods.

Fresh unfixed fat globules are soluble in ether, chloroform, alcohol, xylol, benzene, and other fat solvents. For this reason fixing fluids should be free from these substances. Formaldehyde fixes fat-containing material but does not dissolve its fat globules.

The following important types of fats and lipoids are found in the body: true fats, fatty acids, oils, soaps, cholesterins, cholesterols, waxes, and myelins.

Scharlach R stain for fat—Krajian modification

The most commonly used stain for fat is scharlach R (scarlet red). Sudan III was used originally, but it is less brilliant.

1. Fix tissues in 10% formalin and cut frozen sections in the usual manner.
2. Pass the section quickly through 70% alcohol.
3. Place for 3 min. in Krajian (saturated) scharlach R solution (p. 1662). (Use only the clear portion of the stain to prevent forming a precipitate.)
4. Wash quickly in 70% alcohol.
5. Rinse in tap water.
6. Stain in Harris hematoxylin for 30 sec. and wash in water.
7. Differentiate in 2% aqueous sodium cyanide for 10-15 sec.
8. Wash in water, transfer to a slide, and drain off the water.
9. Mount in warm glycerin jelly.

The addition of benzoic acid to the staining solution materially intensifies the resulting color and prevents deterioration. True fats stain intensely; cholesterins stain less intensely. This is a rapid and permanent stain and is highly recommended.

Osmic acid stain for fat

1. Fix thin slices of tissue, not over 2 mm. thick, in Flemming solution for 1-3 days.

   Flemming solution:

Osmic acid, 2%	4 ml.
Chromic acid, 1%	15 ml.
Glacial acetic acid	1 ml.

2. Wash under running water for 6-12 hr.
3. Dehydrate in 80%, 95%, and then absolute alcohol, about 2 hr. in each.
4. Clear in chloroform. Do not use ether, xylol, or toluol for clearing because they dissolve the fat. Embed in paraffin.
5. Cut sections and dissolve the paraffin with xylol.
6. Mount in chloroform-balsam.

Fat globules stain black to dark gray; lipoidal granules, brownish.

This is a useful and permanent method.

Osmic acid fat stain for frozen sections

1. Fix tissues in 10% formalin for 24 hr. or longer.
2. Cut frozen sections.
3. Place in 1% aqueous osmic acid for 1-2 hr.
4. Wash for 10 min. in several changes of tap water.
5. Place in absolute alcohol or anhydrous isopropanol for 15 min. to obtain the secondary staining of fat not yet colored.
6. Wash in tap water.
7. Mount in glycerin jelly.

Fat globules assume a brown-black color. This is a useful fat stain for frozen sections.

Nile blue sulfate stain for fat—Lorraine Smith

1. Fix tissues in 10% formalin and cut frozen sections.
2. Stain in saturated aqueous Nile blue sulfate for 5-10 min.
3. Wash in water.
4. Differentiate in 1% aqueous acetic acid until the blue color ceases to diffuse from the section.
5. Wash thoroughly in a large basin of water.
6. Mount in glycerin jelly.

This stain has valuable properties. It gives a double stain, coloring neutral fats red; cholesterin ester and cholesterin fatty acids, light red; cerebrosides, light blue; and fatty acids and soaps, deep blue.

Stain for lipoids—Ciaccio

1. Fix thin blocks of tissue for 2 days in the following solution:

Potassium dichromate, 5%	80 ml.
Formaldehyde (commercial, 40%)	20 ml.
Glacial acetic acid	5 ml.
or formic acid	4 to 5 drops

2. Treat in 3% aqueous potassium dichromate for 2 days.
3. Wash under running water overnight.
4. Dehydrate in graded alcohols, beginning with

70%, and reduce the time in 95% and absolute alcohol as much as possible.
5. Clear in xylol for 1 hr.
6. Place in xylol and paraffin mixture for 1½ hr. in a paraffin oven at 55° C.
7. Transfer to pure paraffin for 1½ hr. in a paraffin oven; then embed.
8. Cut sections and affix to slides.
9. Dissolve the paraffin with 2 changes of xylol.
10. Wash in 2 changes of absolute alcohol.
11. Stain in saturated solution of Sudan III (95 ml. 85% alcohol plus 5 ml. acetone). Stain in a stoppered slide jar for 30-60 min. at 30° C.
12. Differentiate very rapidly in 50% alcohol.
13. Wash in water.
14. Counterstain in Harris hematoxylin for 5 min.
15. Wash in water until section assumes a blue color.
16. Mount in warm glycerin jelly.

The lipoid substances appear as fine orange granules; the nuclei, blue black. This method gives a positive stain for lipoid granules.

MYELIN OR MEDULLARY SHEATH STAINS

It has been stated that cerebrosins and lecithins constitute the normal myelin sheath.

Weigert-Pal method for myelin

1. Fix tissues in 2.5% potassium dichromate for several weeks in an incubator; or fix in 10% formalin first and then treat with potassium dichromate solution.
2. Wash in running water overnight.
3. Dehydrate in graded alcohols, clear, and embed in either paraffin or celloidin.
4. Cut sections 10-20μ thick.
5. Stain in Weigert-Pal lithium-carbonate-hematoxylin mixture (p. 1659) for 24-48 hr.
6. Wash sections in water and treat with 0.25% aqueous potassium permanganate for ½-3 min.
7. Wash in water.
8. Treat sections in the following differentiating fluid for ½-3 min.:
   Oxalic acid, 1% aqueous . . . 1 part
   Potassium sulfite, 1% aqueous . 1 part
   Differentiation is complete when the white matter of the brain tissue is blue black and the gray matter is practically colorless.
9. Wash sections in water and counterstain in lithium carmine or safranin if desired.
10. Dehydrate in absolute alcohol, clear in carbol-xylol and then xylol, and mount in gum damar.

By this method myelin sheaths appear black; recent areas of degeneration, pale, gray; old ones, colorless.

We have omitted the original Weigert method and have replaced it with Pal's modification, which is more rapid and gives sharper myelin sheaths. This is a slow but very useful method.

Spielmeyer method for myelin sheath

1. Fix tissues in 10% formalin 24 hr. or longer.
2. Wash in running water.
3. Cut frozen sections 20-30μ thick.
4. Place in 2.5% aqueous iron ammonium sulfate for 6 hr.
5. Rinse in water; then place in 70% alcohol for 10 min.

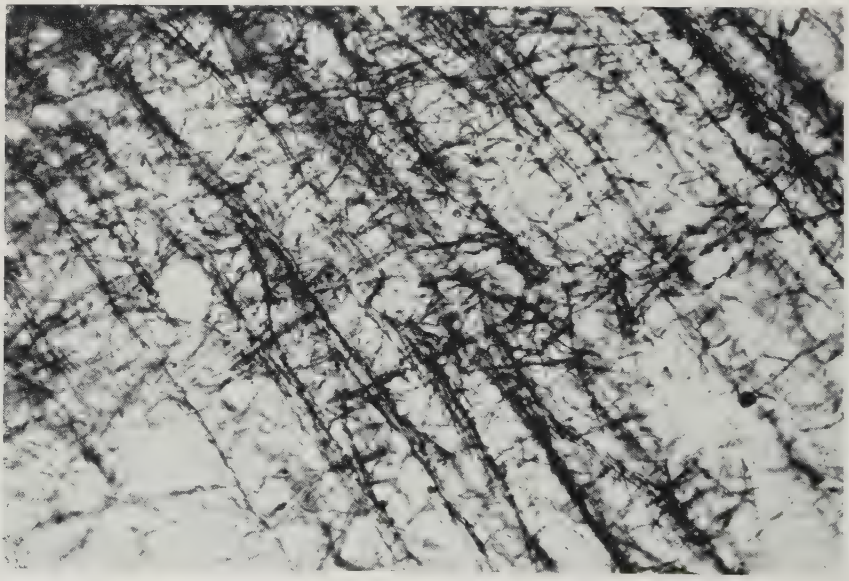

Fig. 558. High-power magnification of myelin sheath. Spielmeyer method. Frozen section. (From Krajian, A. A., and Gradwohl, R. B. H.: Histopathological technic, St. Louis, 1952, The C. V. Mosby Co.)

6. Stain sections for 10-24 hr. in Spielmeyer hematoxylin (p. 1659).
7. Rinse sections in water.
8. Differentiate in a weaker solution of iron ammonium sulfate.
9. Wash thoroughly in tap water.
10. Dehydrate in absolute alcohol.
11. Clear in xylol and mount in gum damar.

The hematoxylin solution must be old and should be used over and over, that is, the used portion should be filtered back into the original bottle. The staining power improves with age.

The washing in 70% alcohol removes fatty substances which might interfere with even staining. Occasional irregular staining indicates that the fat has not been entirely removed. Such sections may be carried back through water to 70% alcohol and again stained and differentiated.

This is a good stain to show the fine detail of myelinated fibers.

Krajian myelin sheath stain

1. Fix tissues in 10% formalin. Cut frozen sections 10-15μ thick.
2. Place sections in **4% Congo red in glycerin** for 10 min. (Congo red 4%, 8 ml.; glycerin, 2 ml.).
3. Wash thoroughly in tap water.
4. Place in 2% aqueous potassium iodide for 2 min.
5. Wash and place in 3% aqueous sodium cyanide for 2 min.
6. Wash thoroughly in tap water.
7. Place in 10% aqueous ferric ammonium sulfate for 10 min. at 55° C.
8. Wash in tap water.
9. Place in 2% ripe hematoxylin solution for 5 min. (2 ml. ripe hematoxylin, p. 1659; 8 ml. distilled water).
10. Wash in tap water.
11. Destain in 2% aqueous ferric ammonium sulfate until the section appears light blue, about 30-45 sec.
12. Wash thoroughly in tap water.
13. Differentiate in 0.15% aqueous potassium permanganate for 10-20 sec.
14. Wash in tap water.
15. Place in 3% aqueous sodium cyanide until sections flatten and assume a light blue appearance.
16. Wash in tap water and attach to a glass slide.
17. Dehydrate in 2 changes of absolute alcohol.
18. Clear in oil of origanum for 2 min.
19. Clear in pure xylol for 2-5 min.
20. Mount in gum damar.

This method has all the advantages of the longer methods and shows very fine details of the fibrils, yet it can be completed in 1 hr. It is highly recommended.

Pal-Kulschitzky method for myelin sheath

1. Fix tissues in 10% formalin for a few days or longer and place them in the following solution for 4-5 days or longer at room temperature:

Potassium dichromate . . .	5 gm.
Fluorchrome	2 gm.
Distilled water	100 ml.

2. Pass the blocks through graded alcohols for dehydration and then in ether-alcohol mixture, thin celloidin, thick celloidin, and embed.
3. Cut sections 35μ thick or thicker and place in 80% alcohol.

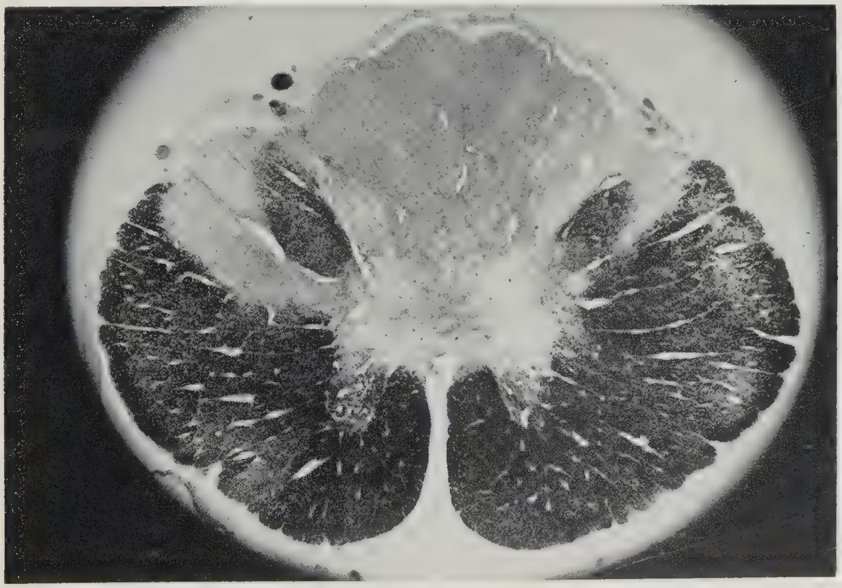

Fig. 559. Tabes dorsalis. Posterior column degeneration of myelin sheath in spinal cord. Krajian myelin sheath method. Frozen section. (From Krajian, A. A., and Gradwohl, R. B. H.: Histopathological technic, St. Louis, 1952, The C. V. Mosby Co.)

4. Stain sections at 37° C. for 24 hr. in Pal-Kulschitzky hematoxylin (p. 1659).
5. Wash sections individually in tap water.
6. Place in 0.3% aqueous potassium permanganate about 1 min. or longer.
7. Wash in distilled water.
8. Differentiate in equal parts of 1% aqueous oxalic acid and 1% aqueous potassium sulfite.
9. Wash in tap water, in which the sections can be kept for any length of time. If differentiation is unsuccessful, the sections may be carried back from water into potassium permanganate solution and from there again to water and oxalic-potassium sulfite solution. This procedure can be carried out several times until differentiation is completed.
10. Dehydrate in graded alcohols, clear in pure xylol, and mount in gum damar.

Wolter modification of Pal-Kulschitzky myelin sheath stain

Wolter has modified this method so that it may also be used for frozen sections.

1. Cut frozen sections about 40μ thick and place them in 70% alcohol; then place in dichromate and fluorchrome solution for 24 hr. at 37° C. (p. 1709).
2. From the latter (the mordanting fluid) pass the sections through 80% alcohol to the hematoxylin solution and keep in hematoxylin 24 hr. at 37° C.
3. Staining is completed as above, commencing with the washing after hematoxylin.

This method usually yields satisfactory results and is valuable for rapid staining of myelin sheaths.

Morgan myelin stain for paraffin sections

Morgan's method of staining myelin is useful in fresh as well as in old formol-fixed material.

1. Fix brain tissue in 10% formalin, embed in paraffin, and section.
2. Mordant sections for 2 hr. in 4% aqueous iron alum (ammonium ferric sulfate).
3. Stain 8-16 hr. in well-ripened Heidenhain hematoxylin (p. 1658).
4. Destain in 2% iron alum for a few minutes until the larger fiber tracts become well outlined.
5. Rinse in tap water.
6. Complete the differentiation in 0.5% hydrochloric acid. In a few seconds the background becomes colorless and the fibers well differentiated.
7. Wash sections in running water for at least 1 hr. to remove acid and alum.
8. If desired, counterstain with well-ripened neutral red.
9. Dehydrate, clear in xylol, and mount in gum damar or balsam.

In successful preparations the myelinated fibers stain dark blue, the background clear and white. For destaining with 2% alum the process should be stopped by placing the sections in tap water before all the blue of the hematoxylin has been extracted from the background, and the treatment with the hydrochloric acid should be very brief and carefully watched. When the proper stage has been reached, stop the decolorizing by transferring the sections to tap water.

Scharlach R stain for demonstration of myelin sheath

The improved scharlach R solution, ordinarily used to demonstrate fat, may be successfully employed to bring out myelin sheath in the tissues of the central nervous system, especially in spinal cords (see scharlach R stain for fat, p. 1662).

XANTHYDROL METHOD FOR UREA CRYSTALS[31]

The following technic, originated by Krajian,[32] is useful in differentiating at autopsy actual uremic from nonuremic cases. In other words, it has been found that patients dying with uremia have urea crystals in the brain tissue, whereas patients having a disease simulating uremia do not have urea crystals in the brain tissue.

Regular method

1. Cut thin blocks of tissue 2-3 mm. thick. Immerse 5-6 hr. in a freshly prepared solution of xanthydrol (5 gm. xanthydrol in 100 ml. glacial acetic acid).
2. Wash under running water for 1 hr.
3. Fix in dilute solution of formalin (1:10) 6 hr. or longer. In urgent cases rapid fixation with heat may be used.
4. Wash in tap water.
5. Cut frozen sections 10μ thick.
6. Transfer to a glass slide.
7. Pour several drops of dehydrated alcohol over the section from a drop bottle and blot. Repeat this process once more.
8. Dip in thin celloidin (p. 1666) in the usual manner.
9. Blow the breath over the section.
10. Stain in 1% aqueous eosin for several minutes.
11. Wash in tap water.
12. Dehydrate in 3 changes of dehydrated alcohol from a drop bottle.
13. Place in carbolxylol for 2 min.
14. Clear in 2 changes of pure xylol, 1 min. in each.
15. Mount in gum damar.

Because of the high diffusibility of urea, the tissue must be kept from contact with any fluid prior to its immersion in xanthydrol. One should especially avoid contamination of the

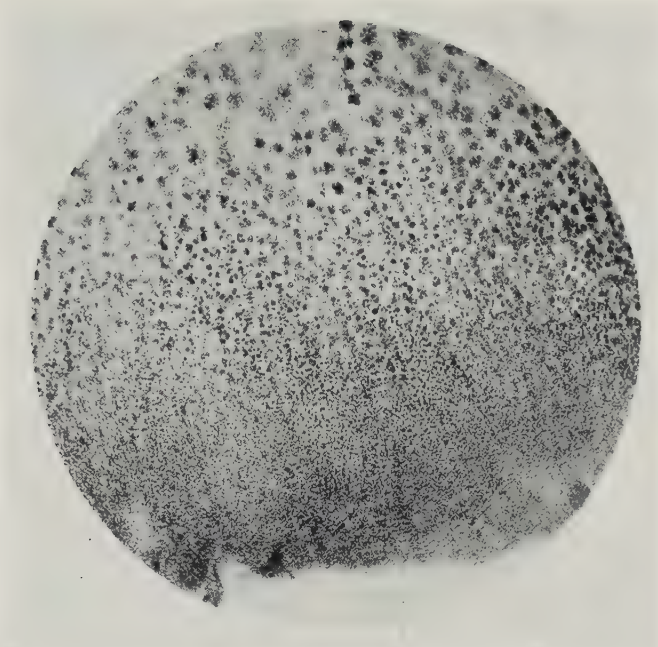

Fig. 560. Xanthydrol method for urea by regular method (6 hr. fixation). Low-power magnification. Krajian method. (From Krajian, A. A., and Gradwohl, R. B. H.: Histopathological technic, St. Louis, 1952, The C. V. Mosby Co.)

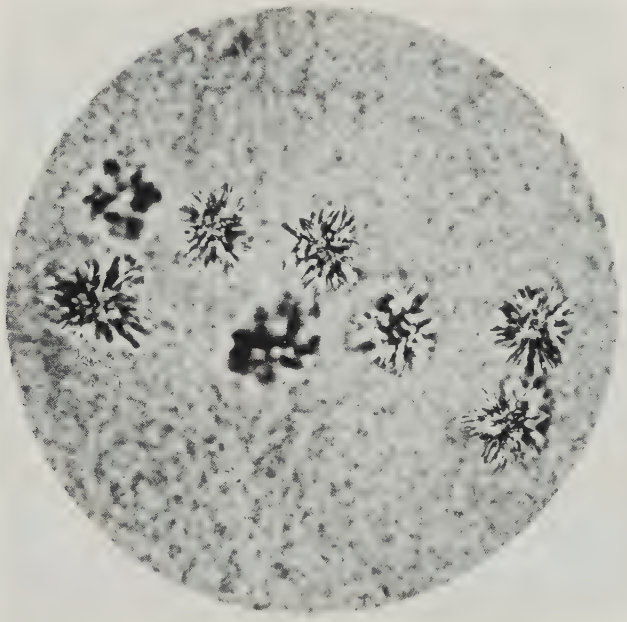

Fig. 561. Xanthydrol method for urea. Rapid method 1½ hr. fixation in an oven at 70° C. High-power magnification. Krajian method. (From Krajian, A. A., and Gradwohl, R. B. H.: Histopathological technic, St. Louis, 1952, The C. V. Mosby Co.)

tissue with urine during the autopsy. The blocks must be very thin since the rate of penetration by the xanthydrol-acetic acid solution is slow. The use of hematoxylin to stain the nuclei tends to disturb the crystals; accordingly, it is preferable merely to stain the background with eosin.

Rapid xanthydrol method

1. Fix thin blocks in hot 5% xanthydrol solution 1½ hr. in an oven at 70° C.
2. Wash in tap water for 1-2 min.
3. Fix in hot 10% formalin for 15 min. at 70° C.
4. Rinse in tap water.
5. Cut frozen sections as superficially in the block as possible since penetration by the xanthydrol is very shallow.
6. Stain and mount as in the longer method.

Smear method for xanthydrol test

For very rapid, approximate, or preliminary diagnosis, use the following method:

1. Boil very small bits of brain tissue in a test tube for 2 min. in 5% xanthydrol solution.
2. Smear tissue on a glass slide.
3. Flood with absolute alcohol 2 or 3 times.
4. Stain as in the other methods.

STAINING METHODS FOR MICROORGANISMS IN TISSUE SECTIONS

Several methods have been devised or modified for demonstrating gram-positive and gram-negative organisms, but the Gram-Weigert stain remains the method of choice.

Gram-Weigert method of staining microorganisms in tissue

1. Fix tissues in 10% formalin and cut very thin paraffin, celloidin, or frozen sections and mount each in the usual manner.
2. If paraffin sections are made, remove paraffin with 2 changes of xylol and then 2 changes of absolute alcohol.
3. Stain in 1% aqueous eosin for 5 min.
4. Wash in water.
5. Stain in Sterling gentian violet for 3 min. for frozen sections or for 10 min. for paraffin sections.
6. Wash off with Gram's iodine solution and flood with the same solution for 3 min.
7. Blot in filter paper.
8. Decolorize with several changes of equal parts of aniline oil and xylol until color ceases to wash out.
9. Clear in 2 changes of xylol, blotting after each change.
10. Mount in gum damar.

As a counter stain, a weak carbolfuchsin or 1% aqueous neutral red may be employed instead of 1% eosin.

Gram-positive organisms and fungi stain a beautiful violet color, but gram-negative organisms are not ordinarily seen.

MacCallum modification of Goodpasture method for demonstrating gram-negative organisms in tissue

1. Fix tissues in Zenker-formalin solution (Helly fluid), embed in paraffin, and cut very thin sections, mount, and carry through the usual process to water.
2. Stain 10-30 min. or longer in Goodpasture fuchsin solution, formula 1 (p. 1661).
3. Wash in water.
4. Differentiate in 40% formaldehyde. Only a few seconds are required. The bright red color changes to rose.
5. Wash in water.
6. Counterstain in saturated aqueous picric acid for 3-5 min. until the section becomes purplish yellow.
7. Wash in water.
8. Differentiate in 95% alcohol. The red reappears and some of it is washed out, as is also some of the yellow of the picric acid.
9. Wash in water.
10. Stain in Sterling gentian violet (p. 1661) for 5 min. or longer.
11. Wash in water.
12. Mordant in Gram's iodine for 1 min.
13. Blot dry without washing.
14. Clear in a mixture of equal parts of aniline and xylol until color ceases to wash out.
15. Clear in 2 changes of xylol.
16. Mount in gum damar.

Gram-negative bacteria stain red; gram-positive bacteria, blue; tissue, red and blue; fibrin, deep blue. This is a useful stain to demonstrate gram-negative organisms.

Application of Gram stain to paraffin sections—Glynn[33]

1. Bring paraffin sections through xylol and alcohol to water in the usual manner.
2. Stain with carbol gentian violet for 2 min.
3. Drain but do not wash.
4. Apply Gram's iodine for 1 min.
5. Apply acetone until no more color is removed, about 10-15 sec.
6. Wash in water. Do not allow the section to dry.
7. Apply 0.05% basic fuchsin in 0.05N hydrochloric acid for 3 min.
8. Drain but do not wash.
9. Apply saturated aqueous picric acid for 30 sec.-1 min.
10. Wash in water.
11. Differentiate and dehydrate in acetone for 10-15 sec.
12. Clear in xylol.
13. Mount in balsam.

A staining rack and dropping bottles rather than staining jars are recommended since these permit use of uncontaminated reagents.

Preliminary fixation of tissue can be accomplished by the common fixatives; formaldehyde solution (1:10), Zenker fluid, Zenker fluid plus dilute solution of formaldehyde, or Bouin fixative can be used with success. Better histologic detail seems to be obtained by the use of Zenker fixative without acetic acid.

When viewed under the low power of the microscope, the tissue is lightly stained. Gram-positive bacteria are deep violet and easily identified under low power. When cellular exudation is not too abundant, the deep red gram-negative bacteria can also be seen under low power in contrast to the lighter red nuclei. Under oil immersion both types are sharply differentiated.

Nuclear chromatin stains red; cytoplasm, faint yellow. The nuclei of nerve cells show differentiation of nucleoli and Nissl bodies. Axons are unstained. Myelin sheaths are violet. Fibrin and the fibers of connective tissue are pale pink. Erythrocytes are yellow.

Gram-positive bacteria are deep violet. Staphylococci, streptococci, mycelia of actinomycetes, and vegetative forms of spore-bearing species are solidly stained. Diphtheria bacilli show barred and granular forms. Human tubercle bacilli are less deeply stained than other gram-positive organisms and show distinct beading.

Gram-negative bacteria are uniformly red. The clubs of actinomycetes are also red and contrast sharply with the gram-positive mycelium.

The chief advantage of this stain is that it not only provides simultaneously good histologic and bacterial differentiation but it also stains all bacteria that may be present. This is particularly useful in the study of tuberculous tissue where very young tubercle bacilli may not be acid-fast and secondary invaders are easily identified.

Krajian method of demonstrating gram-negative organisms in tissue

1. Prepare thin frozen or paraffin sections (5-7μ) in the usual manner and bring them down to water.
2. Mordant in 5% aqueous thorium nitrate for 5 min.
3. Rinse in tap water.
4. Stain 3 minutes in Krajian modification of MacCallum hematoxylin (p. 1658).
5. Wash in tap water.
6. Decolorize in 1% acid alcohol until the excess color ceases to come off.
7. Wash in tap water.
8. Treat with a mixture consisting of equal volumes of 10% potassium iodide and 10% zinc sulfate for 5 min.
9. Rinse in tap water.
10. Counterstain with carbolfuchsin (Ziehl-Neelsen) for 7-10 min.
11. Wash in tap water.
12. Treat with 5% sodium sulfite for 2 min.
13. Rinse in water.
14. Treat with 3% acetic acid for 3 min.
15. Blot and apply aniline-xylol (equal volumes of aniline oil and xylol) for 30 sec.
16. Treat with pure creosote for 2-5 min., agitating the section for even destaining and clearing. Stop when no more pink color is seen.
17. Clear for 2 min. in pure xylol and mount in gum damar.

Gram-positive organisms assume hematoxylin color; gram-negative organisms, bright red.

The thorium nitrate solution should be prepared fresh.

Rapid staining method for gram-positive and gram-negative organisms in frozen and paraffin sections[34]

Christian Gram[35] in 1884 devised his method for demonstrating bacteria in tissue sections. Weigert's[36] modification of Gram's method has been useful for demonstrating fibrin and bacteria and is still widely used, but both methods demonstrate only gram-positive organisms. Numerous attempts have been made to demonstrate both gram-positive and gram-negative organisms in paraffin sections of tissues that had been fixed in Zenker solution or in formalin, and methods accomplishing this have been reported by MacCallum,[37] Lyon,[38] Lillie,[39] Brown and Brenn,[40] Rudnikoff and Stawsky,[41] Glynn,[33] and others.

In these modifications the staining solutions as devised by Gram remained practically unchanged. No attempt had been made to devise a new method using some other dye or chemical, and no recommendations had been made as to the applicability to frozen sections.

The solutions used by Gram and those used in the modifications of his method are gentian violet, methyl violet, and crystal violet as gram-positive stains, Gram solution and compound solution of iodine (Lugol solution) as differentiators; rosaniline hydrochloride, basic fuchsin, dilute carbolfuchsin, and safranin as gram-negative stains, and acetone, alcohol, ether, and aniline oil-xylol as decolorizers.

The need for rapid diagnosis led to investigation of the usefulness of a different dye

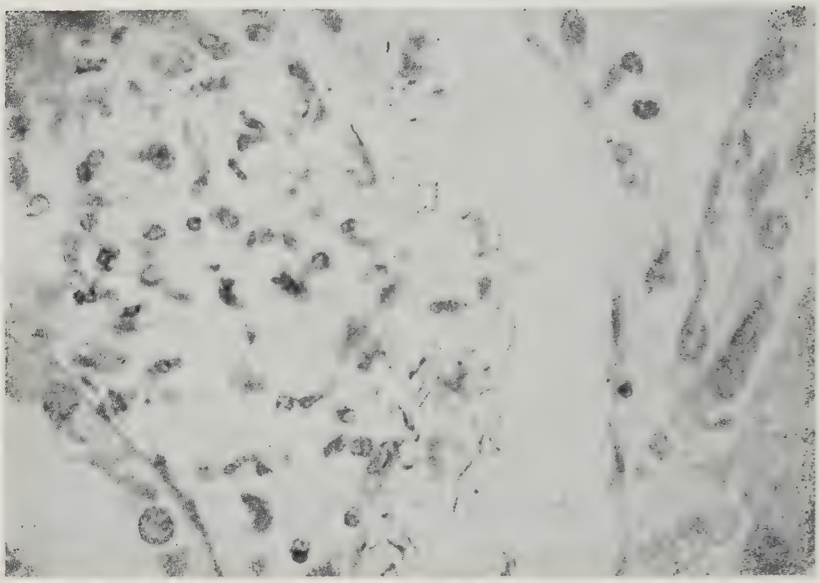

Fig. 562. Streptococci in kidney, stained blue. (Krajian stain; ×1620.) (From Krajian, A. A., and Gradwohl, R. B. H.: Histopathological technic, St. Louis, 1952, The C. V. Mosby Co.)

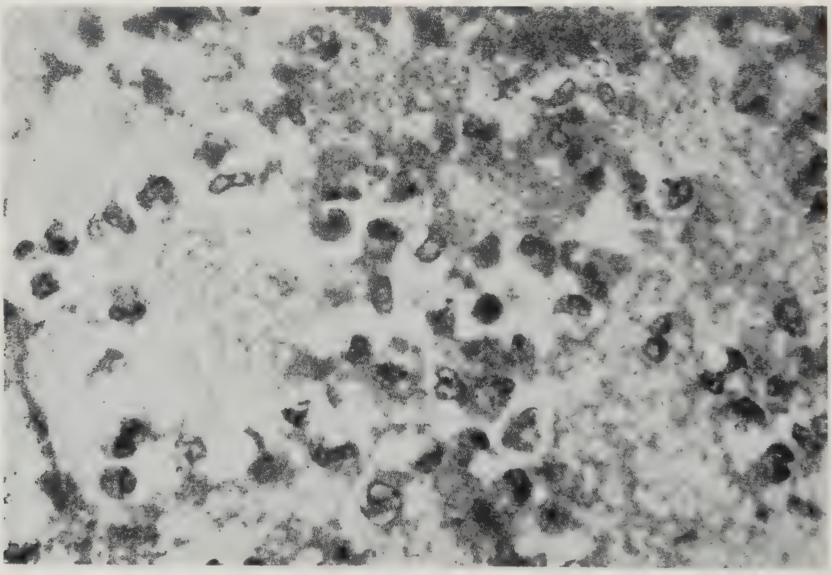

Fig. 563. *Klebsiella* in pneumonia, stained red. (Krajian stain; ×1620.) (From Krajian, A. A., and Gradwohl, R. B. H.: Histopathological technic, St. Louis, 1952, The C. V. Mosby Co.)

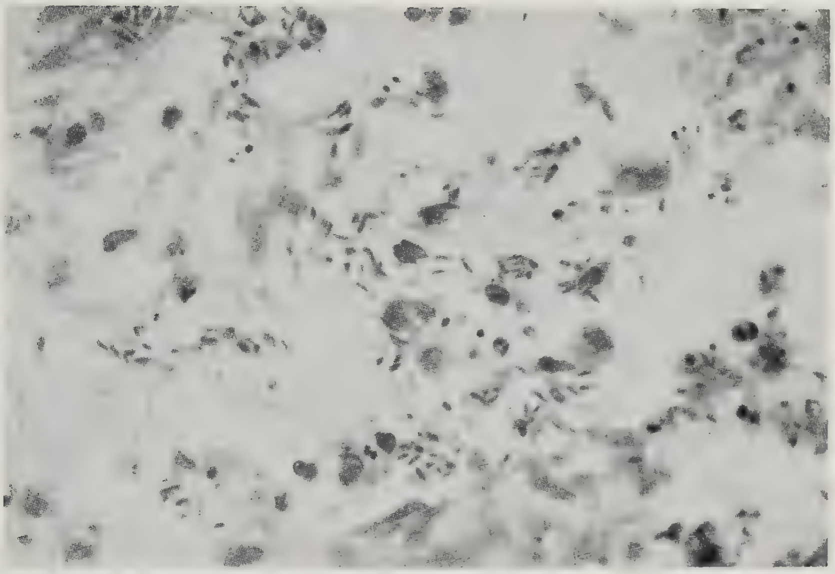

Fig. 564. *Sporotrichum* in testicle, stained blue. (Krajian stain; ×1620.) (From Krajian, A. A., and Gradwohl, R. B. H.: Histopathological technic, St. Louis, 1952, The C. V. Mosby Co.)

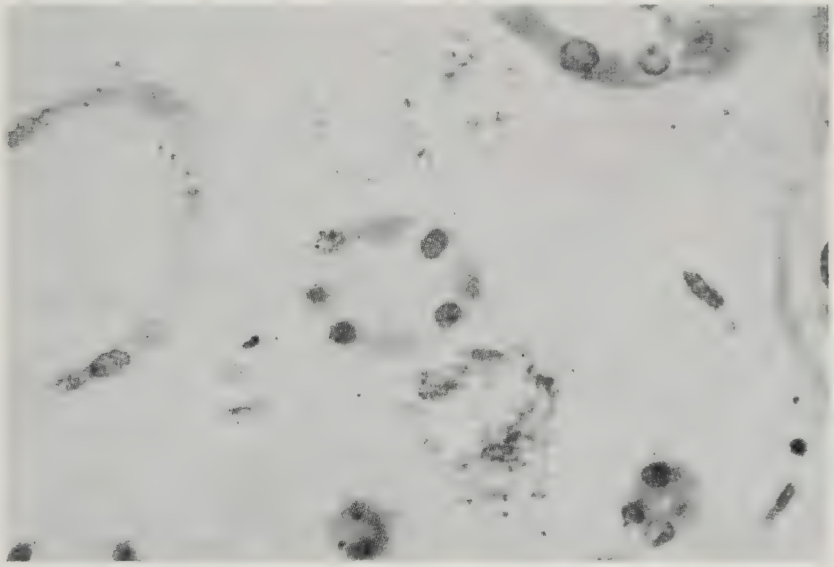

Fig. 565. *Escherichia coli* in kidney tubules, stained red. (Krajian stain; ×1620.) (From Krajian, A. A., and Gradwohl, R. B. H.: Histopathological technic, St. Louis, 1952, The C. V. Mosby Co.)

and different solutions. A simple method was devised which is easily applied to frozen and paraffin sections of formalin-fixed tissue and which gives satisfactory simultaneous differential staining of gram-positive and gram-negative organisms. For example, 4 different sections (frozen or paraffin) mounted on the same slide, one each of a kidney containing *Candida,* a lung with *Klebsiella,* a testicle containing *Sporotrichum,* and a kidney with *Escherichia coli,* were stained, with successful differentiation of the organisms by the method described. The technic has also been used on tissues containing streptococci, *Clostridium perfringens, Haemophilus influenzae, Actinomyces,* meningococci, gonococci, *Corynebacterium diphtheriae,* and Negri bodies.

The solutions used are methylene blue as a gram-positive stain, fuchsin-creosote as a gram-negative stain, and creosote-xylene as a differentiator.

Frozen section method for staining gram-positive and gram-negative organisms in tissue

1. Prepare frozen sections 7-10μ thick and mount in the usual manner under thin celloidin (p. 1666).
2. Stain for 3 min. with Loeffler methylene blue.
3. Wash in tap water and dehydrate rapidly with 3 applications of anhydrous isopropanol or absolute ethyl alcohol.
4. Differentiate rapidly with **creosote-xylol** (1 part creosote plus 2 parts xylol), agitating the slide constantly for 5-10 sec.
5. Pour off and apply **creosote-fuchsin** (2.5 ml. 6% alcoholic basic fuchsin added to 50 ml. creosote-xylol), agitating the slide about 15-20 times, changing the solution once.
6. Blot and apply creosote-xylol 2 or 3 times, agitating the slide constantly for even decolorization or until most of the excess red color leaves the section.
7. Blot, clear for 2 min. in xylol, and mount in gum damar.

Paraffin section method for staining gram-positive and gram-negative organisms in tissue

1. Deparaffinize sections with 2 applications of xylol and 2 applications of absolute alcohol or isopropanol.
2. Hydrate to tap water and then proceed with the method described above.

Nuclei are red; gram-positive organisms, blue; gram-negative organisms, red; devitalized gram-positive organisms, red; *Candida* and *Actinomyces,* blue; Negri bodies, bright red with bluish chromatin bodies; and fibrin, sometimes blue and sometimes red.

All the staining solutions are stable.

ACID-FAST STAINS

Ziehl-Neelsen method of staining acid-fast organisms in tissue

The Ziehl-Neelsen method is the standard method of staining acid-fast bacilli in sections. It is used to stain both tubercle and Hansen bacilli.

1. Fix tissues in Zenker fluid or formalin and make paraffin or frozen sections. Mount frozen sections as usual.
2. Remove paraffin with 2 changes of xylol and absolute alcohol.
3. Stain lightly in Harris hematoxylin.
4. Wash in tap water until blue.
5. Stain in carbolfuchsin over a Bunsen burner for 10 min., gently steaming. This method is used for rapid diagnosis; better results are obtained if sections are left in carbolfuchsin solution 16-24 hr. at room temperature.
6. Wash in water.
7. Decolorize a few seconds in 1% hydrochloric acid in alcohol.
8. Continue the decolorization in 70% alcohol until no more pink color is seen.
9. Dehydrate in absolute alcohol; then blot.
10. Clear in 2 changes of xylol.
11. Mount in gum damar.

Do not use carbolxylol for clearing since it causes the red color of the bacilli to fade.

Stain Hansen bacilli only 5 min. by the steaming method and decolorize 15 sec. in acid alcohol.

Hansen and tubercle bacilli appear bright red; nuclei of cells take the hematoxylin stain.

Krajian method of demonstrating acid-fast organisms in tissue sections[42]

The importance of a consistently satisfactory and dependable method for identification of tubercle and Hansen bacilli and of allied acid-fast organisms in the granulomatous lesions of biopsy and necropsy material cannot be overemphasized. The methods described in microtechnics call for application of a nuclear stain first, then carbolfuchsin (Ziehl-Neelsen) for the staining of organisms, then a decolorizer, and finally dehydrating and clearing.

The unsatisfactory feature in these accepted standard methods has always been in the use of the decolorizer. Carbolfuchsin not only stains the organisms but it also is absorbed by the connective tissue system. If the decolorizer (acid alcohol) is overapplied to remove the color from the connective tissue fibers, it will also affect the color of the organism and fade the nuclear stain. To overcome this obstacle there has been developed a satisfactory and dependable method, making changes in the type of nuclear stain and decolorizer and introducing a differentiating step. The method is easily applied to frozen and paraffin sections fixed in ordinary fixatives.

1. Cut frozen sections 7-10μ thick.
2. Transfer to a glass slide, dehydrate, blot in filter paper, and dip once in thin celloidin (p. 1666); blow over the surface until dry.
3. Wash in tap water until the surface is wet.
4. Place on a tripod or on a warming table, apply carbolfuchsin, and steam gently with a flame for 3 min.
5. Discard the staining solution, wash with tap water, and apply **arsenic acid alcohol** (1 gm. arsenic acid in 100 ml. 60% ethyl alcohol) with a medicine dropper 2-4 times, agitating the slide constantly for even destaining or until most of the red color is removed.
6. Wash in tap water and apply Loeffler methylene blue solution for 2 min.
7. Wash in tap water and dehydrate with 3 applications of anhydrous isopropanol or absolute ethyl alcohol.
8. Immediately apply iso-creosote (equal parts of anhydrous isopropanol or absolute ethyl alcohol and beechwood creosote) 2 or 3 applications, agitating the slide constantly for even differentiation. This removes the excess blue stain from tissue as well as from organisms. This is the crucial step; if overdifferentiated, the background will be very light blue without affecting the organisms; light blue is the correct color.
9. Blot immediately in filter paper.
10. Clear in 3 changes of xylol, 1 min. each.
11. Mount in gum damar.

For **paraffin sections,** remove paraffin with 2 applications of xylol, 2 min. each, remove xylol with 2 applications of isopropanol or absolute alcohol, wash in tap water, and proceed with the method described.

Figs. 566 and 567 demonstrate the results obtained with this method.

Acid-fast stain of paraffin sections—Fuller

This method is excellent for photomicrographic purposes—tubercle bacilli are stained brilliantly red, whereas nuclei take various

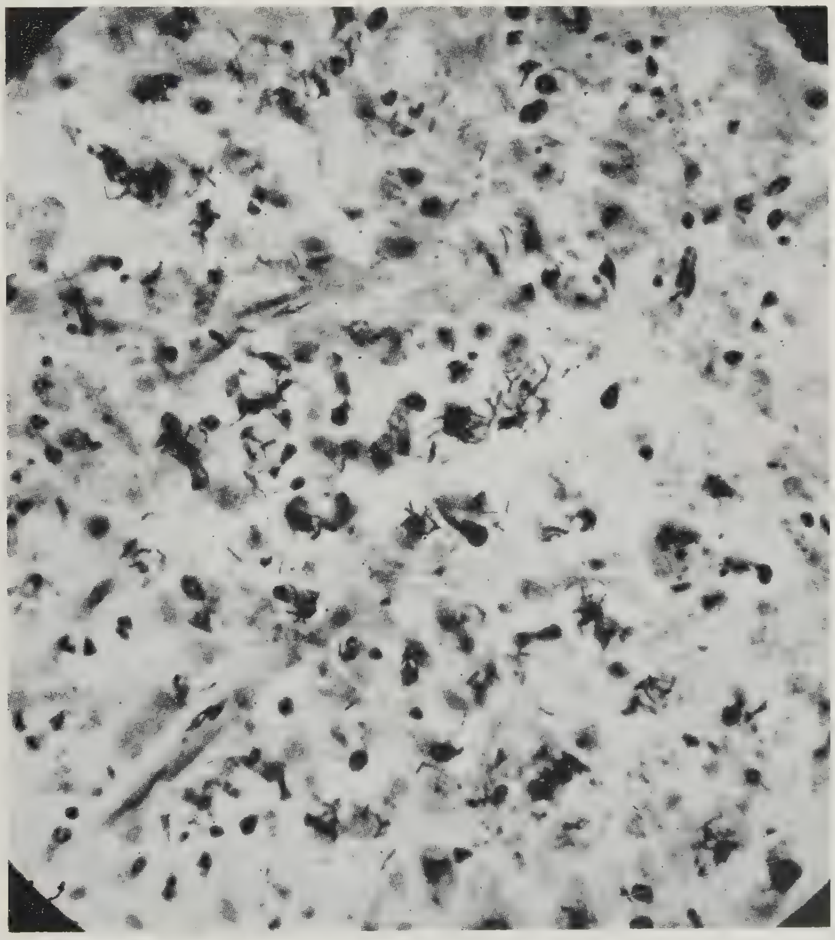

Fig. 566. Tubercle bacilli in lung tissue from a case of miliary tuberculosis. (Krajian acid-fast stain; ×1620.) (From Krajian, A. A.: Am. J. Clin. Path. [Tech. Supp.] 7:45, 1943.)

Fig. 567. Hansen bacilli in fibrous tissue from a case of Hansen's disease of the arm. (Krajian acid-fast stain; ×1620.) (From Krajian, A. A.: Am. J. Clin. Path. [Tech. Supp.] **7**:45, 1943.)

shades of green, so that good contrast is obtainable.

1. Deparaffinize sections in the usual manner and hydrate to water.
2. Mordant in 5% iron alum in a paraffin oven for 5 min. at 45°-50° C.
3. Rinse in water.
4. Stain in Fuller hematoxylin (p. 1659) in a paraffin oven for 5 min.
5. Place directly in the picric acid solution (2 parts saturated alcoholic picric acid and 1 part 95% alcohol) for 5 min. or longer if necessary, until the stain remains only in the nuclei.
6. Wash thoroughly under running water, 15 min. or longer, or until sections are free of picric acid.
7. Place section on heating bar or warming table and pour Fuller aniline fuchsin (p. 1661) over them. Heat until steam comes off, but do not boil.
8. Decolorize in acid alcohol for a few seconds, until the fuchsin begins to come off in clouds; rinse in tap water and continue decolorization until the sections are barely pink. (Acid alcohol is prepared by mixing 3 ml. concentrated hydrochloric acid with 100 ml. 95% alcohol.)
9. Rinse in 1% ammoniated water for a few seconds.
10. Wash thoroughly under running water for 10 min.
11. Stain in 1% light green for 5 min.
12. Wash in water, and dehydrate rapidly in 95% alcohol, followed by absolute alcohol.
13. Clear in xylol for 5 minutes and mount in gum damar.

Krajian modification of Ziehl-Neelsen stain

1. Stain thin frozen, paraffin, or celloidin sections lightly in Harris hematoxylin.
2. Wash in tap water until blue.
3. Stain for 5 min. with carbolfuchsin, gently steaming. Keep the slide fully covered with the staining solution.
4. Wash in tap water.
5. Destain in picric acid alcohol (1 part saturated aqueous picric acid and 1 part 95% alcohol) for 15-30 sec., changing the solution

2 or 3 times and agitating the section for even destaining.

6. Wash thoroughly in a large basin of tap water.
7. Treat with 2% sodium cyanide for 10-15 sec. and wash thoroughly in tap water.
8. Dehydrate completely with several changes of absolute alcohol or anhydrous isopropanol (this also removes the excess fuchsin stain).
9. Blot dry and clear in 2 changes of pure xylol, 2 min. each.
10. Mount in gum damar.

Do not use carbolxylol for clearing because it fades the red color of the bacilli.

Tubercle and Hansen bacilli appear bright red; the nuclei, blue.

Flexner method of staining Hansen bacilli in tissue

1. Stain sections in Harris hematoxylin to obtain a sharp nuclear stain.
2. Wash in water.
3. Stain in Ziehl-Neelsen carbolfuchsin for 2-5 min., steaming, or for 30-60 min. at room temperature.
4. Wash in water.
5. Treat with Gram's iodine ½-1 min.
6. Wash in water.
7. Blot in filter paper, clear, and differentiate in aniline oil.
8. Clear in pure xylol. Mount in gum damar.

Hansen bacilli stain red; nuclei, light blue.

Kinyoun carbolfuchsin method for demonstrating tubercle bacilli in tissue

Solution 1:

Basic fuchsin	2 gm.
Phenol crystals	8 gm.
Alcohol, 95%	20 ml.
Distilled water	100 ml.

Solution 2:

1. Prepare a 0.5% solution of acetic acid by adding 0.5 ml. glacial acetic acid to distilled water and diluting to 100 ml. with distilled water.
2. Dissolve 0.5 gm. methylene blue in this 0.5% acetic acid.

Solution 3:

1. Add 15 ml. hydrochloric acid to 95% alcohol.
2. Dilute to 100 ml. with 95% alcohol.

Procedure:

1. Remove the paraffin from the sections by passing them through 3 changes of xylol in the usual manner.
2. Place slides for 1 min. each in the following solutions: absolute alcohol, 95% alcohol, 70% alcohol, distilled water.
3. Stain with Kinyoun carbolfuchsin for 1 hr. at room temperature.
4. Rinse with distilled water.
5. Decolorize in the hydrochloric acid solution until pink.
6. Counterstain in the methylene blue solution for 1 min.
7. Wash in distilled water.
8. Dehydrate in the usual manner.
9. Mount in balsam, gum damar, or Clarite.

Fluorescence method of demonstrating Mycobacterium tuberculosis in tissues—Tanner

The use of fluorescence in microscopy for demonstrating *Mycobacterium tuberculosis* in smears has been considered on p. 597. The use of fluorescence microscopy for demonstrating this organism in tissues has been reported in European literature.[43-45] Tanner[46] gives an excellent method, using this technic for the demonstration of tubercle bacilli in tissue.

Reagents:

1. Auramine stain.
    (a) Solution A.

Distilled water	87 ml.
Phenol	3 ml.

    (b) Solution B.

Ethyl alcohol, 95%	10 ml.
Auramine-O	0.1 gm.

Add solution B to solution A.

2. Decolorizing solution.

Alcohol, 70%	100 ml.
Hydrochloric acid, c.p., concentrated	1 ml.
Sodium chloride, c.p.	0.5 gm.

3. Methylene blue, 1% solution.
    (a) Dissolve 100 mg. methylene blue in 100 ml. distilled water, grinding in a mortar, and adding small portions of the solvent until all the dye is in solution.
    (b) Filter after 24 hr.

Procedure:

1. Cut sections of tissue blocks, fixed in 10% formalin and embedded in paraffin, at 5μ. Mount on clean glass slides with a minimal amount of egg albumin. When the sections are dry, remove the paraffin in the usual manner and cover the deparaffinized sections with the auramine staining solution for 5 min.
2. Wash the sections and cover with the decolorizing solution for 20 min.
3. Wash with tap water and cover with fresh decolorizer for another 20 min.
4. Wash with tap water and counterstain with 0.1% aqueous methylene blue for 1 min.
5. Wash. Dry. Examine with a fluorescence microscope without using a cover glass.

The methylene blue gives a black or dark blue background but does not interfere with the fluorescence of the organisms.

Some sections, according to Tanner, gave satisfactory results without the methylene blue, but the use of that counterstain gives better contrast and is recommended as a routine procedure in tissue sectioning. The results with both methods are satisfactory, the bacilli standing out as bright yellow rods on a nearly black background. The organism can be identified readily by using an 8 mm. objective and a ×25 ocular.

GIEMSA STAINING OF TISSUE

Giemsa stain for bone marrow study

1. Fix very thin pieces of bone marrow in Zenker fluid for 12-16 hr. Wash under running water for 16-24 hr. Embed in paraffin in the usual manner and cut sections 5μ or thinner.
2. Deparaffinize with 2 applications of xylol, 2 min. each.
3. Remove xylol by 2 applications of absolute alcohol.
4. Treat with tincture of iodine for 5 min. to remove the bichloride of mercury precipitate.
5. Treat with 1% aqueous sodium thiosulfate for 5-10 min.
6. Wash thoroughly in tap water followed by neutral distilled water.
7. Prepare a **dilute Giemsa stain** as follows:

Giemsa stock solution . . .	3 ml.
Methyl alcohol (Merck) . .	3 ml.
Neutral distilled water (add 2 drops 1% sodium bicarbonate to 100 ml. distilled water)	100 ml.

8. Place sections in dilute Giemsa solution for 1 hr. Change the stain twice and leave in the third solution overnight.
9. Place sections in distilled water.
10. Differentiate each slide separately in 95% alcohol to which a few drops of colophonium in absolute alcohol are added.
11. Dehydrate in 2 changes of absolute alcohol.
12. Clear in neutral xylol and mount in cedarwood oil or gum damar.

Nuclei of cells and neutrophil granules stain red violet; basophil granules, blue violet; cytoplasm of lymphocytes, blue; eosinophilic granules and red blood cells, pale red.

Refer to hematology section for other procedures for Giemsa stain of bone marrow.

Giemsa stain for protozoologic and hematologic work

For the demonstration of protozoa and bacteria fix thin pieces of tissue in mercuric alcohol (4 gm. mercuric chloride in 95% alcohol) for 2 days, changing the fixing solution after 24 hr.

For hematologic work fix thin pieces of tissue in Helly fluid for 12-16 hr. and wash under running water for 24 hr.

After primary fixation dehydrate and embed in paraffin in the usual manner.

1. Cut sections 3-5μ thick.
2. Deparaffinize in 2 applications of xylol, 2 min. each.
3. Remove xylol by 2 applications of absolute alcohol or anhydrous isopropanol.
4. Treat with tincture of iodine for 5 min. to remove the bichloride of mercury precipitate.
5. Treat with 1% aqueous sodium thiosulfate for 5-10 min.
6. Wash thoroughly in tap water, followed by neutral distilled water.
7. Stain in freshly prepared dilute Giemsa stain for 16-24 hr. The dilution is prepared by adding 1 drop of stock Giemsa stain to each 1 ml. neutral distilled water. After the first hour replace the dilute Giemsa mixture with a fresh supply.
8. Wash in distilled water.
9. Dehydrate and differentiate in 9 parts acetone plus 1 part xylol; then in 5 parts acetone plus 5 parts xylol; and finally in 1 part acetone plus 9 parts xylol.
10. Clear in neutral xylol. Mount in gum damar.

At times better results are obtained by clearing the sections in carbolxylol or creosote first, followed by neutral xylol.

Nuclei of protozoa stain red; nuclei of cells and neutrophil granules, red violet; basophil granules, blue violet; cytoplasm of lymphocytes, blue; eosinophilic granules and red blood cells, pale red.

Giemsa stain of tissue—Schilling method, Gradwohl modification

1. Immerse the tissue in Susa fixative (p. 1642) for 5-48 hr., depending on the size.
2. Wash in tap water for 3-5 hr., changing the water frequently.
3. Place in 50% alcohol for ½ day, changing alcohol several times.
4. Transfer to 70% alcohol for ½ day, changing alcohol several times.
5. Transfer to 95% alcohol for ½ day, changing alcohol several times.
6. Place in absolute alcohol not longer than 1 hr. Larger blocks should be left longer than 1 hr.
7. Clear in pure xylol. The tissue must be transparent.
8. Place the tissue in a mixture of equal parts of paraffin and xylol at a temperature not to exceed 37°-40° C. overnight. Use embedding paraffin with a melting point of 56°-58° C. Tissuemat may be used. Keep the paraffin oven at a temperature 2° above the melting point of paraffin.
9. Place tissues in pure paraffin or Tissuemat in a paraffin oven for 4 hr. Transfer to fresh paraffin or Tissuemat in a paraffin oven for 2-4 hr. Embed in fresh paraffin or Tissuemat in the usual manner.
10. Cut sections about 5μ thick, mount on slides using Mayer albumin fixative, and allow to dry thoroughly.
11. All solutions for staining sections should be in staining jars.
12. Place the slides in xylol for 5 min. to remove the paraffin.
13. Carry through absolute alcohol, 1 min.; 95% alcohol, 1 min.; 80% alcohol, 1 min.; 70% alcohol, 1 min.
14. Place in iodine-alcohol (100 ml. 70% alcohol and 1 ml. tincture of iodine) for 1-2 hr. or until tissues assume a brown color. Omit this step for formalin-fixed sections.
15. Treat in 0.2% sodium thiosulfate not longer than 10-15 min. or until the brown color is removed.

16. Wash for 30 min. in a jar of tap water.
17. Wash for 30 min. in a jar of distilled water.
18. Dilute Giemsa stain by adding 1 drop of Giemsa stain to each ml. of neutral distilled water, shaking while adding each drop. Avoid shaking too vigorously.
19. Stain for 30 min. on a staining bridge, flooding the slide with dilute Giemsa stain.
20. Renew the stain at the end of the 30 min. staining period, diluting a fresh supply for the restaining process. Restain for 30 min.
21. Wash briefly in a jar of distilled water.
22. Place the slide under the low-power objective of a microscope and decolorize as follows: Use a weak solution of acetic acid made by adding 1 or 2 drops of 1% acetic acid to 50 ml. distilled water. Have at hand a jar of slightly alkaline water, made by adding 2 or 3 drops of 1% potassium carbonate to 100 ml. tap water.
23. Place the Giemsa-stained slide under the microscope.
24. Flood the slide with the weak acetic acid solution, and as soon as the pink color of the eosin is observed, place the slide in the jar containing slightly alkalinized water. The rapidity of this change is important, because decolorization will continue as long as the acid remains not neutralized on the tissue. Carry out dehydration in staining jars.
25. Place the slide in the following: solution 1 for about 5-10 sec.; then in solution 2 for about 5-10 sec.; and then in solution 3 for 10 sec. or more.

    Solution 1:

Xylol	5 parts
Acetone	95 parts

    Solutions 2 and 3:

Xylol	30 parts
Acetone	70 parts

26. Place in xylol. If the section does not become transparent, place again for a few seconds in solution 3 and then back in xylol. Continue this process until the section is clear; then leave in xylol for several minutes. Keep the acetone solutions tightly stoppered to prevent rapid evaporation and absorption of undue amount of moisture. Mount in gum damar.

STAINING AMEBAE IN TISSUE

Heidenhain iron hematoxylin

Heidenhain iron hematoxylin is a standard method to demonstrate the cysts of *Entamoeba histolytica,* chromatin, nuclear membrane, centrosomes, and various secretory products. It is applicable after any standard method of fixation. Zenker fluid and alcohol are preferred.

1. Cut very thin frozen, paraffin, or celloidin sections and mount on slides in the usual manner. Remove the precipitate from mercury bichloride-fixed sections by treatment with iodine and place them for 1-24 hr. in a staining dish containing 5% aqueous iron alum (5 gm. iron and ammonium alum dissolved in 100 ml. distilled water).
2. Wash in tap water.
3. Place in staining dish containing Heidenhain hematoxylin formula 2 (p. 1658) for 1-4 hr.
4. Wash in tap water.
5. Differentiate in 2% aqueous iron alum. Control the destaining under the microscope by taking the section out of iron alum solution, dipping it in water, and examining under low-power magnification. Repeat the process until the sections are suitably destained.
6. Wash in a large basin of tap water for several minutes until all traces of iron alum are removed from the section.
7. Dehydrate first in 95% alcohol and then in absolute alcohol.
8. Blot and clear in 2 changes of xylol.
9. Mount in gum damar.

The nuclei of cysts, amebae, the chromatin, and nuclear membrane stain blue.

Krajian elastic tissue stain for amebae in tissue

1. Prepare thin frozen, paraffin, or celloidin sections and mount on slides in the usual manner.
2. Stain in Krajian elastic tissue solution (p. 1658) for 5 min.
3. Wash in tap water.
4. Destain in 1% acid alcohol until the background begins to clear.
5. Wash in tap water.
6. Treat with 5% aqueous zinc sulfate for 2 min.
7. Rinse in tap water.
8. Counterstain for 2 min. in van Gieson solution (p. 1663).
9. Rinse in tap water and blot dry.
10. Differentiate and dehydrate with oil of origanum-absolute alcohol (equal parts) solution for 2 min.
11. Clear in carbolxylol for 2 min.; follow with pure xylol for 3 min.
12. Mount in gum damar.

The nucleoli of amebae stain brownish blue; cytoplasm, pink; connective tissue, dark red.

STAINING NEGRI BODIES IN TISSUE

To establish the diagnosis of rabies it is necessary to find Negri bodies in the nerve cells of the central nervous system. These are generally round or oval and stain deeply with fuchsin; their granules take a blue color. Refer to p. 882 for further information.

Method 1—Goodpasture carbolfuchsin and methylene blue method

1. Fix suspected brain tissue in Zenker fluid, wash, dehydrate, and embed in paraffin in the usual manner.
2. Cut very thin sections and mount on slides as usual. Carry through to water.
3. Remove the mercury precipitate by treating in tincture of iodine and then in 5% sodium hyposulfite.

4. Wash very thoroughly in tap water.
5. Stain in Goodpasture fuchsin solution formula 2 (p. 1661) for 10-30 min.
6. Wash off excess stain in running water.
7. Blot with fine filter paper.
8. Decolorize in 95% alcohol until the section becomes pink.
9. Wash in tap water and counterstain for 15-60 sec. with Loeffler methylene blue.
10. Wash in tap water.
11. Decolorize and at the same time dehydrate in absolute alcohol for a few seconds until the excess blue is removed.
12. Clear in 2 changes of pure xylol.
13. Mount in gum damar.

This method is useful for the demonstration of Negri bodies, bacteria, and rickettsiae. The staining solution is not stable. It will be convenient to keep the required alcoholic solution of fuchsin on hand, adding it to the phenol and aniline oil at the time of use.

Method 2—Negri body stain in tissue section

1. Embed Zenker-fixed brain tissue in paraffin in the usual manner, cut thin sections, and dry.
2. Remove paraffin with 2 applications of xylol, 2 min. each.
3. Wash with 2 applications of anhydrous isopropanol or absolute alcohol, 1 min. each.
4. Treat with tincture of iodine for 10 min. to remove the mercury.
5. Wash in isopropanol or 95% alcohol.
6. Wash thoroughly in water.
7. Stain in dilute fuchsin-methylene blue (p. 1661) for 7-10 min., gently steaming.
8. Rinse in tap water and blot.
9. Treat with anhydrous isopropanol or absolute alcohol for 15-25 sec.
10. Blot dry and immediately dip in and out in carbolxylol until the background is completely red. Control this step under low magnification of a microscope; if the nuclei are very deep blue, continue the carbolxylol treatment.
11. Clear in 2 changes of xylol, 2 min. each.
12. Mount in gum damar.

The stock staining solution may be kept for a long period. Shake thoroughly before diluting it.

The diluted solution does not keep longer than 15 min., and for this reason fresh solution should be prepared before use.

This is a highly satisfactory method to demonstrate Negri bodies in tissue sections.

Negri bodies in smear preparation—Frothingham

1. Choose small pieces of gray matter from the hippocampus or vermis of the cerebellum and place on a clean slide. Prepare smears and air-dry. Fix in absolute alcohol for a few seconds.
2. Stain smears in cold Frothingham fuchsin-methylene blue (p. 1661), dry, and examine under oil-immersion objective.

The Negri bodies are exceptionally brilliant red with blue granules.

SPIROCHETE STAINS

Among numerous similar organisms *Treponema pallidum* stands out as peculiar in its resistance to stains. Many methods have been devised to demonstrate it, in both the living and dead state.

Krajian 20 min. stain for Treponema pallidum in frozen sections

In 1939 Krajian described his excellent and practical method for demonstrating *Treponema pallidum* in biopsy material particularly designed to facilitate the diagnosis of primary syphilis. Gradwohl stated that it is the best and simplest method yet devised. It gives a clear-cut picture of the organism of syphilis, even in many instances in which dark-field examinations have failed to demonstrate it.

The dark-field method is positive in about 90% of cases in the first week of the lesion and in 50% in the fifth week. The morphology of the spirochetes found on the surface of mucosal lesions by dark-field and smear methods may be of less significance than those found deep in the tissues of biopsy sections because here their recognition is not affected by saprophytic organisms and free oxygen.

The 20 min. method of Krajian follows.[47, 48]

Reagents:

1. Primary solution.

Uranium nitrate	1 gm.
Formic acid, c.p., 85%	3 ml.
Glycerin, c.p.	5 ml.
Acetone, c.p.	10 ml.
Alcohol, 95%	10 ml.

2. Silver nitrate solution, 10%.
   (a) Dissolve 10 gm. silver nitrate, c.p., in enough distilled water to make 100 ml. solution. The 1% solution is made from this.
3. Silver nitrate solution, 1%.
   (a) The 10% silver nitrate solution will keep for months. Dilute it just before using by adding 3 ml. 10% silver nitrate to enough distilled water to make 30 ml. solution.
   (b) This solution may be used a maximum of 3 times during the course of the same day. Do not use it if it has a brownish cast.
4. Developing solution.

Hydroquinone	0.31 gm.
Sodium sulfite	0.1 gm.
Acetone	2.5 ml.
Formaldehyde, 40%	2.5 ml.
Pyridine	2.5 ml.

Saturated solution of gum mastic in 100% alcohol	2.5 ml.
Distilled water	15 ml.

(a) Dissolve the hydroquinone in formalin and acetone; then dissolve the sodium sulfite in this solution. Then add the other reagents and mix. Finally add the gum mastic. With the addition of the water the mixture assumes a smooth creamy appearance.

(b) This solution may be used a maximum of 3 times during a day's work but should preferably be used in small quantities and used only once. The stock solution, if kept out of the light, will remain good for at least 1 or 2 wk. Keep out of the cold to prevent separation of the gum.

5. Saturated alcoholic solution of gum mastic.
   (a) Saturate 25 gm. gum mastic with 35 ml. absolute alcohol. Shake several times a day for 3-5 days until clear. Allow to precipitate and use only the clear supernatant portion. Clarification can be hastened by centrifuging.

Procedure:

1. If the tissue has not been previously fixed in 10% formalin, boil a small piece of biopsy material in 10% formalin in a Pyrex test tube, agitating it for 1 min., or drop blocks of tissue about 5 mm. thick in 10% formalin at 67° C. and place in an oven at 67° C. for 10 min.
2. Freeze and cut immediately. Cut frozen sections about 7-10μ thick. Wash in distilled water.
3. Place the *primary solution* and the *developing solution* in small Stender dishes in a paraffin oven at 60° C. to keep them warm. Have 3 small Stender dishes containing distilled water. Place about 5-10 ml. 95% alcohol in another Stender dish.
4. In another Stender dish place 5 ml. 95% alcohol and add about 3 drops of saturated solution of gum mastic from the end of a small glass lifter.
5. The 1% silver nitrate solution should be in a 250 ml. Pyrex beaker.
6. Place the tissue in the primary solution at 56°-60° C. for 5 min. This can be kept in a paraffin oven to maintain its temperature.
7. Rinse in distilled water in a Stender dish. The tissue should open and float on the water.
8. Pick up the section with a glass lifter and, keeping it on the lifter, pass 3 times quickly but gently through the weak gum mastic mixture in a Stender dish.
9. Place the section in another Stender dish of distilled water. The section should open and float on the water.
10. Transfer the section to a wide-mouthed 250 ml. Pyrex beaker containing 30 ml. 1% silver nitrate. Put the beaker on an asbestos board over a low flame and under a 60-watt electric light, which should be about 4 ft. above the beaker. Heat the silver nitrate under the electric light until bubbles form, keeping the temperature between 70° and 73° C. for 7 min.
11. Without washing, carry individual sections from the silver nitrate to the warm developing solution, using the glass rod lifter. Alternately lift in and out of the solution, exposing every part of the section to the electric light. When replacing each time, take care that the section opens out on the developing solution. This cannot be accomplished unless the solution is quite warm. Repeat this alternate exposing and developing process about 6-8 times. The tissue turns brown.
12. Transfer to 95% alcohol in a Stender dish to remove excess gum mastic.
13. Transfer to another Stender dish containing fresh distilled water. The tissue should straighten out here. If it does not, replace for a few seconds in the alcohol and then place in the distilled water.
14. Place the tissue again in the **cooled** silver nitrate solution and expose to the electric light for an additional 10-30 sec. to cause the treponemes to assume a good black color.
15. Transfer to a large basin of distilled water. **Do not use tap water.**
16. Transfer to a glass slide. Dehydrate by dropping isopropanol over the sulface; blow gently at first and then blow a little harder to remove the water. Dehydrate in isopropanol about 30 sec.
17. Blot under several thicknesses of No. 1 Whatman filter paper, place isopropanol over the slide, and allow to dehydrate for at least 1 min. Again blot with Whatman No. 1 filter paper after draining off the excess isopropanol.
18. Dip once in thin celloidin (p. 1666). Wipe the bottom of the slide dry. Blow over the surface of the celloidin until it is thoroughly dry.
19. Place the slide on a staining dish and cover with isopropanol for 60 sec. to dehydrate.
20. Place in xylol for several minutes. Place in a second xylol to clear. Clean excess celloidin from around the tissue and mount with gum damar. Examine with the oil immersion objective.

Pointers: The spirochetes should stain black against a light brown background. If they are brown, either the second silvering process was not carried out properly or the developing solution was too cold. Or the developer might have separated, in which case make fresh developer.

When the gum mastic separates out of the developer, make a fresh solution. The primary solution keeps indefinitely.

If some of the spirochetes are brown and some are black, the sections were not spread properly in the developing solution. Be sure the solution is hot so that the tissues will open properly.

If some portions of the tissue do not show spirochetes and it is believed that they must be there, it may be due to improper fixation of the tissue. Unfixed portions of the section do not permit staining of the spirochetes.

When gum mastic is old or is in solution, it deteriorates.

If the lesion has been covered or treated with Mercurochrome or other chemicals the staining will be affected.

Dirty glassware will cause precipitates in the section. Clean with sulfuric acid-dichromate cleaning solution.

If the tissue suddenly shrinks when it is removed from the silver nitrate solution and placed in the water, this may be due to the fact that the water is not really distilled water, or the silver nitrate for the second silvering process was too hot and the temperature change too sudden. Sometimes going back to the hot developer and then through the other solutions will help unfold such a tissue. Or too weak a gum mastic solution was used.

It is good practice to stain a known positive section along with the specimen for diagnosis as a check on the solutions.

Never use a metal needle for removing tissues. Use the glass rod lifter.

This method is also applicable to paraffin sections, provided the period of staining in each step is doubled. It has been used successfully in our laboratories in demonstrating treponemes in primary sores where dark-field examinations have been negative. A small piece of tissue of the chancre, after injection of a few drops of Novocain solution, is snipped off with a pair of sharp scissors, and the above technic is carried out.

Krajian method for Treponema pallidum in smears

The silver stain for smears is capable of impregnating within a 15 min. period even the most resistant spirochetes and offers both convenient and permanent records.

Recognition of the morphologic characteristics of treponemes on the surface of mucosal lesions may be of less significance than recognition of them when deep in the tissue, but the finding of spirochetes with the morphologic characteristics of *T. pallidum* in smears from a suspicious lesion constitutes at least presumptive evidence of the syphilitic character of the lesion.

1. Moisten a swab in alcohol and roughly rub the lesion until it bleeds. Several minutes after all the bleeding stops, a clear serous exudate will appear on the abraded surface; from this fluid prepare and air-dry smears.
2. Flood the smears with warm (60° C.) primary solution (p. 1722) for 5 min. Dry in the air.
3. Wash in distilled water.
4. Treat with a weak solution of gum mastic for 2 min. (3 drops saturated alcoholic solution of gum mastic mixed with 7 ml. 95% alcohol).
5. Pour off the gum, blow the breath over the surface of the smear, and rinse in distilled water.
6. Set the slide on a metal stand or tripod, flood with 1% silver nitrate, and heat from under until bubbles arise, but do not boil the solution. Maintain the temperature for 3 min.; then repeat the silvering process once.
7. Pour off the silver nitrate; then without washing apply a thin coat of developing solution and leave the slide under an electric light for 2 min., warming gently with a flame. The developing solution is the same as that on p. 1722 except that 0.06 gm. sodium sulfite is used in place of 0.1 gm.
8. Wash with distilled water, dry in filter paper, and examine with an oil immersion objective.
9. For permanent mounts, dehydrate with absolute alcohol, blot, clear in xylol, mount in gum damar.

Clinical application of a rapid staining method for Treponema pallidum

A rapid staining technic for identifying *T. pallidum* is useful, for identification by the dark-field technic is a problem. Because of the usual location of the primary syphilitic lesions, saprophytic spiral forms, which are normal inhabitants, cause great confusion, particularly of the material from mouth and anal lesions. Many of those who have made a study of spirochetes have stated that they are unable to identify *T. pallidum* definitely in the presence of other spiral form organisms and therefore refuse to make a diagnosis under such circumstances.

Since the saprophytic types are surface inhabitants, the biopsy method completely avoids the confusion. It was stated by Noguchi and Stitt that *T. pallidum* is the only spirochete that retains its characteristic form after death; therefore, finding morphologically characteristic spiral form organisms deep in the tissue makes the diagnosis much simpler and reliable.

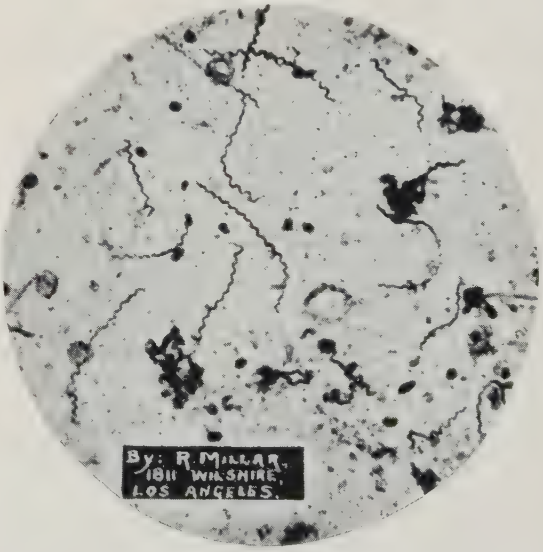

Fig. 568. *Treponema pallidum* in smear preparations. Krajian method.

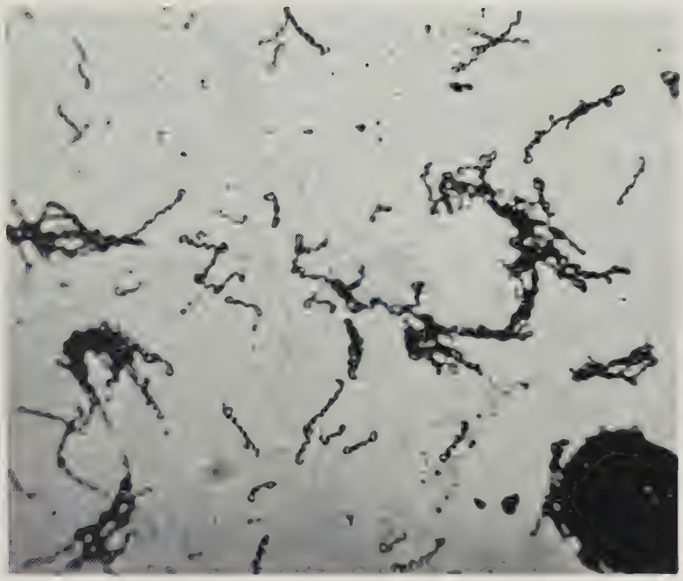

Fig. 569. *Leptospira icterohaemorrhagiae.* Smear preparation from culture. Krajian method. (From Krajian, A. A., and Gradwohl, R. B. H.: Histopathological technic, St. Louis, 1952, The C. V. Mosby Co.)

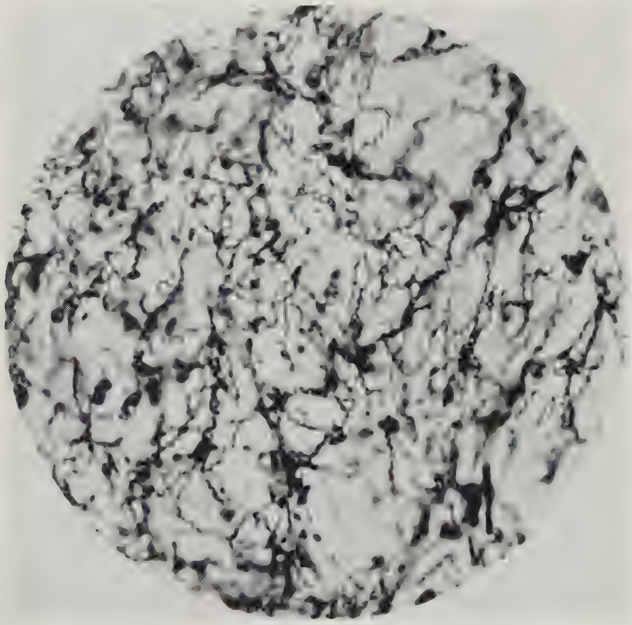

Fig. 570. *Treponema pallidum* in liver section from a case of congenital syphilis. Krajian method. (From Krajian, A. A., and Gradwohl, R. B. H.: Histopathological technic, St. Louis, 1952, The C. V. Mosby Co.)

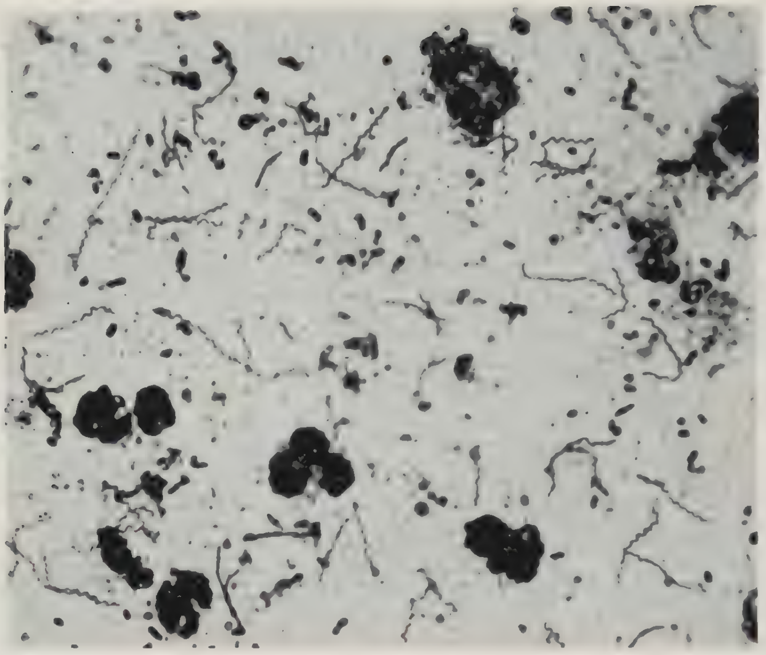

Fig. 571. *Treponema pallidum* in a section from primary lesion. Krajian method. (From Krajian, A. A., and Gradwohl, R. B. H.: Histopathological technic, St. Louis, 1952, The C. V. Mosby Co.)

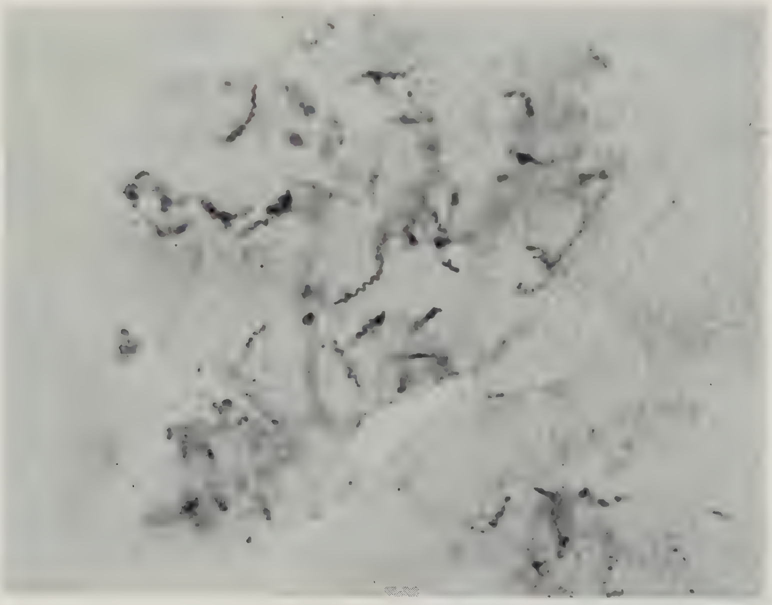

Fig. 572. *Treponema pallidum* in skin lesion. Secondary syphilis. Krajian method. (From Krajian, A. A., and Gradwohl, R. B. H.: Histopathological technic, St. Louis, 1952, The C. V. Mosby Co.)

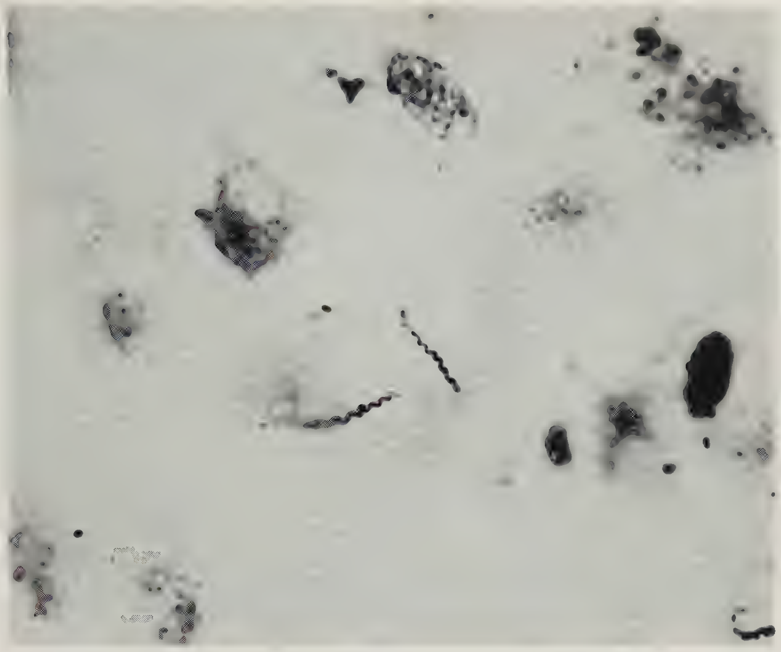

Fig. 573. *Treponema pallidum* in gumma of testicle. Tertiary lesion. Krajian method. (From Krajian, A. A., and Gradwohl, R. B. H.: Histopathological technic, St. Louis, 1952, The C. V. Mosby Co.)

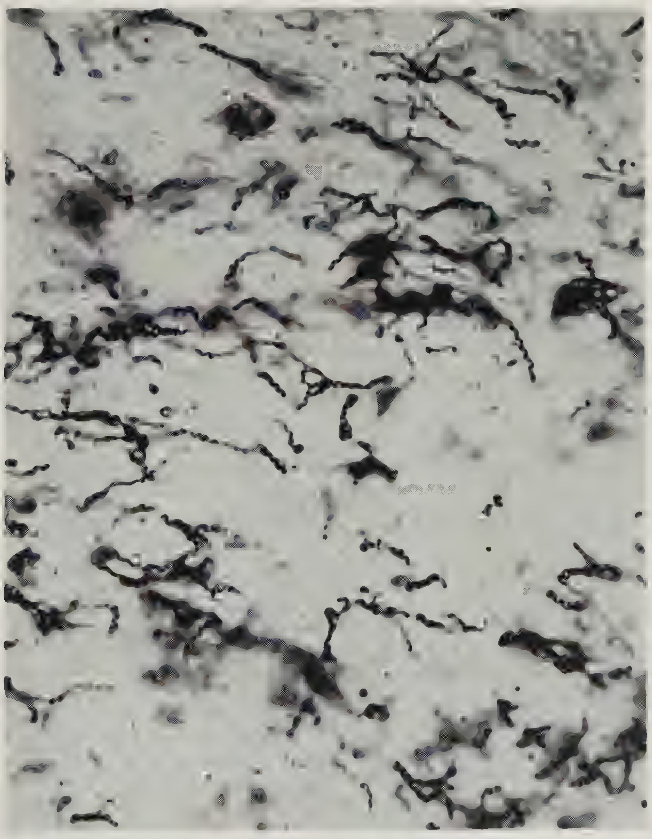

Fig. 574. Case of syphilitic aortitis. Note various forms of *Treponema pallidum,* especially broken and granular types. Krajian method. (From Krajian, A. A., and Gradwohl, R. B. H.: Histopathological technic, St. Louis, 1952, The C. V. Mosby Co.)

Levaditi-Manouelian stain for Treponema pallidum in tissue

1. Fix thin blocks of tissue in 10% formalin for 24 hr. or longer.
2. Harden in 95% alcohol for 24 hr.
3. Place the blocks in distilled water and wait until they sink to the bottom of the container.
4. Impregnate in 2% aqueous silver nitrate 3-6 days in an incubator at 37° C.
5. Rinse the block in distilled water for 2 min.
6. Reduce for 24 hr. at room temperature in the following solution, keeping the container in a dark place:

Pyrogallic acid	3 gm.
Formalin, 40%	5 ml.
Distilled water	100 ml.

7. Wash in distilled water for 15 min.
8. Dehydrate in graded alcohols, commencing with 70% alcohol and ending with absolute alcohol; then clear and embed in paraffin in the usual manner.
9. Cut thin paraffin sections, about 5μ thick.
10. Dissolve the paraffin in xylol and mount in gum damar.

Treponemes are jet black with a yellow background.

The Levaditi and Manouelian method is included for historical purposes.

Morphologic variations of Treponema pallidum

Morphologic variations of *T. pallidum* are best observed in tissue sections and smears. The typical form has regular, delicately curved, corkscrew-like, coil spring or knotty type appearance. Atypical forms are irregular in size and shape.

In tissue they are longer and thinner, especially when in large numbers (in very early lesions), when they are forced to struggle for existence. They become thicker and shorter when certain obstacles arise, such as slight administration of oxygen, or when in pus or exudate.

It has been stated that spirochetes have a quiescent stage during which they change morphology because of the knots, buds, wirelike, ringlike, granular, fragmented, sawlike, stretched, and other unusual forms. Most investigators believe that these atypical forms are part of the evolutionary cycle of the organism; others think that they are products of degeneration. These degenerative and atypical forms are generally seen in gummas where there is extensive destruction of the tissue; here can be observed many peculiar forms, small particles, or remnants of the destroyed organisms. These peculiar forms are generally observed in smears or tissue sections from experimental animals in which there has been a delay of several days in fixing them. They are also seen in unfixed syphilitic human organs. These findings suggest that the atypical forms are products of degeneration.

1. Tightly woven treponemes with tapering ends, as seen in congenital syphilis. 2. Long, delicate forms, as seen in primary syphilitic lesions. 3. Coil spring type, as seen in condylomas. 4. Knotty type, as seen in umbilical cords. 5. Atypical forms, broken and granular, as seen in tertiary lesions (gummas). 
STAINING FUNGI IN TISSUE

Actinomyces

It is generally thought that filaments seen in tissue in the actinomycoses, when stained by the Gram-Weigert method, retain the gentian violet. While examining biopsy sections from various skin lesions to demonstrate *T. pallidum* by the Krajian method, several cases were encountered which showed filaments of streptothrix. The same sections when stained by Gram-Weigert method gave negative results. It was concluded that some of these filaments belong to the gram-negative group. It is advantageous to use both methods in suspected cases.

Coccidioides and Blastomyces

Coccidioides and *Blastomyces* are easily stained and demonstrated by the routine hematoxylin-eosinol method. See Figs. 575 and 576.

STAINING PIGMENTS IN TISSUE

Pigments found normally or abnormally in the human body may be roughly divided into 3 groups according to their origin: (1) hematogenous pigments, (2) autogenous pigments, and (3) exogenous pigments.

Hematogenous pigments

From the standpoint of pathology, hemosiderin is the most important of the hematogenous pigments.

Hemoglobin occurs as yellowish brown granules and droplets. It is soluble in water and dilute alcohol but not in absolute alcohol.

Hematin occurs as a dark brown or bluish black pigment.

Hemofuscin occurs as light yellow granules. It does not give the iron reaction with potas-

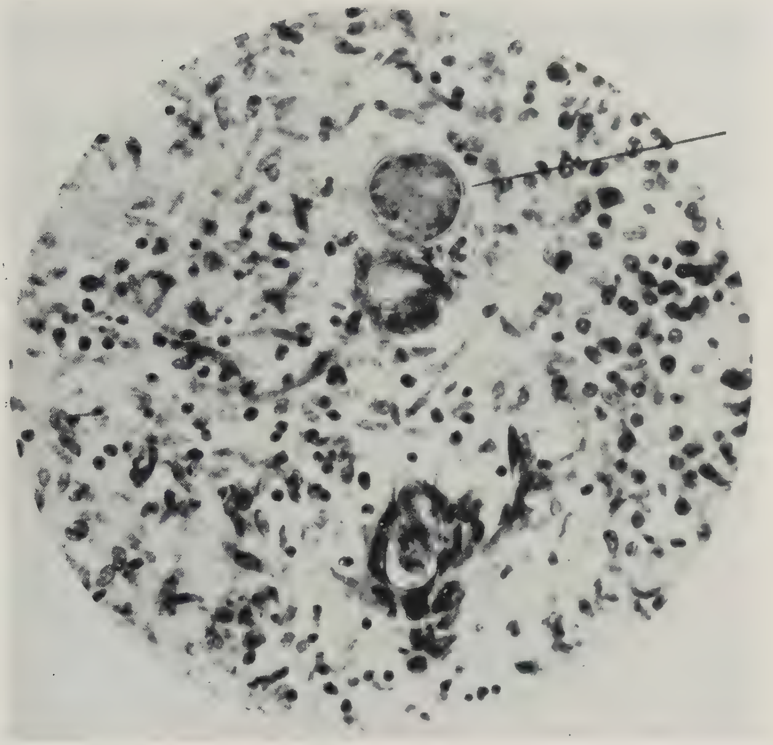

Fig. 575. *Coccidioides.* Hematoxylin-eosinol stain. Frozen section. Line leads to *Coccidioides.* (From Krajian, A. A., and Gradwohl, R. B. H.: Histopathological technic, St. Louis, 1952, The C. V. Mosby Co.)

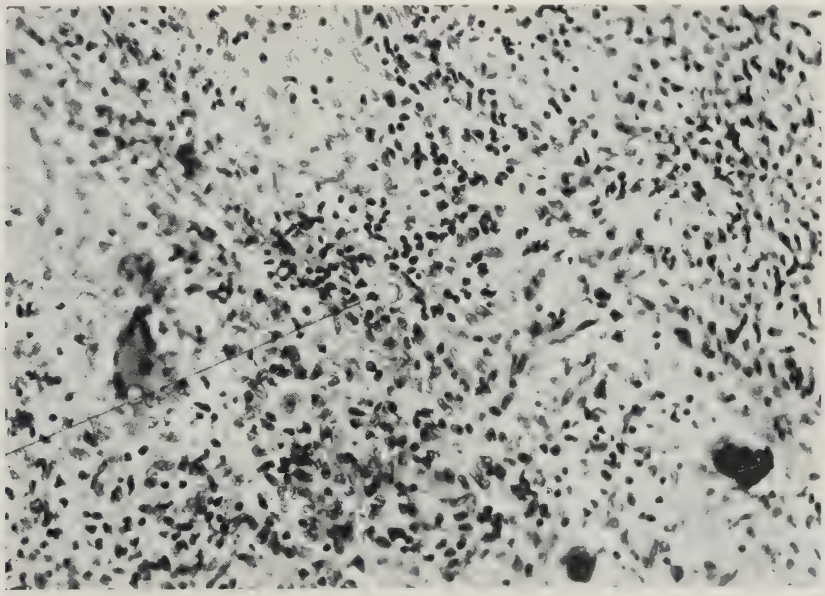

Fig. 576. *Blastomyces* in biopsy section. Hematoxylin-eosinol stain. Frozen section. Line leads to *Blastomyces.* (From Krajian, A. A., and Gradwohl, R. B. H.: Histopathological technic, St. Louis, 1952, The C. V. Mosby Co.)

sium ferrocyanide, is not soluble in hydrogen peroxide, and is found in liver and other organs in hemochromatosis.

Hemozoin occurs as black granules formed by malarial parasites living in red blood cells; it can be distinguished from carbon by its solubility in concentrated sulfuric acid. Hemozoin pigments do not give iron reaction.

Hemosiderin occurs as bright yellowish brown granules and masses. It is not soluble in water, alcohol, ether, or alkalies but is soluble in acids. It does not stain with fat stains.

Hematoidin occurs as orange-colored or red rhombic plates or as radiating bunches of yellow needles. It contains no iron, is not soluble in water, alcohol, or ether, but dissolves in chloroform. It is found in old hemorrhages, especially in infarcts of the spleen and brain.

Bile pigments occur as yellowish granules and masses. They are not soluble in water, alcohol, or ether.

Mallory fuchsin stain for hemofuscin:

1. Fix tissues in Zenker fluid, alcohol, or formalin, and make paraffin, celloidin, or frozen sections. Mount on slides and carry through alcohols into water as usual.
2. Stain in Harris hematoxylin until the nuclei stand out sharply.
3. Wash in tap water.
4. Stain for 10-20 min. in Mallory basic fuchsin (p. 1661).
5. Wash in water.
6. Differentiate and dehydrate in 95% alcohol, followed by absolute alcohol.
7. Clear in xylol and mount in colophonium.

Iron reaction with potassium ferrocyanide:

1. Make frozen, paraffin, or celloidin sections in the usual manner and stain for 10-20 min. in the following mixture:

Potassium ferrocyanide, 2% aqueous, freshly prepared	1 part
Hydrochloric acid, 1%	3 parts

2. Best results are obtained if the fluid is warmed. Heat the mixture in a clean Pyrex test tube until beads of vapor form on the inner surface of the glass, about 70° C. Then place the sections in it or pour the mixture over them in a Stender dish. The reaction takes place within ½-2 min.
3. Wash thoroughly in several changes of distilled water. Fix the sections to the glass slide with thin celloidin (p. 1666).
4. Counterstain in eosin. Rinse in water.
5. Dehydrate completely with 2 changes of absolute alcohol.
6. Clear in pure xylol.
7. Mount in gum damar.
8. Clear celloidin sections in oil of origanum.
9. Use distilled water for the solutions and washings.

Nuclei and hemofuscin stain bright red; hemosiderin, blue.

Staining slices of gross specimens for iron pigments: The potassium ferocyanide and hydrochloric acid method may easily be applied to slices of fresh tissue for diagnostic purposes or after fixation. Attractive museum preparations may be made and preserved.

Fresh tissues: Cut thin slices of tissue from suspected iron-containing organs and place in the potassium ferrocyanide-hydrochloric acid mixture. If iron is present, the blue reaction takes place within 2-10 min.

Museum specimens:

1. Fix large slices of liver or other organs containing iron in Kaiserling solution 1 (p. 2068) for several days.
2. Wash thoroughly under running water overnight.
3. Preserve in 80% alcohol.
4. Cut into thin slices to obtain smooth surfaces.
5. Place the slices in freshly prepared potassium ferrocyanide solution (p. 1730) warmed to 70° C. The reaction takes place in 2-5 min.
6. Wash under running water for 24 hr.
7. Mount in 80% alcohol along with an unstained slice for contrast. Do not use Kaiserling solution 3 because it causes the blue color to diffuse.

Autogenous pigments

Autogenous pigments occur normally in hairs and in the deeper layers of the epidermis, most abundantly in persons of dark complexion. These pigments produced in the body are termed "melanin." Melanin is a dark brown substance of great coloring power which occurs in cells as brown or black granules. It contains no iron or fat and does not react with iron or fat stains. It is not soluble in ordinary reagents except in alkalies. It is stained black by the silver nitrate method.

Masson melanin stain:

1. Make frozen, paraffin, or celloidin sections in the usual manner and carry through the various solutions to water.
2. Wash the sections in slightly ammoniacal distilled water (1 drop ammonium hydroxide to 100 ml. distilled water) for 2 or 3 hr.
3. Transfer sections to Fontana liquid for 2-3 hr.

Fontana liquid:

- (a) Add ammonium hydroxide to 5% aqueous silver nitrate until the precipitate which is formed is just dissolved.
- (b) Then add 5% silver nitrate drop by drop until the liquid is opalescent.
- (c) Let the fluid clear by standing.

4. Wash in distilled water.
5. Place sections in toning solution for 10 min.

Toning solution:

(a)

Ammonium sulfocyanate, 2% aqueous	3 ml.
Sodium hyposulfite	3 gm.
Distilled water	100 ml.

(b) Gold chloride,
    1% aqueous . . . . . 100 ml.
  Mix equal parts of (a) and (b) just before use.

6. Wash in distilled water.
7. Wash for 1 min. in 5% sodium hyposulfite.
8. Wash in several changes of distilled water.
9. Dehydrate in 95% alcohol; then in absolute alcohol.
10. Clear in xylol and mount in gum damar.

Melanin pigments assume a black color.

Exogenous pigments

Various substances enter the human body and are deposited there as pigments, among which the most important are carotin, carbon, iron, and silver.

Carotin is an orange yellow pigment derived from carrots, squash, and certain other vegetables. It is easily soluble in fats and fat solvents. It is not stained with fat stains.

Carbon occurs commonly and abundantly in the lungs and bronchial lymph nodes. At times it is carried to the spleen and liver, where recognition is important. It must be distinguished from malarial pigment. The distinguishing characteristics are its extreme black color and its insolubility in concentrated sulfuric acid, in which all other pigments dissolve.

Silver appears brown or black; it is turned black by ammonium sulfide and is removed by a mixture of potassium ferrocyanide and sodium hyposulfite.

Arsenic pigments—microchemical detection of arsenic in tissue[49]:

1. Fix the tissue in 10% formalin for 24-48 hr.
2. Wash in running water for at least 6 hr.
3. Cut in small pieces not over 2 mm. thick.
4. Place pieces of the tissue in a 1 oz. ground glass-stoppered bottle and fill the bottle nearly full with fresh neutral hydrogen sulfide solution. Place a small amount of petroleum jelly on the stopper and insert tightly; then bind down with a tape or cord. Incubate the bottle and contents between 70° and 80° C. for 4 days. Staining qualities may be better preserved if the tissue is incubated at a lower temperature for a longer time, 56° C. for 6 days. Change the neutral hydrogen sulfide daily.
5. Wash under running water for 6-12 hr.
6. Dehydrate by successive passages through 50, 70, 80, 95%, and absolute alcohol, each containing about 10% ether.
7. Embed in celloidin or paraffin and cut sections about 5μ thick. Remove the embedding medium from the section on the slide in the usual manner.
8. Place sections for 20 min. in 10% alcoholic hydrochloric acid to dissolve all sulfides except the arsenic trisulfide. Unfortunately this also seriously impairs the staining qualities of the tissue.
9. Wash in 70% alcohol for 20 min. and stain with hematoxylin and eosin as for routine section preparation.
10. Differentiate with 95% alcohol.
11. Clear in oil of cloves. Remove the excess with xylol.
12. Mount in gum damar.

Krajian argentaffin cell stain of frozen sections:

1. Cut thin frozen sections of formalin-fixed tissue.
2. Place for 30 min. in 10% ammonium hydroxide at 56° C.
3. Impregnate for 2 hr. at 55° C. in **ammoniacal silver solution.**
   (a) To 15 ml. 10% aqueous silver nitrate add strong ammonium hydroxide (28%) drop by drop, shaking well, until the precipitate of silver oxide is just dissolved; then add a few drops of 10% silver nitrate until there is a persistent opalescence.
4. Rinse in distilled water.
5. Tone in 1:300 gold chloride for 5 min.
6. Treat for 5 min. in 5% sodium hyposulfite solution.
7. Wash in distilled water.
8. Transfer to glass slides in the usual manner.
9. Dehydrate with isopropanol or absolute alcohol.
10. Clear in xylol.
11. Mount in gum damar.

Argentaffin granules stain opaque black; nuclei, light brown.

Calcium salts: The term "calcification" is applied to infiltration of tissue with calcium phosphate and calcium carbonate. The salts appear under the microscope as small refractive granules which may be mistaken for fat. They are dissolved in 5% nitric or hydrochloric acid.

Silver method for calcium in tissue—von Kossa:

1. Fix tissues in neutral 10% formalin or alcohol and make frozen, paraffin, or celloidin sections.
2. Place sections in 1.5% aqueous silver nitrate for 30-60 min.
3. Wash in distilled water.
4. Counterstain in safranin.
5. Dehydrate in absolute alcohol.
6. Clear in xylol and mount in gum damar.

Calcium salts appear as opaque black areas in the section.

Purpurin method for calcium in tissue:

1. Fix tissues in 10% neutral formalin or alcohol and make paraffin, celloidin, or frozen sections.
2. Stain in saturated alcoholic solution of purpurin for 5-10 min.
3. Rinse in 0.75% sodium chloride for 3-5 min.
4. Differentiate in 70% alcohol until the stain ceases to wash out of the section.
5. Dehydrate rapidly in absolute alcohol.

6. Clear in oil of origanum and mount in gum damar.

Calcium salts stain red.

CHROMATIN STAIN

1. Fix tissues preferably in mercuric chloride-acetic acid. Embed in paraffin and cut sections in the usual manner.
2. Stain in **Unna pyronine methyl green** stain for 10-30 min.

Methyl green (pure)	0.15 gm.
Pyronine	0.25 gm.
Alcohol, 95%	2.5 ml.
Glycerin	20 ml.
Phenol, 0.5% aqueous	100 ml.

The solution keeps indefinitely.

3. Wash in distilled water.
4. Blot in filter paper.
5. Dehydrate rapidly in absolute alcohol.
6. Clear in xylol and mount in gum damar.

Chromatin and nucleoli are fairly selectively stained green. Cytoplasm and bacteria stain red. The stain is not permanent.

CHROMAFFIN TISSUE STAINS

Wiesel method for chromaffin

1. Fix tissues for 1-4 days in the following fluid:

Potassium dichromate, 5% aqueous	10 ml.
Formalin, 10%	20 ml.
Distilled water	20 ml.

2. Treat with 5% potassium dichromate for 1-2 days.
3. Wash overnight under running water.
4. Dehydrate, clear, and embed in paraffin.
5. Stain sections for 20 min. in 1% aqueous toluidine blue or wasserblau.
6. Wash in water for 5 min.
7. Stain for 20 min. in 1% aqueous safranin. This may be omitted if desired.
8. Treat with 95% alcohol until the sections turn blue.
9. Dehydrate in absolute alcohol.
10. Clear in xylol. Mount in gum damar.

Chromaffin cells stain green; nuclei, red; cytoplasm of adrenal cortical cells, light blue.

Better results are obtained by omitting the safranin.

Giemsa method for chromaffin

1. Fix tissues in formol-dichromate mixtures as in the Wiesel method.
2. Wash in running water.
3. Make frozen sections (preferable) or embed in paraffin and cut sections.
4. Stain sections for 3-24 hr. in dilute Giemsa stain (1 drop Giemsa stain for every ml. neutral distilled water).
5. Wash in water.
6. Blot in fine paper.
7. Dehydrate with acid-free acetone and control differentiation under a microscope.
8. Clear in xylol and mount in thick cedarwood oil. Mounting in gum damar or balsam causes the sections to fade.

Medullary cells stain bright red to violet; cortical cells, blue to blue violet; red blood cells, pink.

PANCREATIC ISLET CELL STAINS

Lane-Bensley method

To distinguish between the α and β cells of the pancreatic islet tissue, Lane devised the following technic.

1. Fix small fragments of pancreatic tissue for 3-4 hr. in the following fluid:

Potassium dichromate	2.5 gm.
Mercuric chloride	5 gm.
Distilled water	100 ml.

2. Dehydrate, clear, and embed in paraffin in the usual manner.
3. Cut sections 3-5μ thick. Carry through solutions to water.
4. Stain for 24 hr. in Bensley neutral gentian violet (p. 1661).
5. Blot section in filter paper.
6. Dehydrate and partly differentiate by a few seconds' treatment with absolute alcohol.
7. Blot rapidly.
8. Flood the slide with oil of cloves and control the differentiation under a microscope until acinus cells show purple zymogen granules and their ground cytoplasm is brownish yellow.
9. Clear sections in pure xylol.
10. Mount in gum damar.

α **cells:** Cytoplasm barely stained; nuclei, pale purple.

β **cells:** Cytoplasmic granules, brilliant purple; nuclei, light purple.

Acinus cells: Zymogen granules, purple; ground cytoplasm, yellow.

No acetic acid should be added to the dichromate solution since it dissolves the granules of islet cells.

Bensley acid fuchsin methyl green stain

1. Fix tissues for 24 hr. in the following solution:

Osmic acid, 4% aqueous	2 ml.
Potassium dichromate, 2.5% aqueous	8 ml.
Glacial acetic acid	1 drop

2. Embed in paraffin in the usual manner and cut sections 5μ thick. Zenker-fixed tissues can also be stained by this method.
3. Free the sections from paraffin by toluol; then carry through absolute alcohol to water.
4. Treat with 1% aqueous potassium permanganate for 1 min.
5. Treat with 5% oxalic acid for 1 min.
6. Wash thoroughly in water.
7. Stain for 5 min. in aniline acid fuchsin solution (p. 1661) previously warmed to 60° C.
8. Wash thoroughly in water.

9. Dip for a few seconds in 1% aqueous methyl green.
10. Wash in water.
11. Dehydrate rapidly in absolute alcohol.
12. Clear in toluol and mount in gum damar.

Acinus cells stain green with green nuclei; zymogen granules, red; basal filaments and mitochondria, red; granules of α cells, deep red; granules of β cells, green.

Goodpasture acid polychrome methylene blue stain

This stain is used to differentiate α and β cells of islet tissue.

1. Fix thin pieces of fresh pancreas for 24 hr. in the following:
   Formalin, neutral . . . . . 10 ml.
   Zenker fluid without acetic acid 90 ml.
2. Wash under running water overnight.
3. Dehydrate in graded alcohols and embed in paraffin. Cut very thin sections, 3-5μ thick. Dissolve the paraffin in xylol; wash in alcohol and then in water.
4. Treat in 1% aqueous potassium permanganate for 1 min.
5. Treat in 5% aqueous oxalic acid for 1 min.
6. Wash thoroughly in tap water.
7. Stain in aqueous solution containing 1% eosin and 1% potassium dichromate for 1-5 min.
8. Wash rapidly in tap water.
9. Stain in acid polychrome methylene blue (p. 1660) for 1-5 min.; then wash rapidly in tap water.
10. Differentiate and dehydrate rapidly in 95% alcohol and then in absolute alcohol.
11. Clear in xylol and mount in gum damar.

Zymogen granules stain deep purple. Cytoplasm is light blue; nuclei, light purple; α granules bright red; β granules, dark blue.

Krajian method for zymogen granules

1. Prepare thin paraffin sections of Zenker- or formalin-fixed tissue.
2. Deparaffinize with 2 applications of xylol.
3. Remove xylol by anhydrous isopropanol or absolute ethyl alcohol, 3 applications.
4. Remove any mercury precipitate by Gram's iodine for 5 min. (if Zenker-fixed).
5. Differentiate in 5% strontium nitrate for 5 min.
6. Stain in **1% aqueous azocarmine** for 10 min.:
   Azocarmine . . . . . . 1 gm.
   Distilled water . . . . . 100 ml.
   Heat the solution for 20 min.
   Filter after cooling and acidify with 1 ml. glacial acetic acid.
7. Wash in tap water and place in 5% strontium nitrate for 5 min.
8. Wash in tap water and stain with **aniline blue–orange G** for 5 min.:
   Aniline blue . . . . . . 0.5 gm.
   Orange G . . . . . . 2 gm.
   Acetic acid . . . . . . 8 ml.
   Distilled water . . . . . 100 ml.
   Heat the mixture for several minutes, cool, and filter.
9. Wash in tap water and differentiate with 5% strontium nitrate for 3 min.
10. Wash and dehydrate 3 times with isopropanol or absolute alcohol.
11. Blot dry and partially clear with creosote-xylol for 5 min.
12. Pass through 2 changes of xylol, 3 min. each, and mount in Permount.

Zymogen granules are distinct bluish purple; reticulum and collagen fibers, brilliant blue; background, red. If formol-fixed tissue is used, mordant the section with thorium ferric for 10 min. after removal of the mercury.

PLASMA CELL STAIN

Unna method

Plasma cells are abundant in subacute and chronic infectious diseases.

1. Fix tissues in absolute alcohol. Fair results are obtained from tissues fixed in mercuric chloride, mercuric chloride-formol, or formalin.
2. Make paraffin or celloidin sections in the usual manner and carry through hydrating solutions to water.
3. Stain for 20-40 min. in Unna pyronine methyl green (p. 1660).
4. Wash in tap water.
5. Blot in filter paper.
6. Dehydrate very rapidly in absolute alcohol.
7. Clear in xylol.
8. Mount in gum damar.

Cytoplasm of plasma cells stains red; nuclei, bluish green. Lymphocytes also stain bluish green but are easily distinguished morphologically by their nuclei.

MAST CELL STAIN

Unna method

1. Fix tissues in absolute alcohol and make thin paraffin or celloidin sections. Carry through to water.
2. Stain in Unna polychrome methylene blue for 2 hr. in a paraffin oven or overnight at room temperature.
3. Wash in distilled water.
4. Dehydrate in 2 changes of 95% ethyl alcohol and blot.
5. Clear in oil of origanum for 5 min.
6. Treat with neutral xylol.
7. Mount in gum damar.

Mast cell granules stain red; nuclei, blue.

MITOTIC FIGURE STAIN

Mitotic figures are brought out sharply when tissue is perfectly fresh, that is, immediately after removal from a living organism. The details of mitotic figures are not so perfect in tissues removed at autopsy.

Tissue should be cut into very thin slices, not over 2 or 3 mm. thick, and fixed in a suitable fluid. Alcohol and Zenker fluid are preferable.

Staining with alum hematoxylin or safranin gives satisfactory results, but phosphotungstic acid-hematoxylin is highly recommended.

Mallory phosphotungstic acid-hematoxylin

1. Fix tissues in Zenker fluid for 16-24 hr.
2. Wash under running water overnight.
3. Dehydrate in graded alcohols, beginning with 70% and finally in absolute alcohol.
4. Embed in paraffin or celloidin, and cut sections. Carry through to water.
5. Treat with Lugol iodine solution for 5-10 min. to remove mercury precipitate.
6. Wash in 2 changes of 95% alcohol to remove every trace of iodine.
7. Wash in distilled water.
8. Treat in 0.25% aqueous potassium permanganate for 5-10 min.
9. Wash in tap water.
10. Treat in 5% aqueous oxalic acid for 5 min.
11. Wash thoroughly in several changes of tap water.
12. Stain in phosphotungstic acid-hematoxylin (p. 1658) for 24 hr.
13. Transfer directly to 95% alcohol, follow with absolute alcohol, and dehydrate quickly.
14. Clear in xylol (filter paper blotting method for celloidin sections).
15. Mount in gum damar.

Mitotic figures stain blue, as do the neuroglia, fibroglia, myoglia fibrils, and fibrin.

OXIDASE GRANULE STAIN

The following method is said to be useful for differentiating the granulocytic elements from the lymphocytic series of leukocytes; the myelogenous elements give a positive reaction, whereas the lymphocytes give a negative reaction.

Graham alpha-naphthol-pyronine method

The material must be formol-fixed, and freshly cut frozen sections must be used. After standing for 24-48 hr. in water, the granules may fail to react.

1. Stain sections lightly in Harris hematoxylin. The solution must not be too acid.
2. Wash in water and then for about 5 min. in saturated aqueous lithium carbonate. Return to water for a few minutes.
3. Stain for 10 min. in **alpha-naphthol-pyronine** staining solution:

Alpha-naphthol (Merck recrystallized or reagent grade)	1 gm.
Alcohol, 40%	100 ml.
Hydrogen peroxide	0.2 ml.

To 2 ml. of this solution add immediately before use 1 drop of 2% aqueous pyronine.

4. Wash in water; then place for 15-20 min. in saturated aqueous lithium carbonate. Wash thoroughly in several changes of water.
5. Differentiate and dehydrate in 80% alcohol, followed by 95% alcohol. Transfer to a slide and clear with xylol by the blotting method.
6. Mount in gum damar.

The oxidase granules stain intensely red; nuclei, greenish blue to blue.

HISTOPATHOLOGIC METHODS FOR NERVOUS SYSTEM TISSUE

NUCLEAR STAINS

Hematoxylin-eosin stain

Refer to pp. 1666, 1668, and 1691.

Ethyl violet-orange G stain

Stain:

Ethyl violet	1 gm.
Orange G	0.5 gm.
Distilled water	100 ml.

1. Stir to mix thoroughly.
2. Place in or on an oven for 12-24 hr. to precipitate.
3. Decant the supernatant fluid.
4. Wash the precipitate several times with distilled water.
5. Place in or on an oven to dry.
6. Dissolve in absolute alcohol (saturate).
7. For use add 1 part of the alcoholic solution to 3 parts of 20% alcohol.

Procedure:

1. Fix tissues in Zenker fluid and make paraffin sections in the usual manner. Formol-fixed paraffin sections can also be used if mordanted in Zenker fluid for 3 days. Carry through the hydrating solutions to water.
2. Fix in 3% potassium dichromate.
3. Treat in Lugol solution for 5 min.
4. Wash in water.
5. Stain in neutral ethyl violet-orange G for 12-24 hr.
6. Blot sections and wash in anhydrous acetone.
7. Dip in toluol and flood slide with pure clove oil.
8. Differentiate in a mixture of 3 parts of clove oil and 1 part of 95% alcohol.
9. Rinse in clove oil and wash in toluol.
10. Blot and clear in 2 changes of pure xylol.
11. Mount in gum damar.

Schultze-Stohr nerve cell stains for ganglion cells

1. Fix tissues in 10% formalin for 48 hr. or longer.

2. Cut frozen sections 30μ thick and place in distilled water.
3. Place in a solution consisting of 0.5 part of N/1 sodium hydroxide (4%) in 50 parts of distilled water for 24 hr. to remove granular precipitate.
4. Wash in a large quantity of distilled water for 1 hr., changing the water several times.
5. Place in 0.5% aqueous silver nitrate for 16 hr. or longer. The solution must remain clear when sections are placed in it.
6. Reduce in **hydroquinone solution,** made as follows:

Hydroquinone	2.5 gm.
Distilled water	100 ml.
Formalin	5 ml.

   The stock solution keeps for 3 mo. in a dark place. For reducing sections add 20 parts of distilled water to 1 part of stock solution.

7. Watch the reduction process under the microscope.
8. Wash quickly in distilled water and blot.
9. Dehydrate in several changes of absolute alcohol.
10. Clear in carbolxylol for 5 min.
11. Wash in 2 changes of pure xylol.
12. Mount in gum damar.

Cell bodies appear brown or black; dendrites, deep black.

Schultze-Stohr stain for brain tissue

1. Cut frozen sections 30μ thick and place in distilled water.
2. Place in sodium hydroxide solution for 24 hr. (6 parts of N/1 NaOH to 50 parts of distilled water).
3. Wash in distilled water for 1 hr. changing water frequently.
4. Place in 2% silver nitrate for 16 hr. or longer. There must be no clouding of the solution.
5. Reduce in hydroquinone solution (see above) for a few seconds and examine under the low power of a microscope. When the solution becomes cloudy, use fresh solution.
6. Wash in 2 changes of distilled water.
7. Dehydrate in 3 changes of absolute alcohol.
8. Clear in carbolxylol and then in 2 changes of xylol.
9. Mount in gum damar.

Stain for basal ganglia

1. Cut frozen sections 30μ thick and place them in sodium hydroxide solution (10 parts of N/1 NaOH to 50 parts of distilled water).
2. Wash in distilled water for 1 hr., changing the water frequently.
3. Place in 10% aqueous silver nitrate for 16-24 hr.
4. Reduce in hydroquinone solution (see above) for a few seconds. Examine under a microscope.
5. Wash in distilled water.
6. Dehydrate in 3 changes of absolute alcohol.
7. Clear in carbolxylol and then in 2 changes of pure xylol.
8. Mount in gum damar.

Stain for cerebellum

1. Cut frozen sections 30μ thick and place them in sodium hydroxide solution for 24 hr. (2 parts of N/1 NaOH to 50 parts of distilled water).
2. Wash in distilled water for 1 hr., changing the water frequently.
3. Place sections in 0.25% aqueous silver nitrate for 16-24 hr.
4. Reduce in hydroquinone solution (see above) for a few seconds, examining sections under a microscope.
5. Wash in distilled water.
6. Dehydrate in 3 changes of absolute alcohol.
7. Clear in carbolxylol and then in 2 changes of pure xylol.
8. Mount in gum damar.

Stain for medulla, spinal cord, and sympathetic ganglia

1. Cut frozen sections 30μ thick and place in sodium hydroxide solution for 24 hr. (10 parts of N/1 NaOH to 50 parts of distilled water).
2. Wash in distilled water for 4 hr., changing the water frequently.
3. Place sections in 10% aqueous silver nitrate for 16-24 hr.
4. Reduce in hydroquinone solution (see above) a few seconds, examining under a microscope.
5. Wash in distilled water.
6. Dehydrate in 3 changes of absolute alcohol.
7. Clear in carbolxylol and then in 2 changes of pure xylol.
8. Mount in gum damar.

Stain for glia

1. Cut frozen sections 30μ thick and place them in sodium hydroxide solution for 24 hr. (0.5 part of N/1 NaOH to 50 parts of distilled water).
2. Wash in distilled water for 48 hr., changing the water frequently.
3. Place sections in 0.5% aqueous silver nitrate for 16-24 hr.
4. Reduce in hydroquinone solution (see above) for a few seconds, examining sections under a microscope.
5. Wash in distilled water.
6. Dehydrate in 3 changes of absolute alcohol.
7. Clear in carbolxylol and then in 2 changes of pure xylol.
8. Mount in gum damar.

Stain for peripheral nerves

1. Cut frozen sections 30μ thick and place in sodium hydroxide solution for 24 hr. (10 parts of N/1 NaOH in 50 parts of distilled water).
2. Wash in distilled water for 1-2 hr., changing frequently.
3. Place in 10% aqueous silver nitrate for 24 hr.
4. Reduce in hydroquinone solution (see above). Since the reduction is very rapid and difficult to control, dilute the stock solution 100 times with distilled water and watch the process under the microscope.

5. Wash in distilled water.
6. Dehydrate in 3 changes of absolute alcohol.
7. Clear in carbolxylol and then in 2 changes of pure xylol.
8. Mount in gum damar.

When the nerve begins to appear during reduction, the section should at once be put into distilled water. If kept too long in the reduction fluid, the rest of the section stains the same dark color. If kept too short a time, the nerves cannot be identified; they stain incompletely or not at all. After the sections have been taken out of the reducing fluid and placed in distilled water, they cannot be returned to any fluid previously used. Thus sections should be taken out frequently from the reducing fluid and examined under a microscope to find the nerves.

NISSL GRANULE STAINS

Nissl's original method is long and complicated. The following methods may be used advantageously to demonstrate Nissl granules.

Toluidine blue stain for Nissl granules

1. Fix very thin blocks of tissue in 95% alcohol for 2-4 days.
2. Make thin paraffin or celloidin sections in the usual manner and hydrate in the usual manner.
3. Stain in 1% aqueous toluidine blue overnight at room temperature or 2 hr. in an oven at 55° C.
4. Rinse rapidly in water.
5. Dehydrate for 1 min. in 95% alcohol.
6. Differentiate in the following solution, controlling the extraction of stain under a microscope:

Creosote, pure	5 ml.
Cajuput oil	4 ml.
Xylol	5 ml.
Absolute alcohol	15 ml.

7. Rinse in absolute alcohol.
8. Clear in 2 changes of xylol.
9. Mount in gum damar.

Nissl granules stain blue against an unstained cytoplasmic background; nuclei remain nearly colorless.

Cyanin stain for Nissl granules

1. Cut frozen sections 5-10μ thick.
2. Transfer to slide.
3. Dehydrate and fix with celloidin in the usual manner for frozen sections.
4. Place in the following stain for 24-36 hr.:

Chrome alum	10 gm.
Distilled water	200 ml.

Mix and heat with 0.3 gm. cyanin.

Boil 20 min. Make up to original volume with distilled water. This keeps indefinitely. It should be filtered just before use.

5. Rinse in water.
6. Differentiate in 95% alcohol. Change 4 or 5 times.
7. Dehydrate rapidly in absolute alcohol.
8. Clear in xylol.
9. Mount in gum damar.

Cresyl echt violet stain for Nissl granules

1. Make thin frozen or paraffin sections in the usual manner.
2. Stain in 1% aqueous solution of cresyl echt violet (filtered) for 36 hr. at room temperature.
3. Wash in distilled water.
4. Differentiate in 95% alcohol until the background is white or nearly so.
5. Complete the dehydration in 3 changes of absolute alcohol.
6. Clear in 4 changes of pure xylol.
7. Mount in gum damar.

NERVE FIBER STAINS

Bielschowsky silver stain

Ammoniacal silver solution:

Silver nitrate, 10%	30 ml.
Sodium hydroxide, 40%	40 drops

1. A precipitate forms. Wash the precipitate a dozen times with distilled water, using approximately 1 L. water.
2. Add 50 ml. distilled water to the washed precipitate, and then add ammonium hydroxide drop by drop until the precipitate dissolves—avoid excess.
3. Dilute to 150 ml. with distilled water. Store in the dark.

Procedure:

1. Fix tissues in 15% formalin for 48 hr. or longer.
2. Wash several hours under running water.
3. Cut frozen sections about 10-15μ thick.
4. Wash thoroughly in distilled water.
5. Place in pyridine for 24-48 hr.
6. Wash in many changes of distilled water until the pyridine is completely eliminated.
7. Transfer to 3% silver nitrate for 24 hr. in a dark place at room temperature.
8. Take the sections one by one from the silver nitrate and wash quickly in distilled water.
9. Transfer to ammoniacal silver solution for about 10 min. until the sections become yellowish brown.
10. Wash quickly in distilled water.
11. Reduce in 20% aqueous formalin. If working with a number of sections, it is advisable to retransfer them to a fresh bath of 20% formalin. Reduction takes place at the end of 30 min. or less.
12. Wash in distilled water.
13. Tone in 2% gold chloride. Acidify the gold bath slightly with acetic acid to obtain a faintly purple background, or neutralize with a few drops of diluted sodium or lithium carbonate solution for a grayish background. A slightly acid solution of chloroplatinic acid may be used instead of gold chloride.
14. Wash in distilled water.
15. Treat in 5% sodium hyposulfite solution.
16. Wash in tap water.

17. Dehydrate completely in 3 changes of absolute alcohol.
18. Clear in carbolxylol 5 min.
19. Wash in 2 changes of pure xylol, and mount in gum damar.

Neurofibrils stain grayish black.

Cajal nerve fiber stain

This is an impregnation method for unmyelinated fibers in formalin-fixed tissues. Cajal nerve fiber stain is absolutely constant and is especially applicable to cerebellum.

1. Fix pieces of nerve tissue, especially cerebellum, in 15% formalin for 2 wk.
2. Cut frozen sections 15-20μ thick.
3. Place in 10% formalin. Wash rapidly in 2 changes of distilled water.
4. Place immediately in a freshly prepared mixture of 10 ml. 2% silver nitrate solution and 5 drops of pure pyridine.
5. Leave in the silver solution for 3-4 hr. if the

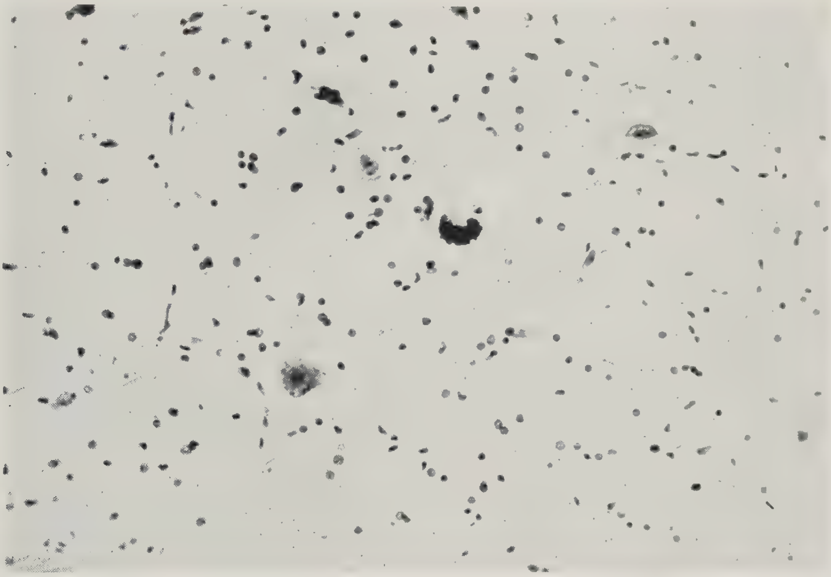

Fig. 577. Nerve cell stain. Cyanin method. Frozen section. (From Krajian, A. A., and Gradwohl, R. B. H.: Histopathological technic, St. Louis, 1952, The C. V. Mosby Co.)

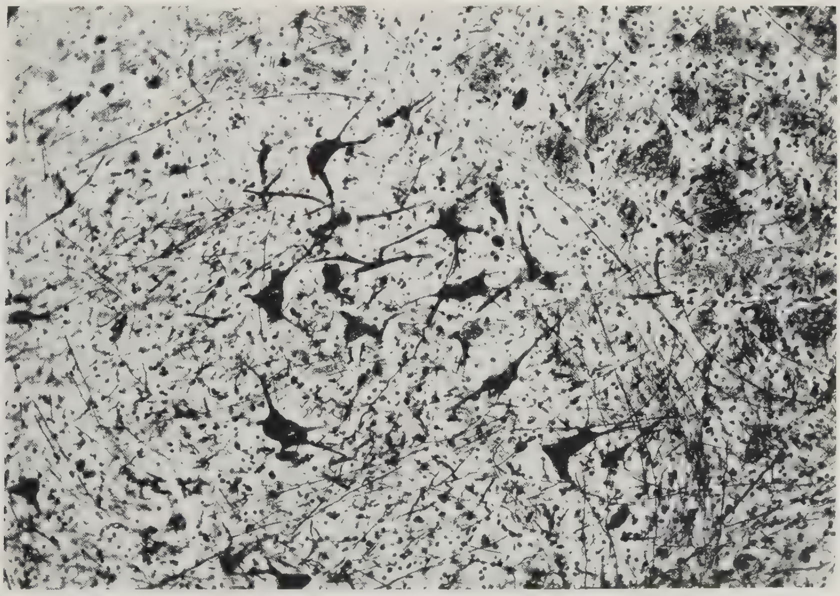

Fig. 578. Anterior horn cells of spinal cord. Reduced silver method (Cajal). Frozen section. (From Krajian, A. A., and Gradwohl, R. B. H.: Histopathological technic. St. Louis, 1952, The C. V. Mosby Co.)

tissues are fresh. Sections of old material should be left 20-40 hr. or until they are a tobacco color. Keep them in a dark place. If time is a factor, heat the solution for a few minutes.
6. Place in 10 ml. 95% alcohol for 1 min. If the impregnation is not intense (dark brown), add 2 or 3 drops of 2% silver nitrate solution to the alcohol bath.
7. Place sections without washing in the following **reducing solution:**

Hydroquinone, pure	0.2 gm.
Formalin (Merck)	30 ml.
Distilled water	70 ml.

Leave in this solution about 20 min.
8. Wash in distilled water.
9. Dehydrate in 3 changes of absolute alcohol.
10. Clear in carbolxylol for 5 min. Wash in 2 changes of pure xylol and mount in gum damar.

Unmyelinated fibers and chromatin stain black. If the sections are left in 95% alcohol for 6 hr. or longer before being placed in the reducing solution, the medullated fibers are well impregnated, but the cells remain unstained.

Only 1 section at a time should be placed in the alcohol bath.

NERVE ENDINGS AND PLEXUSES

Gold chloride method

Impregnation with gold chloride, when successful, produces a good picture of nerve endings and nerve plexuses.

1. Cut thin slices of fresh tissue.
2. Wash and place in physiologic saline and then in filtered lemon juice until they become clear. This requires 5-10 min.
3. Rinse with distilled water and place in 1% gold chloride (about 10 times their volume) in the dark for 30-40 min.
4. Rinse with distilled water and place in a mixture of 1 part of formic acid in 3 parts of distilled water. Keep in the dark for 24-48 hr., during which time the gold is reduced.
5. Wash in many changes of distilled water.
6. Tease apart the tissue block and mount in glycerin jelly (see Kaiser formula, p. 1655) or embed in paraffin in the usual manner, section, and mount in gum damar.

Nerve endings and plexuses stain violet to black.

MITOCHONDRIA STAIN

Bailey-Davis method

1. Fix tissues in Regaud fluid or 10% formalin and mordant 7-10 days in 3% potassium dichromate.
2. Wash, dehydrate, and embed in paraffin in the usual manner.
3. Cut sections 3-5μ thick. Carry thorough xylol, alcohols, to distilled water.
4. Place in 0.25% potassium permanganate for 30 min. or longer (up to 2 hr.) or in 1% solution for 20-30 min.
5. Wash in distilled water.
6. Bleach in 1% oxalic acid until colorless.
7. Wash in distilled water very thoroughly.
8. Stain in Mallory phosphotungstic acid hematoxylin (p. 1658) for 12-24 hr.
9. Wash out excess stain in 95% alcohol.
10. Dehydrate in 2 changes of absolute alcohol.
11. Blot and clear in 2 changes of pure xylol.
12. Mount in gum damar.

Cowdry mitochondria stain

1. Fix tissues in Regaud mixture (p. 1641). The commercial formalin may profitably be neutralized by saturation with magnesium carbonate. The mixture may be applied by immersion or injection, the latter being recommended for large objects. It should be changed every 4 days.
2. Mordant 8 days in 3% potassium dichromate, changing every second day.
3. Wash in running water overnight.
4. Dehydrate, clear, and embed in the usual manner.
5. Cut paraffin sections and pass slides to water in the usual manner.
6. Place in 1% potassium permanganate for 30 sec. or longer.
7. Place in 5% oxalic acid for 30 sec.
8. Rinse in several changes of distilled water for about 1 min. each. Incomplete washing prevents staining with fuchsin.
9. Stain in Altman aniline fuchsin (p. 1661). To stain, dry the slide with a towel, leaving the small area to which the section is attached. Cover the section with stain and heat over a small flame until strong aniline oil fumes come off; allow to cool; let the stain remain on the section about 6 min.; return the stain to the bottle.
10. Absorb most of the stain with a towel and rinse in distilled water so that the only remaining stain is in the section. If a large amount of stain is left, it will form a precipitate with methyl green. On the other hand, if too much stain is removed, the coloration of mitochondria will be faint.
11. Allow a few drops of 1% methyl green to flow over the section from a pipet, holding the slide over a piece of white paper so that colors may be seen. Apply the methyl green for about 5 sec. at first and modify as required. This is the crucial point of the method.
12. Drain off the excess stain, plunge into 95% alcohol for a few seconds, then rinse in absolute alcohol, clear in toluol, and mount in gum damar.

Note:

1. The methyl green may remove all the fuchsin, even when applied for only a short time. This is due to incomplete mordanting of the mitochondria by the chrome salts in fixation. It may be avoided by omitting the

permanganate and oxalic acid steps or by treating the section with 2% potassium dichromate for a few seconds just before staining. The purpose of potassium permanganate and oxalic acid is to remove the potassium dichromate.

2. The fuchsin may stain so intensely that the methyl green removes it imperfectly or not at all. This is due to too much mordanting. It may be corrected by prolonging the permanganate and oxalic acid treatment.

3. At times, after obtaining a good differentiation, the methyl green is washed out before the slide is placed in toluol, in which event omit the 95% alcohol and pass directly to absolute alcohol.

MYELIN SHEATH STAINS

Weigert-Pal method

The Weigert-Pal method is slow but very useful. Refer to p. 1708 for the method.

Spielmeyer method

The Spielmeyer procedure is a good stain for fine detail of myelinated fibers. Refer to the method on p. 1708 and Fig. 558, p. 1708.

Courville-Krajian method

Krajian myelin sheath stain has all the advantages of the longer methods, shows very fine detail of the fibrils, and can be completed in 1 hr. Refer to the method on p. 1709 and Fig. 559, p. 1709.

Pal-Kulschitzky method

Pal-Kulschitzky method usually yields satisfactory results and is valuable for rapid staining of myelin sheath. Refer to the method on p. 1709.

Morgan method

Morgan myelin sheath stain is a useful method to demonstrate myelin in paraffin sections. It is described on p. 1710.

NONMEDULLATED NERVE FIBERS

Ranson method

1. Fix segments of nerve for 48 hr. in a mixture of 99 ml. absolute alcohol and 1 ml. ammonium hydroxide.
2. Rinse tissues in distilled water.
3. Place in pyridine for 24 hr.
4. Place in many changes of distilled water for 24 hr.
5. Place in 2% silver nitrate for 3 days in the dark.
6. Rinse in distilled water.
7. Reduce for 24-48 hr. in 4% pyrogallol in 5% formalin.
8. Wash in water.
9. Dehydrate in graded alcohols, embed in paraffin, and cut sections.

This is a modification of the Cajal technic for neurofibrils. Nonmyelinated fibers appear black; myelinated axons, yellow; endoneurium, pale yellow.

NEUROGLIA FIBER STAINS

Cajal gold chloride and sublimate method

Fixative:

Formalin	15 ml.
Ammonium bromide	2 gm.
Distilled water	85 ml.

Gold chloride solution:

Distilled water	60 ml.
Bichloride of mercury	0.5 gm.
Gold chloride, 1% (Merck brown)	10 ml.

Fixing bath:

Sodium hyposulfite, saturated solution	5 ml.
Distilled water	70 ml.
Alcohol, 95%	30 ml.
Sodium bisulfite, saturated solution	5 ml.

Procedure:

1. Fix tissues for 2-10 days in the special fixative.
2. Cut frozen sections 20-25μ thick and place in distilled water to which a few drops of formalin have been added. After a quick wash transfer 4-6 sections into separate glass dishes of about 6 cm. diameter, each containing 15 ml. of the gold chloride solution.
3. After about 4 hr. the sections will have acquired an intense purple color. Place them in the fixing bath for 5-10 min.
4. Wash in 50% alcohol, transfer sections to slides, and blot in filter paper.
5. Dehydrate in 3 changes of absolute alcohol.
6. Clear in oil of origanum for 5 min.
7. Wash in 2 changes of pure xylol and mount in gum damar.

Precautions: Use pure brown gold chloride (Merck). If sections are left longer in the bath, good results may be obtained with ordinary gold chloride, but Cajal does not advise its use. Use only crystallized mercuric chloride. Temperature must not be lower than 12° C. for human brain tissue; it should be between 18° and 22° C. For cerebellum, medulla, and spinal cord, between 22° and 26° C. is preferred. Fixation for 3-15 days is preferable, but fibrous neuroglia may be fixed up to a year. The material must be in the fixative within 6 hr. after death.

Neuroglia are stained a dark purple on a much lighter purple background.

Globus modification of Cajal gold sublimate method for neuroglia

Globus provided a method of rendering tissue hardened in formalin available for staining with gold chloride which may be used if the tissue has not been in formalin too long.

1. Prepare frozen sections of formalin-fixed material 15-30μ thick.
2. Wash quickly in several changes of distilled water.
3. Place in 10% ammonium hydroxide for 24 hr. at room temperature or for a shorter period in an incubator.
4. Carry rapidly through 2 changes of distilled water.
5. Place in 10% solution of 41% hydrobromic acid for 2-4 hr.
6. Wash quickly in 2 changes of distilled water to which a few drops of ammonium hydroxide have been added. Place in Cajal gold chloride solution (p. 1739).
7. The sections assume an intense purple color after about 4 hr. Place 5-10 min. in Cajal fixing bath (p. 1739).
8. Wash in 50% alcohol, float, and transfer sections to slides. Blot in filter paper.
9. Dehydrate in 3 changes of absolute alcohol.
10. Clear in oil of origanum for 5 min.
11. Wash in 2 changes of pure xylol and mount in gum damar.

ASTROCYTES

Achucárro's fourth variant of Hortega

Tannin bromide solution:

Tannin	3 gm.
Ammonium bromide	1 gm.
Distilled water	100 ml.

Procedure:

1. Fix tissues in 10% formalin.
2. Cut frozen sections and wash thoroughly in distilled water.
3. Place for 10 min. in tannin-bromide solution at 45°-50° C.
4. Before the sections cool wash in 20 ml. distilled water containing 2 drops of ammonium hydroxide, until they have regained their flexibility and transparency.
5. Place at once in dilute Bielschowsky silver (1:10) (p. 1736) until sections assume a yellowish color.
6. Transfer to a fresh dish as soon as the liquid becomes turbid (use about 3 dishes).
7. Wash in distilled water.
8. Reduce in 20% formalin (neutralized with chalk).
9. Wash and dehydrate in absolute alcohol.
10. Clear in carbolxylol, wash in xylol, and mount in gum damar.

GLIA FIBRIL STAINS

Mallory phosphotungstic acid hematoxylin

Mallory phosphotungstic acid hematoxylin is particularly useful for demonstrating fibrin and neuroglia, fibroglia, and myoglia fibrils. It also brings out the detailed structure in mitotic figures, including the spindles and centrosomes. See p. 1734.

Alzheimer method for glia fibril

1. Fix tissues for at least 1 wk. in 10% formalin. Cut frozen, paraffin, or celloidin sections 5-10μ thick. Mount on slide and carry through customary hydrating solutions to distilled watter.
2. Mordant in a mixture of 19 ml. 1% chromic acid and 1 ml. glacial acetic acid.
3. Wash quickly but thoroughly in distilled water.
4. Place sections for 1 hr. in a paraffin oven at 55° C. in a saturated aqueous solution of acid fuchsin in a jar.
5. Wash in water until no more color comes off.

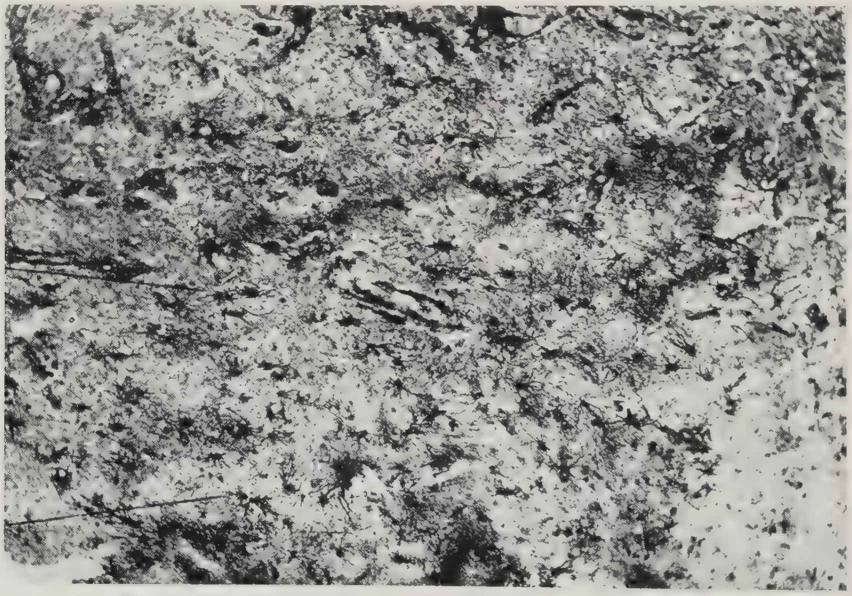

Fig. 579. Astrocytes in glioblastoma, Achucárro method. Frozen section. Lines lead to astrocytes. (From Krajian, A. A., and Gradwohl, R. B. H.: Histopathological technic, St. Louis, 1952, The C. V. Mosby Co.)

6. Agitate sections in a mixture of 30 ml. saturated alcoholic picric acid and 60 ml. distilled water.
7. Wash in 2 changes of distilled water.
8. Place sections in saturated aqueous solution of light green, which has been diluted with an equal amount of distilled water, for about 30 min.
9. Wash in water.
10. Dehydrate in 95% alcohol and then in 2 changes of absolute alcohol.
11. Clear in 2 changes of pure xylol and mount in gum damar.

Glia fibrils stain bright red against a very pale green background.

Heidenhain method for glia fibril

1. Fix tissues in 10% formalin.
2. Embed in paraffin in the usual manner.
3. Cut sections 5-10μ thick.
4. Remove the paraffin by xylol and place in 2.5% (violet) iron alum solution for 6-12 hr.
5. Wash in distilled water rapidly but thoroughly.
6. Stain in 0.5% old aqueous hematoxylin (p. 1658) 30 min. or longer.
7. Wash in distilled water.
8. Differentiate in a weak solution of iron alum, controlling the differentiation under a microscope.
9. Wash thoroughly in tap water.
10. Rinse in distilled water.
11. Dehydrate in 95% alcohol; follow with absolute alcohol.
12. Blot and clear in 2 changes of pure xylol.
13. Mount in gum damar.

OLIGODENDROGLIA STAINS

Hortega silver carbonate method

Hardening solution:

Hydrobromic acid, 40%	5 ml.
Distilled water	95 ml.

Strong silver carbonate solution:

Silver nitrate, 10%	5 ml.
Lithium carbonate, saturated solution	20 ml.
Ammonium hydroxide	Sufficient to dissolve precipitate
Distilled water	75 ml.

1. When the 2 chemicals are combined, there is a voluminous precipitate of silver carbonate. The ammonia should then be added drop by drop, stirring all the while, until the precipitate disappears and ammoniacal silver goes into solution. A small amount of black, dustlike precipitate remains undissolved and may be filtered off.
2. The solution keeps well in the dark.

Procedure:

1. Harden tissues for 12-48 hr. in Cajal fixative, p. 1739.
2. Bromurate by heating blocks in fresh hardening solution for 10 min. at 45°-50° C.
3. Cut frozen sections 15-20μ thick.
4. Wash in 2 changes of distilled water. Add 10 drops of ammonium hydroxide to the first water.
5. Impregnate. Place sections in strong silver carbonate solution and leave there for 1-5 min.
6. Wash. Agitate gently for about 15 sec.
7. Reduce by dipping sections in 1% formalin but do not agitate.
8. Wash and tone in 0.2% aqueous gold chloride.
9. Fix in 5% sodium hyposulfite for 1 min.
10. Wash in distilled water, dehydrate, clear, and mount in the usual manner.

Oligodendroglia will stain selectively. There may be faint staining of astrocytes, and microglia may stain well.

Penfield modification of Hortega silver carbonate method

1. Harden tissues in ammonium bromide solution (p. 1739) for 2-48 hr. Blocks should be not more than 3 mm. thick.
2. Place blocks in 95% alcohol for 36-48 hr.
3. To eliminate the alcohol wash blocks about 4 hr. in several changes of distilled water in large volume.
4. Cut frozen sections. If the alcohol is not sufficiently washed out, cutting will be difficult.
5. Pass through 2 changes of distilled water.
6. Leave in strong silver carbonate (p. 1741) for 15 min.-2 hr., as determined by trial. The most favorable time to remove sections is when they are just beginning to turn brown.
7. Plunge directly into 1% formalin and agitate at once.
8. Wash in water.
9. Tone in 0.2% gold chloride solution until gray.
10. Fix in 5% sodium hyposulfite for 1 min.
11. Wash, dehydrate, clear, and mount as usual.

This method, like that of Hortega, is variable, although the results are brilliant when successful.

MICROGLIA STAIN

Hortega silver carbonate method for microglia

1. Fix thin pieces of tissue, 2 or 3 mm. thick, in Cajal fixative (p. 1739) 1 or 2 days at 35° C. or 2-4 days at room temperature.
2. Warm the pieces of tissue for 10 min. at 50°-55° C. in a fresh volume of the fixative.
3. Make frozen sections 25-30μ thick.
4. Rinse quickly in 2 changes of distilled water containing 2 drops of ammonium hydroxide for each 50 ml. water.
5. Treat for 10 min. at 15°-20° C. in ammoniacal silver carbonate solution. To make this solution add 5 ml. 10% silver nitrate to 20 ml. 5% sodium carbonate, add ammonium hydroxide drop by drop until the yellow precipitate is just dissolved, and then add 15 ml. water.
6. Reduce in 10% acid-free formalin. Move sections during this process. A simple expedient is to place them in a large Petri dish and blow on the fluid gently.

7. Wash in distilled water.
8. Tone in 0.2% yellow gold chloride solution until the sections turn gray, usually 10-15 min.
9. Treat in 5% sodium hyposulfite for 1 min.
10. Dehydrate in 95% alcohol.
11. Clear in **carbolxylol-creosote** mixture:

Phenol	10 gm.
Xylol	80 ml.
Creosote, pure	10 ml.

12. Mount in gum damar.

Microglia stain deeply; fibrous neuroglia and glia fibers stain faintly.

OLIGODENDROGLIA AND MICROGLIA STAIN

Penfield combined method

Hortega weak ammoniacal silver carbonate solution:

Silver nitrate, 10%	5 ml.
Sodium carbonate, 5%	20 ml.
Ammonium hydroxide	Sufficient to dissolve precipitate
Distilled water	to make 75 ml.

1. Add the ammonium hydroxide drop by drop until the precipitate is just dissolved, stirring constantly. Do not add too much ammonia. A fine black sediment should remain, which does not resemble the more voluminous precipitate of silver carbonate.
2. Filter off this fine sediment.
3. The solution may then be preserved in a dark bottle for long periods.

Procedure:

1. Harden tissue in 10% formalin or formol-ammonium bromide (p. 1739) for an indefinite period. About a week's fixation in formalin gives excellent results.
2. Cut frozen sections 20μ thick and place in 1% formalin or distilled water. Through the succeeding steps handle sections with a glass rod.
3. Place in a dish of distilled water to which 10-15 drops of ammonium hydroxide have been added and cover to prevent escape of the ammonia. Leave in this solution overnight to remove the formalin.
4. Transfer directly to 5% aqueous hydrobromic acid (41%). Place in an incubator at 38° C. for 1 hr.
5. Wash in 3 changes of water.
6. Place in 5% sodium carbonate for 1 hr. Sections may remain in this solution 3-6 hr. without ill effect.
7. Pass, with or without washing, directly into Hortega weak silver carbonate and leave for 3-5 min. At times the sections may be left until they begin to turn yellowish gray. Then transfer to 1% formalin (reducer). Control the duration in the silver solution by taking out a section at intervals of 1-2 min. and examining under a microscope. The sections should turn a smooth gray color in the reducer.
8. Plunge into 1% formalin and agitate.
9. Wash in distilled water.
10. Tone in 1:500 gold chloride at room temperature until all yellow tint disappears and the sections are a smooth bluish gray.
11. Treat in 5% sodium hyposulfite.
12. Wash in distilled water.
13. Float onto slides and flatten out with a teasing needle.

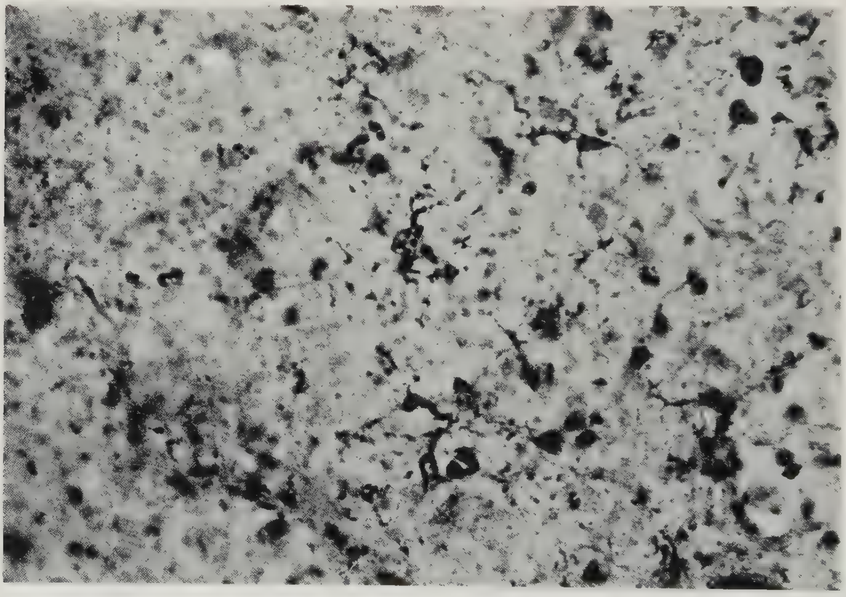

Fig. 580. Early changes of microglia in old gunshot wound of brain. Penfield combined method. Frozen section. (From Krajian, A. A., and Gradwohl, R. B. H.: Histopathological technic, St. Louis, 1952, The C. V. Mosby Co.)

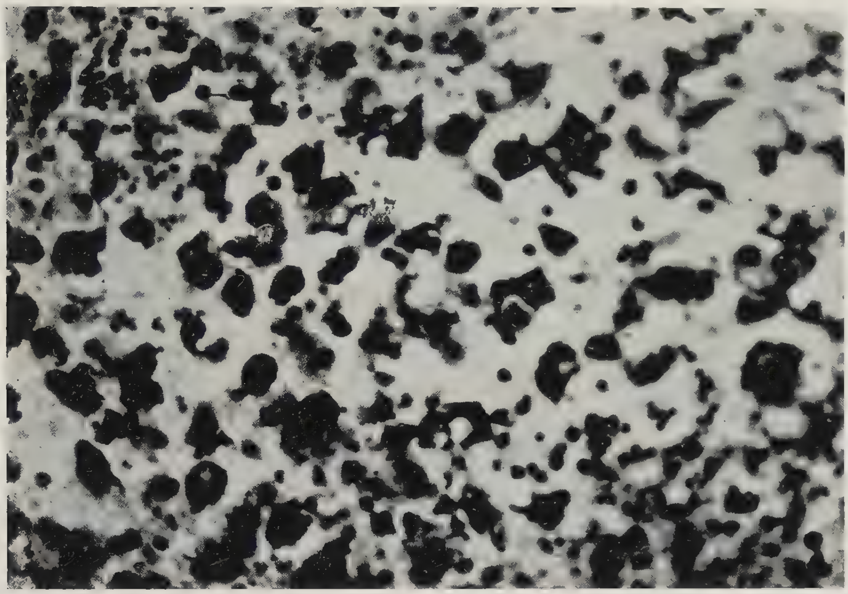

Fig. 581. Microglia developing phagocytes at margin of a brain wound. Penfield combined method. Frozen section. (From Krajian, A. A., and Gradwohl, R. B. H.: Histopathological technic, St. Louis, 1952, The C. V. Mosby Co.)

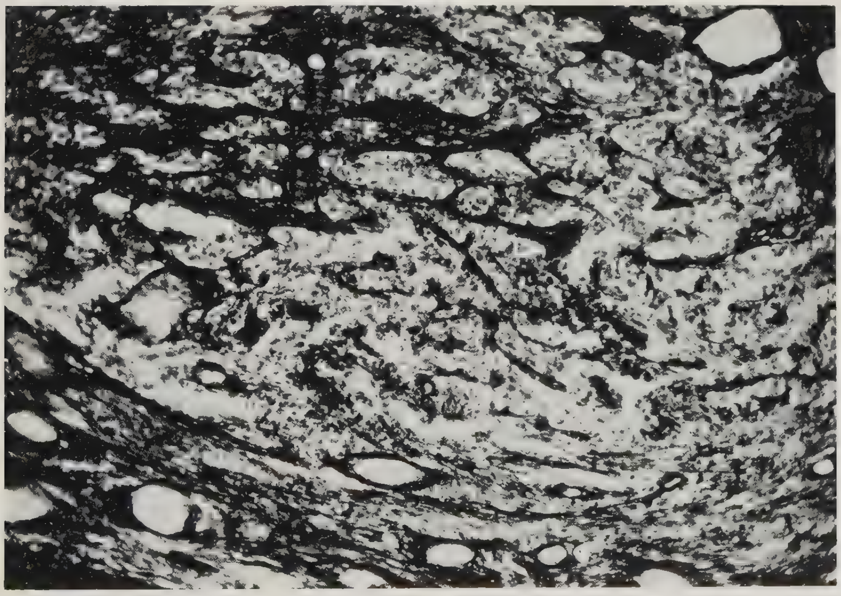

Fig. 582. Reticulum in a ganglion cell tumor. Krajian reticulum stain. Reticular fibers stain black. Frozen section. (From Krajian, A. A., and Gradwohl, R. B. H.: Histopathological technic, St. Louis, 1952, The C. V. Mosby Co.)

14. Dehydrate in 2-4 changes of 95% alcohol from a drop bottle.
15. Follow with a few drops of carbolxylol. When clear, drain the slides and blot immediately with 2 thicknesses of fine filter paper.
16. Mount in gum damar.

The yellow variety of gold chloride is less expensive than the brown and seems to be preferable for toning.

This method is highly recommended.

RETICULUM STAINS

Use Perdrau modification of the Bielschowsky stain, the Krajian rapid method for staining reticulum and collagen fibers in frozen sections, or the Foot method for staining reticulum in paraffin sections.

CONNECTIVE TISSUE STAINS

Use Mallory aniline blue stain or the Van Gieson method. The Heidenhain azocarmine stain is excellent for demonstrating minute details of connective tissue.

Chapter 93

Otohistologic technics

ARAM A. KRAJIAN

USE OF RADIOACTIVE METALLIC SALTS AND OTHER RARE METALLIC SALTS AND CHEMICALS

In otohistology, most present-day staining is done with hematoxylin and aniline dyes; some selective stains are used, such as Mallory aniline blue and van Gieson stains to demonstrate connective tissue.

Because of prolonged immersion of temporal bones in strong acids and subsequent dehydrating and embedding technics, the resulting microscopic sections often fail to show the desired nuclear stain or do not differentiate the various elements of the tissue, such as smooth and striated muscle fibers, connective tissue fibers, ganglion cells, bone tissue, fat globules, fibrin, hair cells, lacuna, caniculi, osteocytes with their processes, etc.

In the histology laboratories of a number of hospitals and universities some metallic salt, such as mercuric chloride, is used as a mordant in Zenker and Helly solutions. Silver nitrate is extensively used in neuropathologic work for the demonstration of nerve fibers, basal ganglia, ganglion cells, nonmedullated nerve fibers, glia, astrocytes, microglia, oligodendroglia, peripheral nerve fibers, and reticulum. Gold chloride is used to demonstrate nerve endings. In our efforts to develop selective staining technics for temporal bone sections, we have made use of hitherto untried radioactive metallic salts such as thorium and uranium nitrate, as well as other metallic salts such as strontium nitrate, bismuth nitrate, iodine, gold chloride, stannous chloride, lead nitrate, magnesium nitrate, cobalt nitrate, molybdenum nitrate, nickel nitrate, palladium nitrate, zirconium nitrate, zinc nitrate.

Several mordants have been developed with the combination of the above metallic salts and other chemical elements. Among the mordants produced, the most effective was thorium-ferric ammonium sulfate combination. Utilizing this mordant, the following new selective stains were developed.

Method 1—New selective hematoxylin

A new selective hematoxylin is described for demonstrating smooth and striated muscle fibers, elastic and connective tissue, bone tissue, nerve fibers, plasma cells, erythrocytes, and leukocytes.

Prepare celloidin sections as on p. 1753.

Reagents:

1. Strong iodine solution.
    (a) Thoroughly mix 2 gm. iodine and 4 gm. potassium iodide in a mortar. Dissolve in 5 ml. distilled water; then add 95 ml of distilled water.
2. Thorium-ferric solution.

Thorium nitrate	4 gm.
Ferric ammonium sulfate	10 gm.
Distilled water	100 ml.

3. Creosote-xylol.
    (a) Equal parts of beechwood creosote and xylol.

Procedure:

1. Place sections in 10% strontium nitrate for 5 min.; then rinse in tap water.
2. Treat in strong iodine solution for 5 min.
3. Wash in 3 changes of tap water and mordant in thorium-ferric solution for 10 min.
4. Wash in 3 changes of distilled water and stain in Harris hematoxylin (p. 1658) for 30 min.
5. Wash and treat for 3 min. in 3% sodium cyanide.
6. Wash in tap water and differentiate in 5% solution of thorium nitrate for 2-5 min. This

Fig. 583. Celloidin sections of temporal bone and frozen sections of brain.

Fig. 583

Celloidin sections of temporal bone
Method 1: Temporal bone section (selective hematoxylin stain)
1. Bone tissue, magenta; cartilage, light red; tendon, grayish red.
2. Neck muscle. Smooth muscle fibers, dark red; striated muscle fibers, dark blue; connective tissue, light red.
3. Bone tissue, magenta; cochlear nerve, blue.
4. Bone tissue, magenta; marrow, dark grayish blue; cartilage, light red.
5. Bone tissue, magenta; connective tissue cells, blue.
6. Cartilage, light pink; cartilage cells, dark blue.
7. Bone tissue, magenta; marrow, blue gray.
8. Bone tissue, magenta; cartilage, pinkish blue; connective tissue, red.
9. Mucous glands. Secretion, gray blue; connective tissue, red; cartilage, reddish blue.
10. Spiral ligament, purplish blue; hair cells, purple; connective tissue, red; tectorial membrane, light pink.
11. Cross section of acoustic nerve, purplish blue.

Method 2: Temporal bone section (new differential nerve stain)

12. Striated muscle fibers, purple; connective tissue, red.
13. Bone tissue, magenta red; fibrin, grayish blue.
14. Bone tissue, magenta red; marrow, grayish blue.
15. Bone tissue, rose red; cochlear nerve fibers, purplish blue.
16. Bone tissue, magenta red; fibrin, grayish blue.
17. Acoustic nerve, purplish blue.
18. Cochlear cavity. Bone tissue, rose red; spiral ligament, brownish red; connective tissue, pink; tectorial membrane, creamy yellow.

Fig. 583 (cont'd)

Celloidin sections of temporal bone (cont'd)
Method 3: Temporal bone section, chemical coloration (gold chloride)
19. Bone tissue, dark blue; marrow, rose.
20. Cochlear bone, dark blue; spiral ligament, light rose; cartilage cells, light rose.
21. Bone tissue, dark blue; cartilage, light blue; cartilage cells, rose.
22. Bone tissue, dark blue; nerve fibers, rose.

Method 4: Temporal bone section, chemical coloration (iodine combination method)
23. Neck muscle. Smooth muscle fibers, dark blue; connective tissue, light blue; striated muscle fibers, dark brown.
24. Striated muscle fibers, dark brown; connective tissue, light blue.
25. Bone tissue, dark blue; nerve fibers, brown; cartilage, light greenish blue; striated muscle fibers, dark brown.
26. Arterial wall, brown; elastic fibers, dark brown; connective tissue, dark blue.
27. Bone tissue, deep greenish blue; marrow, light brown.
28. Striated muscle fibers, dark brown; connective tissue, blue; cartilage, light blue; mucous glands, brown; connective tissue, light blue.
29. Neck muscle. Smooth muscle fibers, dark blue; striated muscle fibers, magenta red (azocarmine counterstain).
30. Striated muscle fibers, magenta red (azocarmine counterstain).

Method 5: Temporal bone section, chemical coloration (zinc permanganate)
31. Compact bone, brown; haversian canal nerve fibers, brown; connective tissue, greenish blue; lacuna, bright blue; nucleus of osteocyte, dark brown; osteocytic processes, brown; devitalized osteocytes, dark brown.
32. Temporal bone. Vestibular membrane, light greenish blue; vestibular nerve, brown; tectorial membrane, light greenish blue; hair cells, dark brown.
33. Mucous glands. Glands, brown; bone tissue, dark blue; connective tissue, light blue; cartilage, light grayish blue; striated muscle fibers, dark brown.

Frozen sections of brain
Method 6: New myelin sheath stain for frozen sections
34. Brain tissue. Myelinated fibers, blue black.
35. Brain section. Myelinated fibers, blue black.
36. Brain section. Brain cells, light pink with brown nuclei.

Fig. 583 (cont'd)

treatment depends on the strength of the solution and the thickness of the sections. It should be controlled under a microscope or until the celloidin around the section clears.

7. Wash in tap water and transfer the section to a glass slide.
8. Blot dry and dehydrate with benzol for 1 min.
9. Pour off the benzol, blot, and dip once in thin celloidin (p. 1666).
10. Clear for 3 min. in creosote-xylol and then 5 min. in pure xylol.
11. Mount in gum damar or Permount.

All solutions are stable and can be used repeatedly.

Bone tissue stains shades of magenta; bone marrow cells, light gray; bone cells, dark blue; red blood cells, grayish blue; connective tissue, shades of light red; striated muscle fibers, blue black; smooth muscle fibers, red; fatty acid crystals, gray blue; walls of blood vessels, dark blue; nerve fibers, deep blue; plasma cell nuclei, blue with cytoplasmic granules; calcium, gray blue; elastic fibers, dark blue; cartilage, light pink.

Method 2—
New differential nerve stain

The following stain demonstrates fibrin, smooth and striated muscle fibers, elastic and connective tissue, bone tissue, hair cells, erythrocytes, and leukocytes by the use of **thorium-ferric ammonium sulfate mordant** and with the addition of lithium and bismuth nitrate.

Prepare colloidin sections (p. 1753).

Reagents:

1. Phospho-hematoxylin.
   Hematoxylin crystals . . . . 0.1 gm.
   Distilled water . . . . 5 gm.
   (a) Dissolve with the aid of heat.
   (b) Mix in 100 ml. 2% phosphotungstic acid.
   (c) For immediate use, ripen by adding 10 ml. 0.25% potassium permanganate.

Procedure:

1. Place temporal bone section in warm (30° C.) 10% lithium nitrate for 5 min.
2. Wash in 2 changes of tap water.
3. Mordant in thorium ferric solution at 30° C. for 10 min. (p. 1745).
4. Wash in 3 changes of tap water and place in warm (30° C.) 2% bismuth nitrate for 10 min. The bismuth solution should be filtered.
5. Wash and stain in warm (30° C.) phospho-hematoxylin.
6. Wash twice in tap water and treat in 2% magnesium nitrate solution for 1 min.
7. Wash and transfer section onto glass slide.
8. Blot dry in filter paper and dehydrate in benzol for 1 min.
9. Pour off benzol, blot dry, and dip once in thin celloidin (p. 1666).
10. Partially clear in creosote-xylol, equal parts, for 5 min.
11. Clear in pure xylol for 5 min. and mount in gum damar.

All the solutions are stable and can be used repeatedly.

Fibrin stains gray blue; nerve fibers, dark blue; ganglion cells, dark rose; elastic fibers, violet blue; striated muscle fibers, violet blue; smooth muscle fibers, dark red; connective tissue, cream color; bone tissue, magenta and red; hair cells, violet blue; walls of fat globules, pale straw; leukocytes, purple blue; erythrocytes, light gray.

The purpose of staining is to recognize the various elements of tissue and the cell components. Some stains are strictly solution phenomena, such as staining neutral fats with oil-soluble dyes (scharlach R or oil red); others are strictly chemical phenomena, such as the production of Prussian blue reaction by hemosiderin in the presence of acid and potassium ferrocyanide; others depend on the presence of mordants, such as hematoxylin with ferric and aluminum salts or numerous other metallic salts.

While investigating the feasibility of procuring a chemical coloration without the aid of dyes on temporal bone sections, we have succeeded in developing 3 new formulas by making use of the following metallic salts and chemicals.

1. Lithium nitrate, iodine solution, gold chloride, orcinol, phloroglucin, thorium-ferric ammonium sulfate, potassium, ferrocyanide, and thorium nitrate solution.
2. Lead nitrate, iodine solution, ferric ammonium sulfate, and potassium ferrocyanide.
3. Zirconium nitrate, zinc nitrate, ferric ammonium sulfate, potassium ferrocyanide, and potassium permanganate.

Method 3—
Chemical coloration of temporal bone sections

Bone tissue, smooth and striated muscle fibers, connective tissue, and nerve fibers are identified by the following **gold chloride method.**

Prepare colloidin sections (p. 1753).

Reagent:

1. Thorium-ferric solution.
   (a) Dissolve 5 gm. thorium nitrate in 100 ml. 10% ferric ammonium sulfate.

Procedure:

1. Place section in 10% lithium nitrate for 3 min.
2. Wash in 2 changes of tap water and treat in strong iodine solution (p. 1745).
3. Wash in 3 changes of tap water and treat in 10% lithium nitrate for 10 sec., dipping section in and out, and wash 3 times.

4. Treat in 1% gold chloride for 3 min. and wash 3 times.
5. Treat in 10% lithium nitrate for 10 sec., dipping section in and out, and wash 3 times.
6. Place in 2% orcinol solution for 3 min. and wash 3 times.
7. Treat in 10% lithium nitrate for 10 sec. and wash 3 times.
8. Place in 5% phloroglucin for 3 min. and wash 3 times.
9. Treat in 10% lithium nitrate for 10 sec., dipping the section in and out, and wash 3 times.
10. Mordant in thorium-ferric solution for 2 min. and wash 3 times.
11. Treat in 10% lithium nitrate for 10 sec., dipping the section in and out, and wash 3 times.
12. Treat in 10% potassium ferrocyanide solution for 10 sec. and wash 3 times.
13. Treat in 10% lithium nitrate for 10 sec., dipping the section in and out, and wash 3 times.
14. Treat in 1% thorium nitrate for 45 sec. or until the background is an even blue and wash 3 times.
15. Treat for a few seconds in 10% lithium nitrate and wash.
16. Transfer the section onto a glass slide and blot dry in filter paper.
17. Dehydrate, pouring benzol over the section for 1 min.
18. Pour off the benzol, blot dry, and dip once in thin celloidin (p. 1666).
19. Partially clear in creosote-xylol (equal parts) for 5 min.
20. Clear in pure xylol for 5 min. and mount in gum damar or Permount.

All the solutions are stable and can be used repeatedly. Gold chloride and orcinol should be filtered before use.

Nerve stains rose color; ganglion cells, dirty rose; bone tissue, shades of blue; striated muscle fibers, dark rose; smooth muscle fibers, dirty blue; red blood cells, dark red; connective tissue, greenish blue; leukocytes, purplish blue; arterial wall, dark red; capsule of fat globules, cream.

This method, besides its colorful reaction to different elements, is also an excellent connective tissue stain, similar to Mallory aniline blue. It also differentiates smooth and striated muscles with different colors.

Method 4—
New chemical coloration method—iodine combination technic

This method demonstrates nerve fibers, smooth and striated muscle fibers, connective tissue, bone tissue, blood vessels, bone marrow, and other elements.

Prepare celloidin sections (p. 1753).

Reagent:

1. Terpineol-xylol.
   (a) Use equal parts and mix.

Procedure:

1. Place sections in 10% lead nitrate for 5 min.
2. Wash in 3 changes of distilled water and mordant in 10% strontium nitrate for 5 min.
3. Wash and treat in 5% phloroglucin for 5 min.
4. Wash and place in strong iodine (p. 1745) for 5 min.
5. Wash 3 times and place in 15% ferric ammonium sulfate for 5 min.
6. Wash twice and place in strong iodine for 5 min.
7. Wash 3 times and place in 15% ferric ammonium sulfate for 5 min.
8. Wash twice and place in strong iodine for 5 min.
9. Wash 3 times in tap water, rinse twice in distilled water, and place in 10% potassium ferrocyanide for 15 sec.
10. Rinse in 2 changes of distilled water, then in tap water, and dip for 5 sec. in 15% ferric ammonium sulfate.
11. Wash and place in strong iodine for 3 min.
12. Wash 3 times in tap water and transfer section onto a glass slide.
13. Blot dry in filter paper; then pour benzol over the section for 1 min.
14. Dip once in thin celloidin (p. 1666).
15. Clear in terpineol-xylol for 5 min.
16. Mount in gum damar or Permount.

All the solutions are stable and can be used repeatedly.

Bone tissue stains blue; connective tissue, greenish blue; smooth muscle fibers, deep blue; striated muscle fibers, golden yellow; walls of blood vessels, yellow; red blood cells, straw; nerve fibers, yellow.

Method 5—
New chemical coloration method—zinc-permanganate technic

This method demonstrates haversian canals, osteocytes with their processes, nerve and connective tissue fibers, smooth and striated muscle fibers, epithelium, spiral ganglion, vascular wall, etc.

Prepare celloidin sections (p. 1753).

Reagent:

1. Zinc-permanganate.

Zinc nitrate	2 gm.
Potassium permanganate . .	0.25 gm.

   (a) Dissolve in a mixture of 3 drops of hydrochloric acid, concentrated, in 40 ml. distilled water.

Procedure:

1. Place section in 5% zirconium nitrate for 3 min. and wash 3 times.
2. Treat for 3 min. in zinc-permanganate and wash 3 times.

3. Treat in 5% zinc nitrate, agitating the section 15-20 times, and wash 3 times.
4. Place in 5% zirconium nitrate for 2 min. and wash 3 times.
5. Treat in zinc-permanganate solution for 2 min. and wash 3 times.
6. Treat in 5% zinc nitrate, agitating 15-20 times, and wash 3 times.
7. Place in 5% zirconium nitrate for 1 min. and wash 3 times.
8. Treat in zinc-permanganate for 1 min. and wash 3 times.
9. Agitate 15-20 times in 5% zinc nitrate and wash 3 times.
10. Place in 10% dioxane for 1 min. (5 ml. dioxane in 45 ml. distilled water) and wash 3 times.
11. Differentiate in 2% phosphotungstic acid for 1 min. and wash 3 times.
12. Treat in 10% potassium iodide for 1 min. and wash 3 times.
13. Mordant in 10% ferric ammonium sulfate for 4 min. and wash 3 times.
14. Treat in 10% potassium ferrocyanide for 20 sec. and wash 3 times.
15. Place in 2% phloroglucin for 1 min. and wash 3 times.
16. Mordant in 10% ferric ammonium sulfate once more for 2 min. and wash 3 times.
17. Dip section 5 times in 10% potassium ferrocyanide and wash 3 times.
18. Treat in 2% phloroglucin for 1 min. and wash 3 times.
19. Treat in 5% zinc nitrate for 1 min. and wash 3 times.
20. Transfer section onto a glass slide and blot in fine filter paper until completely dry.
21. Dehydrate section with benzol, pouring the benzol over the section.
22. Pour off the benzol and blot several times.
23. Dip in thin celloidin (p. 1666) 3 times and blow the breath over the section until dry.
24. Flatten the section by blotting in filter paper 3 or 4 times and dehydrate with anhydrous isopropanol for 1 min.
25. Pour off isopropanol and clear the section in neutral xylol for 5 min.
26. Mount in gum damar.

Lacuna stains brilliant blue; compact bone, greenish yellow; nucleus of osteocytes, brownish; osteocyte processes, dark brown; nerve fibers, brown; connective tissue, blue; striated muscle fibers, dark brown; smooth muscle fibers, greenish blue; vascular walls, brown; epithelium, yellow; erythrocytes, golden yellow; spiral ganglion, dark brown; spiral ligament, greenish yellow.

Method 6—New myelin sheath stain for frozen sections of human and animal central nervous system tissue

The value of frozen sections for demonstrating tissue pathology has recently been emphasized, and the frozen section technic is becoming more generally recognized as its use in large hospitals and clinics has increased. Speed, economy, preservation of cellular structure, and absence of shrinkage are some of the advantages of the frozen section technic.

Since many experiments in otology are conducted on animals, it is important to recognize the histopathologic changes produced by these experiments on the central nervous system by the use of a suitable selective stain.

Present-day methods of staining are performed on celloidin sections. Embedding and sectioning celloidin sections is time-consuming and expensive. We have adopted the frozen section technic and have developed a new rapid and satisfactory method of staining myelin sheath in tissues of the central nervous system.

Reagents:

1. Hematoxylin.
   (a) Dissolve 10 gm. hematoxylin crystals in 100 ml. 95% ethyl alcohol.
   (b) Incubate 10 days or longer.
2. Thorium-ferric solution, 2%.
   (a) Add 1 part of strong thorium-ferric ammonium sulfate (p. 1750) to 5 parts water.
3. Aniline-xylol.
   (a) Equal parts of aniline oil and xylol.

Procedure:

1. Cut frozen sections 10-15μ thick and place in Cellosolve (ethylene glycol monoethyl ether) for 15 min.
2. Wash 3 times in tap water and carry to strong iodine solution (p. 1745) for 5 min. and wash 3 times.
3. Place in 10% potassium iodide solution for 5 min. and wash 3 times.
4. Mordant in a mixture of equal volumes of 2% antimony trichloride and 10% aluminum nitrate solution for 10 min. at 40° C. and wash 3 times.
5. Mordant in thorium-ferric solution (p. 1745) for 15 min. at 40° C.
6. Wash 3 times and stain in ripe hematoxylin, mixing 3 ml. ripe hematoxylin in 15 ml. tap water, for 30 min. at 40° C.
7. Partially decolorize in 3% sodium cyanide solution for 2 min. and wash 3 times.
8. Carry the decolorization further, treating in 2% thorium ferric solution for 1 min. and wash 3 times.
9. Differentiate further in 3% sodium cyanide for 2-4 min. or until the gray matter appears grayish. This step should be controlled under a microscope. If the gray matter is not completely clear, carry section once more to dilute thorium-ferric for 15 sec. and then for 2 min. in 3% sodium cyanide.
10. Wash 3 times and transfer the section onto a glass slide.
11. Blot dry and dehydrate with benzol, pouring the benzol over the section for 1 min.
12. Pour off the benzol, blot, and dip the section once into thin celloidin (about 7 ml. thick celloidin dissolved in 100 ml. ether-alcohol, equal volume).

13. Clear in aniline-xylol, pouring the mixture over the section, for 5 min.
14. Clear in pure xylol for 5 min. and mount in gum damar or Permount.

All the solutions are stable and can be used repeatedly.

Cellosolve may be used twice. Ripe hematoxylin solution should be prepared fresh each time.

Myelinated fibers stain dark blue; nerve cells, cytoplasm light gray, nuclei blue; red blood cells, gray blue; gray matter, light grayish pink.

NEW DECALCIFICATION METHOD FOR TEMPORAL BONES

The following method employs a controlled shaking machine and modified decalcifying fluid.

Reagent:

1. Decalcifying solution. Refer to p. 1644.

Technic of decalcification:

1. Place temporal bones in a 200 ml. specimen bottle and fill with decalcifying solution, pouring the solution on slowly. As the fluid contacts the bone, immense numbers of bubbles arise. Wait until the bubbles disappear; then stopper the bottle tightly and place on a shaking machine at 35 oscillations/min. The shaking machine is the standard Kahn shaker controlled with Variac.*
2. Change the solution twice at 8 hr. intervals, and prick the specimen superficially with a needle once a day. It requires 8-12 changes for a temporal bone to be completely decalcified, depending on the amount of calcium present or the hardness of tissue due to other causes.

The method is also applicable to smaller bones removed at surgery or autopsy, when it requires only 1 or 2 changes for complete decalcification.

3. After complete decalcification, the specimen should be neutralized by placing in 1% lithium carbonate for 24 hr. Then wash for 16-24 hr. under gently running water and place in 40% ethyl alcohol until ready for dehydration and embedding.

Dehydrating:

1. Place specimen in 50% alcohol on the shaker for 2½ hr.
2. Place specimen in 60% alcohol on the shaker for 2½ hr.
3. Place specimen in 70% alcohol on the shaker for 2½ hr.
4. Place specimen in 80% alcohol on the shaker for 2½ hr.
5. Place specimen in 95% alcohol on the shaker for 2½ hr.
6. Place specimen in 95% alcohol on the shaker for 2½ hr.
7. Place specimen in absolute alcohol on the shaker for 2½ hr.
8. Place specimen in absolute alcohol on the shaker for 2½ hr.
9. Place specimen in absolute alcohol and ether, equal volumes, for 2½ hr.
10. Place specimen in absolute alcohol and ether, equal parts, for 2½ hr.

Embedding:

1. Place the dehydrated bones in 2.5% celloidin on a shaking machine for 3 days.
2. Place in 5% celloidin on a shaking machine for 3 days.
3. Place in 7.5% celloidin on shaking machine for 3 days.
4. Place in 10% celloidin on shaking machine for 3 days.
5. Then embed in fresh 10% celloidin.

---

Section Two

EXFOLIATIVE CYTOLOGY

HISTORICAL DEVELOPMENT

Exfoliative cytology is the branch of general cytology concerned with the detection of cancer and various other pathologic conditions in man through microscopic examination of body fluids and secreta. Clinical acceptance of exfoliative cytology was long delayed. Early judgments of its usefulness ranged from overly enthusiastic acceptance to emphatic repudiation of the method. Today the exfoliative cytologic technic is a firmly established laboratory procedure, the merits and deficiencies of which are recognized.

The first report of exfoliative cytologic study is credited to Donné,[1] who in 1838 described the morphologic appearances of cells he had observed in human colostrum. In 1843 Walshe[2] reported gross fragments of malignant tissue in sputum. Pouchet[3] in 1847 was the first to describe the cellular morphology of vaginal secretions. Malignant cells in sputum were first described by Beale[4] in 1860 and later in the same year by Hampeln.[5] Similar studies of exudates were reported by Lücke and Klebs[6] in 1867.

Despite the development of improved methods of fixation and staining during the latter part of the nineteenth century and early years of the twentieth century, reports of cellular examinations of body fluids for the detection of cancer were rare. Renewed interest leading to the present clinical role of exfoliative cytology originates from the investigations of Papanicolaou. Prior to 1928 Papanicolaou had examined vaginal secretions from rodents and human subjects in an attempt to correlate the sex cycle with the appearances and patterns of the cells. Using a staining method he had developed to identify stages in the maturation of exfoliated squamous epithelial cells, he was occasionally able to identify malignant cells in human vaginal secretions. In 1928 he published a brief paper[7] advocating use of the vaginal smear method for detection of human uterine cancer. His unusual approach was viewed with skepticism and failed to stimulate confirmatory investigations. Despite the general disinterest, Papanicolaou continued his investigations and in 1943, in collaboration with Traut, published the now famous monograph, *Diagnosis of uterine cancer by the vaginal smear.*[8]

Following confirmation, exfoliative cytology was finally acknowledged as a potentially sensitive and reliable means of detecting early cancer. Soon this method was applied with enthusiasm to the study of sputum, urine, semen, prostatic and breast secretions, aspirations from the bronchus, gastrointestinal tract and cysts, and pleural, peritoneal, and pericardial fluids.

PHYSICIAN-TECHNICIAN TEAM IN CYTODIAGNOSIS

The effective use of exfoliative cytology for the detection of cancer depends on a thorough microscopic examination of every area of an adequate number of slides. A hit-or-miss examination or an over-all impression does not suffice. The prohibitive time required for adequate examination has necessitated training of nonprofessional assistants to screen cytologic smears preliminary to the diagnosis by a physician. Special training is required for both physicians and cytotechnicians, and a number of teaching centers offer such instruction.

The specially trained cytotechnician has demonstrated unusual competence in screening and often assumes responsibility for negative reports. In many cases the cytotechnician has developed considerable skill in identifying morphologic evidences of malignancy. To maintain the clinical validity of exfoliative cytology, it is of utmost importance that the responsibility for a cytologic diagnosis of cancer be restricted to a specially trained and experienced physician who is able to relate morphologic observations and pertinent clinical findings in the individual patient.

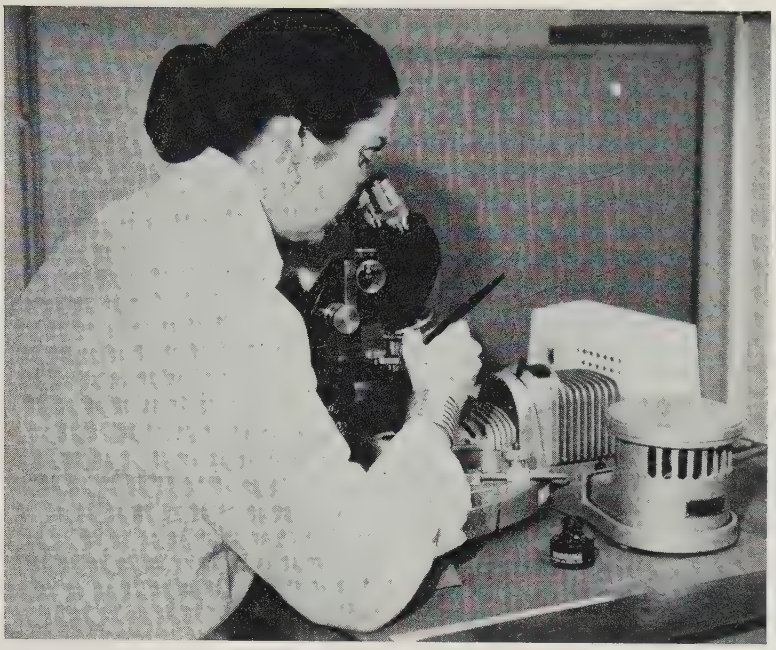

Fig. 584A. Cytologic smears are screened by specially trained cytotechnician who marks cellular abnormalities. Atypical findings are referred to physician for diagnosis.

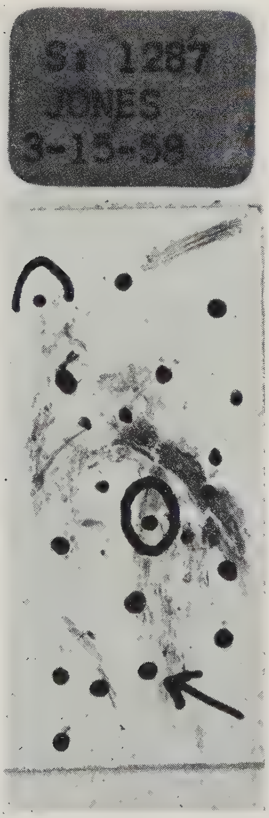

Fig. 584B. Appearance of "positive" smear of sputum following preliminary screening by cytotechnician. Note the use of circle and arrow to call attention to especially important cellular abnormalities.

REPORTING METHODS

Papanicolaou has recommended a method for reporting results of cytologic smear examinations which consists of 5 classes. His method is intended to indicate to the clinician the significance of observed cellular abnormalities as they relate to the possibility of malignancy. The Papanicolaou reporting method is as follows:

Class I—Absence of atypical or abnormal cells.
Class II—Atypical cytology but no evidence of malignancy.
Class III—Cytology suggestive of, but not conclusive for, malignancy.
Class IV—Cytology strongly suggestive of malignancy.
Class V—Cytology conclusive for malignancy.

The reporting of smears that are normal (class I) and those that are malignant (class V) conforms to a relatively uniform standard interpretation by most cytologists; however, reporting of classes II, III, and IV shows wide variations in personal interpretation. Inconsistency in the use of these intermediate classes has made it difficult for one cytologist to evaluate a report made by another worker. In addition, referring physicians often find use of the 5 classes a somewhat elaborate means for answering their question "Is malignancy present or not?" Therefore, to inform the clinician more satisfactorily of the results of cytologic study, many cytologists now use only 3 classes of reports, which indicate (with variations in terminology):

1—"No malignant cells are seen."
2—"Malignant cells are present."
3—"Inconclusive," "Uncertain," or "Opinion deferred."

The latter, inconclusive class combines classes II, III, and IV of the Papanicolaou reporting method and therefore incorporates a wide variety of cellular abnormalities which range from benign atypicalities to those that are frankly suspicious of malignancy.

Successful use of a 3-class method of reporting depends upon establishment of a close rapport between cytologist and referring physician. The cytologists's report should contain a concise statement regarding the significance of findings in each case, with appropriate recommendations for further studies. Whenever possible, any report other than normal (class I), should also be given verbally to the attending physician to promote a clearer understanding.

COLLECTION, PREPARATION, AND STAINING OF CYTOLOGIC SPECIMENS

Successful application of exfoliative cytology to the detection of cancer is directly influenced by the degree of care and attention paid to technical considerations. The method of preparing and processing most of the types of cytologic specimens is often similar; however, the variations in methods best suited for particular specimens deserve special attention.

Since the cytologic identification of exfoliated malignant cells is based upon a morphologic comparison with known normal and benign cellular appearances, it is essential that all cells be visualized in their best possible state of preservation following fixation and staining. Staining reactions must be consistent; otherwise uncertainty may result. An unusual emphasis must be placed upon specimen collection, particularly the specimens that the patient himself collects, such as sputum or urine. When required, the special instructions to the patient for specimen collection must be thorough and explicit to gain understanding and cooperation. Negligent technic in specimen collection and preparation is by far the most frequent basis for failure of the cytologic method to detect evidence of cancer.

Chapter 94

General instructions for cytologic specimens

SAMUEL L. PHARR

An outline of the basic considerations related to the collection, preparation, adhesion, fixation, and staining of cytologic specimens is presented in this chapter. A more detailed account of specific technics for processing individual types of body fluids is given in Chapter 96.

SPECIMEN COLLECTION

The majority of cytologic specimens submitted for diagnosis are collected by an attending physician during the course of a physical examination or as a part of a diagnostic or therapeutic procedure. These specimens include vaginal and cervical smears, bronchial aspiration and lavage, serous cavity fluids, prostatic and breast secretions, and cerebrospinal fluid. Although the attending physician is anxious that the smear examination be a meaningful one, he is often unaware of the critical importance of observing seemingly minor details required for specimen collection. The problem of obtaining properly collected specimens is best resolved through close rapport between the cytologist and the referring physician, preferably through discussion in the laboratory, utilizing microscopic demonstrations of collection errors. Written instructions for the physician's use are at times the only practical solution, but these are limited in effectiveness as compared with verbal and visual means. It is highly desirable that the cytology laboratory establish and adhere to rigid requirements for specimen collection. The desired method of collecting a cytologic specimen is seldom more tedious or time-consuming than an injudicious approach.

Specimens collected by the patient, such as urine and sputum, as well as those specimens that are collected by laboratory personnel, such as gastrointestinal specimens, also have precise requirements. The specific details of these are discussed in Chapter 96.

The importance of correct specimen collection cannot be overemphasized. Failure to disclose malignant cells in cytologic smear preparations, in experienced hands, is seldom attributable to screening error. Tumor cells may fail to shed into the draining secretion because of superficial necrosis or fluid obstruction, or they may be absent because of chance selection of the smeared material. Frequently, however, malignant cells may not be present in smears from patients who have cancer because of some error committed in the method of specimen collection or smear preparation.

SMEAR PREPARATION

Smears prepared for cytologic examination must be made from **fresh** material. New glass slides previously cleaned in alcohol should be used. The patient's identity must be legibly indicated on the slide, preferably with a diamond-point pen, before smears are prepared. Insertion of a paper clip to the identified end of each slide prevents adhesion of slides in the fixative and is also a convenient holder for placing slides into the fixative rapidly.

The method of preparing smears may differ according to the preference of the individual worker or by selection of the method that is best suited for the type of secretion to be examined. There are 4 principal methods of preparing smears for cytologic examination: streaking, spreading, pull-apart, and touch preparation.

Streaking: The method utilizes an applicator stick, gloved finger, wooden spatula, or other means to streak a selected portion of the secretion over ⅔ of a clean glass slide. Care must be taken to streak the material rapidly, attempting to obtain a relatively uniform distribution of the secretion. Smears prepared by this method are more frequently made too thin rather than too thick; either extreme is unsuitable. Streaking is usually employed for preparation of mucoid secretions, such as vaginal secretion aspirated from the posterior fornix, sputum, and gastric contents. Smears must be placed immediately into the fixative before any drying occurs.

Spreading: This method may also be used for preparation of thick, mucoid secretion. A carefully selected portion of the specimen is transferred to a clean glass slide; excess material can be removed by "sawing" with an applicator stick across the sharp glass edge. Holding an applicator stick in each hand, gently spread the material to a moderately thick film by teasing the mucus strands apart. Although spreading is slightly more tedious than streaking, it has the advantage of maintaining cellular interrelationships within strands of mucus. Spreading is especially recommended for preparation of smears of fresh sputum and bronchial aspirates.

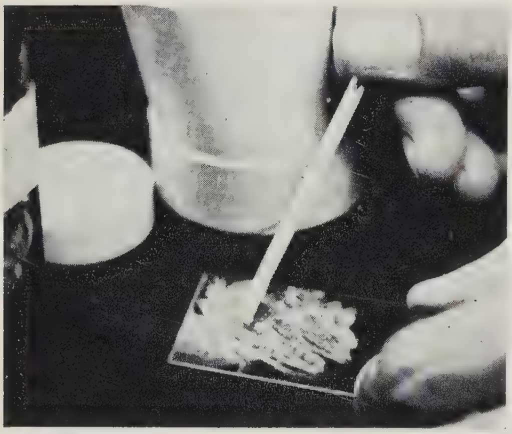

Fig. 585. Cytologic smear preparation by "streaking" method. Note the fixative container is open so that smear can be fixed without delay.

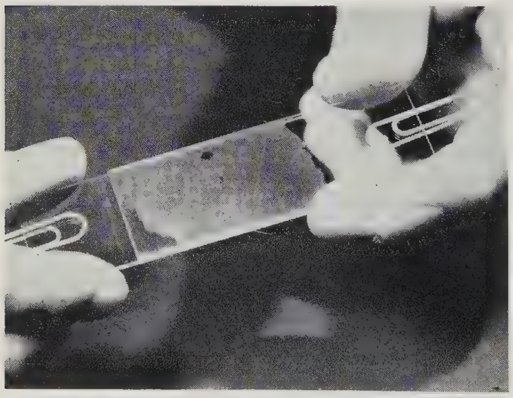

Fig. 586. Smear preparation by pull-apart method.

Pull-apart: Use of this method yields the most desirable smears for cytologic examination because of the resulting uniform distribution of cells. It is applicable, however, only to preparing smears of amucoid secretions, such as serous fluids, concentrated sputum, and enzymatic lavage samples from the gastrointestinal tract. Smears of urinary sediment, vaginal pool, and breast secretions may at times be prepared advantageously by this method.

Two pull-apart smears are prepared simultaneously by placing a drop of secretion or sediment upon one slide and facing it to another clean slide. The material disperses evenly over the surfaces of the 2 slides; slight movement of the 2 slides in opposite directions may be necessary to initiate flow of material. The 2 slides are pulled apart with a single, uninterrupted motion and are then placed immediately into the fixative solution.

Touch preparation: This method is used for the preparation of direct impression smears made from the cut surface of tissues, such as lymph nodes and other surgical or autopsy tissue specimens. The cut surface of freshly incised tissue is touched several times to a clean glass slide **without smearing.** No more than 3 or 4 rapid impressions should be attempted on each slide to avoid drying in thin areas. Each slide is placed immediately into the fixative.

Cytologic smears of scanty secretion or sediment, such as cerebrospinal fluid, buccal smears and others, may be prepared similarly. Scanty material, when spread over a large area of the slide, presents a frequent source of microscopic difficulty due to mechanical distortion and drying. In such cases it is advisable to place a dime-sized circle with a diamond-point pen on the glass surface opposite the side to be smeared. The material collected onto a slightly moistened cotton-tipped applicator stick is touched rapidly within the previously circled area. The circle will aid the microscopist in locating the thin smeared area on the stained slide.

ADHESION

Most body fluids contain sufficient protein in the form of mucus or albumin to provide adequate adhesion of smeared material to the slide throughout fixation and staining. The specimens that require addition of an adhesive agent are urinary sediment, bronchial lavage specimens, and specimens that utilize a proteolytic enzyme during processing, such as tryptic concentrated sputum and enzymatic lavage specimens from the gastrointestinal tract. The adhesive agent used must be permeable to both the fixative and stains and must not retain stain. The latter requirement excludes the use of an egg albumin fixative which is intensely stained by the basic light green counterstain of the Papanicolaou method.

The following methods have been suggested to improve adhesion of material throughout processing for cytologic examination: pooled human serum or plasma, celloidin-ether-alcohol, and leuconostoc culture.

Pooled human serum or plasma

Since the specimens that require addition of an adhesive agent also require centrifugation, use of serum or plasma for this purpose can be easily and effectively employed. Serum or plasma is an effective adhesive agent, and its relatively neutral pH produces no undesirable background staining. Pooled human serum and plasma salvaged from blood chemistry specimens is centrifuged, and the clear supernatant liquid is transferred to small glass bottles in quantities of 2-5 ml. It is stored at freezing temperature until needed. When thawed, it should be discarded after 1 to 2 days.

The method consists in underlaying a portion of liquid serum in the specimen **before** centrifugation. Since it is heavier than the overlying specimen, it forms a separate layer at the bottom of the centrifuge tube. The quantity to be underlaid is determined by the amount of sediment that is expected after centrifugation and is suggested by the turbidity of the specimen. The volume of serum added should be slightly greater than the volume of sediment. During centrifugation the collecting sediment is coated with a film of pooled serum and plasma and serves to produce adhesion of the smeared material during fixation and staining.

An **alternate method** consists in adding a drop of pooled serum and plasma to the surface of one clean slide, a drop of secretion or sediment to another, and then facing the 2 slides. The 2 drops mix and spread over the surfaces of the 2 slides. The slides are pulled apart with an even, uninterrupted motion and are immediately placed in the fixative.

Fig. 587. Serum introduced beneath fluid before centrifugation to improve cellular adhesiveness.

Celloidin-ether-alcohol

Celloidin is readily soluble in a mixture of ether and alcohol but is insoluble in either solution alone; therefore a thin, transparent, and permeable film of celloidin is formed over the surface of smears when transferred from celloidin-ether-alcohol fixative to the alcoholic and aqueous solutions in the Papanicolaou staining procedure. A few drops of chloroform must be added to the absolute alcohol and xylol solutions in the final steps of Papanicolaou staining to prevent fragmentation of the celloidin film in these anhydrous solutions. Celloidin-ether-alcohol solution can be reused after filtration and can be employed routinely for processing all types of cytologic specimens.

The adherent-fixing solution is prepared by adding 1.5 ml. thick celloidin to each liter of equal parts ether and 95% alcohol.

Leuconostoc culture—Rosenthal-Traut[9]

Rosenthal and Traut[9] recommend addition of a nutrient broth culture of *Leuconostoc mesenteroides,* a mucus-producing saphrophyte, to improve adhesiveness of cells in cytologic smears. The culture broth is underlaid in the specimen before centrifugation. It is reported that addition of the liquid culture of *Leuconostoc* to the material to be smeared promotes excellent adhesion of cells. The culture solution does not stain, and the organisms themselves do not interfere with the microscopic examination.

The organisms are cultured at room temperature in equal parts of nutrient broth and 10% sucrose. Inoculated tubes may be kept indefinitely.

FIXATION

Smears prepared for cytologic examination must be immersed in the fixative solution while still moist and before any drying occurs. Structural details of cellular and nuclear morphology are seriously distorted by drying of smear before fixation, and staining reactions lose specificity. Although immediate fixation is required, care must be taken to place each smear in the fixative by a single, uninterrupted motion to avoid rippling of the smeared material. It is also important to avoid striking the bottom of the fixing container forcefully, thus dislodging material from the slide.

Faulty fixation is perhaps the most frequent cause of unsatisfactory cytologic smears. Attention paid to the following points should assist in overcoming this source of technical error:

1. Identify slides **before** preparing smears.
2. Attach a paper clip to the identified end of each slide **before** preparing the smear. Paper clips prevent slides from sticking together in the fixative. Copper or brass paper clips oxidize in ether-alcohol and should not be used.

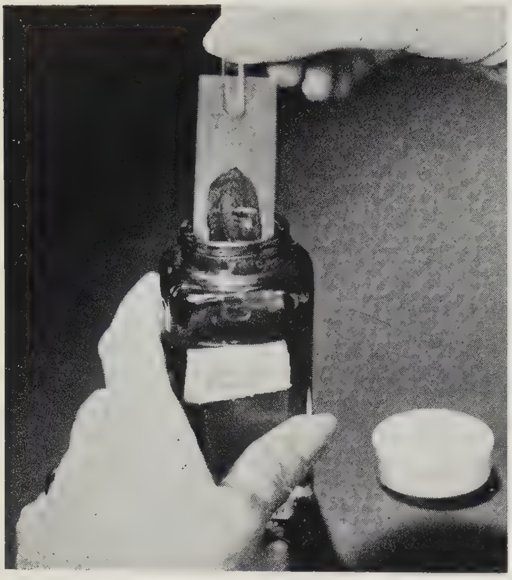

Fig. 588. Cytologic smears must be placed in the fixative immediately after preparation, while still moist. Paper clip is useful as a slide holder and also separates the smears in the fixative.

3. Have the individual fixative bottle open **before** preparing the smear.
4. Do not admire smear after its preparation but place it **immediately** into the fixative.

The minimum fixation time required before staining varies with different specimens. Thin, amucoid smears may be stained after 30 min. fixation; however, it is recommended that all smears be left in the fixative for at least 1 hr. before staining to assure optimum dehydration and adhesion. No untoward consequence results from prolonged fixation; smears may be left in the fixative solution for weeks or months before staining, provided the container is covered tightly to prevent evaporation.

The following solutions may be used for fixation of cytologic smears: ether-alcohol, 95% ethyl alcohol, and Carnoy fluid.

Ether-alcohol: A solution of equal parts of ethyl ether and 95% ethyl alcohol is the conventional solution that is recommended and widely used for fixation of all types of cytologic smears. As previously described, celloidin may also be added to enhance adhesion. The high cost of ethyl alcohol without a tax-free permit may necessitate substitution of methyl or isopropyl alcohol. Ether-alcohol fixative solution may be filtered and reused.

95% Ethyl alcohol: Fixation of cytologic smears in 95% ethyl alcohol has been advocated, substituting methyl or isopropyl alcohol whenever necessary. The omission of ether does not appear to alter the quality or effectiveness of fixation and eliminates the hazard of working with highly flammable ether.

Carnoy fluid:

Alcohol, absolute	6 parts
Chloroform	3 parts
Glacial acetic acid	1 part

Rapid penetration by anhydrous Carnoy fluid allows staining of smears after 5 min. fixation. The solution is more expensive than ether-alcohol or alcohol fixative solutions and cannot be reused effectively. Although Carnoy fluid is not usually suitable for routine usage, it is useful in a number of cytologic research applications and is particularly valuable when rapid fixation and staining are required. It has been recommended for use in membrane filtrate methods.

SMEARS REFERRED ELSEWHERE FOR STAINING

It is often necessary for physicians to mail cytologic smears elsewhere for staining and examination. Since postal regulations forbid mailing flammable solutions, it is not possible to mail smears in the ether-alcohol or alcohol fixative. A number of methods have been suggested to minimize the effect of drying of smears in preparation for mailing.

Air-dried-fixed smears

Many workers find that slides, after adequate fixation in ether-alcohol at the time of preparation, may be removed from the fixative, dried in the air, and mailed without further processing. The simplicity of this method is appealing to the referring physician, and its use undoubtedly encourages greater clinical utilization of the smear technic for cancer detection. The most consequential cellular alterations result from the effect of smear drying **before** fixation, and the changes resulting from smear drying after adequate fixation are undesirable but much less significant.

Glycerin technic

Ayre and Dakin[10] recommend that ether-alcohol-fixed slides be allowed to dry in the air and then be covered with glycerin. The glycerin-coated smear is then placed face to face with another clean slide or with another air-dried, fixed smear from the same specimen. The principal objection to this method has been the loss of considerable material when the 2 faced slides are separated.

Diaphane technic*

A method reported by Papanicolaou and Bridges[11] suggests flooding freshly prepared, unfixed, wet smears with an alcoholic solution of Diaphane.

Diaphane solution[11]:

Ethyl alcohol, 95%	3 parts
Diaphane*	3 parts

After drying, a hard, smooth film which protects the smear surface from contact with the air is formed. When received in the cytology laboratory, smears are placed in a solution of equal parts of ether and 95% ethyl alcohol for 20 min. to remove the Diaphane. Routine Papanicolaou staining follows without modification.

---

*Diaphane is a synthetic resin made by the Will Corporation, Rochester, N. Y.

Polyethylene glycol (Carbowax*) technic

Sills[12] first described a method of dipping ether-alcohol-fixed smears, while still wet, into melted polyethylene glycol prior to mailing. Later, Sills and Garret[13] modified the method whereby 5% polyethylene glycol was added directly to the ether-alcohol fixative. Freshly prepared smears placed in this solution for 30-60 min. and then removed and dried for mailing are thus fixed and coated with a protective film in a single step.

Ehrenreich and Kerpe[14] have reported that equally good results can be obtained more simply by merely flooding freshly made smears, placed on a flat surface, with a 5% solution of polyethylene glycol in ether-alcohol. The slides are allowed to evaporate to dryness. After 5-7 min. an opaque, waxy film is formed and slides can be packaged and mailed.

Polyethylene glycol is water-soluble and does not need to be removed prior to staining by the Papanicolaou method. Smears fixed in this manner are placed directly in aqueous hematoxylin without previous treatment.

Polyethylene glycol fixing solution:

Ethyl alcohol, 95%	50 ml.
Ether	50 ml.
Polyethylene glycol	5 gm.

Polyethylene glycol must be softened in a 56° C. incubator before it is added to the ether-alcohol mixture. A clear, stable solution is obtained after standing for several hours. Dissolution may be hastened by agitation.

Richardson glycol fixative[15]

Richardson has reported a nonvolatile, noncombustible, and nonexplosive fixative for cytologic smears which can then be mailed in conformance with postal regulations. The fixative is reported to have the additional advantage of clearing mucus and hemolyzing erythrocytes. The solution is inexpensive and can be reused.

Richardson glycol fixative:

Monoethylene glycol	3446 ml.
Diethylene glycol	181 ml.
Borax pentahydrate	36 gm.
Water	5776 ml.
Glacial acetic acid	500 ml.

Rehydration technic—Nieburgs[16, 17]

Nieburgs has developed a rehydrating procedure which eliminates fluid fixation at the time of smear preparation. The method was originally designed to improve the quality of self-obtained vaginal smears in a mass survey.

Reagents:

1. Aqueous rehydrating solution.
   (a) Dissolve 0.5 ml. polyoxyethylene sorbitan monoaleate* in 1000 ml. heated distilled water. Allow to cool before use.
2. Ether-alcohol solution.
   (a) Prepare a mixture of equal parts of ether and 70% alcohol.
3. Rehydrating fluid.

Aqueous rehydrating solution	250 ml.
Ether-alcohol solution	1000 ml.

Procedure: Cytologic smears that are to be sent elsewhere for staining and examination are prepared in the usual manner; however, they are not placed in a fixative but are allowed to dry in the air. Afterward they may be packaged and mailed.

Before staining, smears are immersed for 1 min. in the rehydrating fluid.

Slides are rinsed gently in a solution of equal parts of 95% alcohol and ether and are then transferred to a second ether-alcohol rinse, where they remain for 10 min.

NOTE: Following rehydration, small amounts of the rehydrating fluid may be carried into the staining solutions, thereby increasing cellular absorption of stains. The author therefore suggests that staining periods be considerably reduced when rehydrating fluid is used.[17]

---

*Polyethylene glycol is available as Carbowax Compound 1540 from Union Carbide Chemicals Co., Division of Union Carbide Co., New York, N. Y.

*Polyoxyethylene sorbitan monoaleate available as Tween 80, Atlas Powder Co., Wilmington, Del.

Chapter 95

Cytologic staining methods

SAMUEL L. PHARR

PAPANICOLAOU METHOD

The compound staining procedure developed by Papanicolaou[18] has for nearly 2 decades remained the staining method of choice by most cytologists. The principal advantage of Papanicolaou's staining method is the transparency obtained by use of counterstains of high alcoholic content. The color range is predictable and is of great assistance in identification and classification of cells.

Since its description in 1942, Papanicolaou has made only minor changes in the original counterstain formulas and in staining times. The Papanicolaou staining procedure that follows is from the 1960 Supplement to his *Atlas of exfoliative cytology.*[19]

Preparation of Papanicolaou stains[19] * †

Harris hematoxylin:

Stock Harris hematoxylin:

Hematoxylin	5 gm.
Ammonium aluminum sulfate	100 gm.
Ethyl alcohol, 95%	50 ml.
Distilled water	1000 ml.
Mercuric oxide	2.5 gm.

1. Dissolve the hematoxylin in the alcohol.
2. Add the ammonium aluminum sulfate to the water and heat to the boiling point.
3. Add the hematoxylin solution and bring to a full boil once more.
4. Remove from the heat and add the mercuric oxide at once. Stir quickly until a black-purple color develops—a matter of seconds.
5. Plunge the container into cold water.
6. When cool, filter into a dark bottle.

The stock stain must be aged at least 2 wk. before use.

Harris hematoxylin staining solution:

Aged stock Harris hematoxylin	100 ml.
Glacial acetic acid	4 ml.

OG-6 counterstain, stock:

1. Prepare a 10% stock solution of orange G in distilled water.

OG-6 staining solution:

Ethyl alcohol, 95%	950 ml.
Aqueous stock OG solution, 10%	50 ml.
Phosphotungstic acid	0.15 gm.

EA-65 counterstain, stock:

1. First prepare 10% solutions of light green SF yellowish, Bismarck brown, and eosin Y, water- and alcohol-soluble, in distilled water.
2. Next, prepare 3 **alcoholic stock solutions** from the aqueous stock solutions as follows:
   A—Light green SF yellowish: 0.05% solution in 95% ethyl alcohol
   B—Bismarck brown: 0.5% solution in 95% ethyl alcohol
   C—Eosin yellowish: 0.5% solution in 95% ethyl alcohol

EA-65 staining solution:

Alcoholic stock solution A	180 ml.
Alcoholic stock solution B	40 ml.
Alcoholic stock solution C	180 ml.
Phosphotungstic acid	2.4 gm.

1. Filter and store in a dark bottle.

Papanicolaou staining procedure[19]

1. Carry out staining procedure in Coplin jars or staining dishes.
2. After fixation, transfer slides, without drying, directly from the ether-alcohol mixture to 80% alcohol and pass through 70% and 50% alcohols to distilled water.
3. Stain in Harris hematoxylin staining solution for exactly 45 sec.

---

*Stains prepared by the Papanicolaou formulas are obtainable from the Gradwohl Laboratory Supply Co., St. Louis, Mo., and from Ortho Pharmaceutical Corp., Raritan, N. J.

†All dyes used in these preparations are certified stains supplied by National Aniline Division, Allied Chemical & Dye Corp., New York, N. Y.

4. Rinse 3 times in distilled water, using 3 separate containers. Rinsing should be gentle to prevent loss of material from slides.
5. Rinse in 50% alcohol.
6. Place in a solution of 1.5% ammonium hydroxide in 70% alcohol for 1 min.
7. Rinse in 70% alcohol and pass through 80% and 95% alcohols.
8. Stain in OG-6 staining solution for 1¼ min.
9. Rinse in 3 changes of 95% alcohol.
10. Stain in EA-65 staining solution for 3 min.
11. Rinse in 3 changes of 95% alcohol.
12. Dehydrate and clear by passing through the following:
    (a) absolute alcohol
    (b) a mixture of equal parts of absolute alcohol and xylol
    (c) xylol
13. Mount.

MODIFIED PAPANICOLAOU STAINING PROCEDURE—PHARR, WOOD, AND TRAUT[20]

The original Papanicolaou method of staining and stain preparation has been slightly modified by Pharr et al.[20] The formulas of the Papanicolaou counterstains were changed to produce a more distinct tinctorial differentiation between eosinophilic and orangeophilic cytoplasmic staining. This is accomplished by increasing the amount of phosphotungstic acid and omitting Bismarck brown dye from the EA formula. Improved sharpness of color and brilliance of staining reactions result from preparation of counterstains directly in alcohol rather than from aqueous stock solutions. Use of a mechanical stirrer such as a Waring blendor facilitates dissolution of the powdered stains in alcohol.

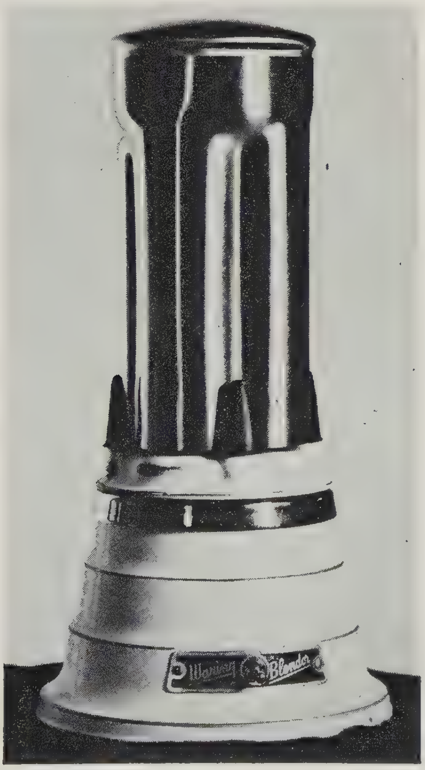

Fig. 589. Mechanical stirrer used for dissolution of Papanicolaou counterstains in alcohol.

Preparation of counterstains—Pharr, Wood, and Traut modification[20] * †

Orange G:

1. Heat 380 ml. 95% ethyl alcohol to the boiling point and pour sufficient heated alcohol into the mechanical stirrer cup to cover the blades.
2. Add 1 gm. orange G.*
3. Fill the stirrer cup with heated alcohol to approximately ¼ its volume.
4. Mix the solution for 5 min., turning the motor off and on occasionally to obtain maximum mixing.
5. Pour off the supernatant liquid after allowing unsuspended stain to settle momentarily.
6. Add additional alcohol to the remaining undissolved stain and mix as before.
7. Repeat until all alcohol has been used and all stain is in solution.
8. Allow the solution to **cool** and then filter. There will be a slight precipitate of orange G stain after cooling.
9. Add 0.4 gm. phosphotungstic acid and 3 ml. glacial acetic acid to the filtered solution.

The orange G staining solution is then ready for use and is stable for 1 mo.-6 wk. Store excess staining solution in a dark bottle.

EA staining solution:

1. Cover the blades of a clean, **dry** mechanical stirrer with a portion of a measured 380 ml. 95% ethyl alcohol. Do not heat the alcohol.
2. Add 2 gm. eosin Y and 1 gm. light green SF yellowish and fill the stirrer cup to approximately ¼ its volume with alcohol. Note that Bismarck brown has been omitted as a constituent of this stain.
3. Mix, as previously described, until all the stain is in solution.
4. Allow to stand overnight, but **do not filter.**
5. Add 0.4 gm. phosphotungstic acid and 3 ml. glacial acetic acid.

The EA staining solution is stable for 1 mo.-6 wk. if it is covered to protect it from deterioration by light or poured back into a dark bottle each time after use.

Stains prepared in this manner have been

---

*All stains used in these preparations are certified stains prepared by National Aniline Division, Allied Chemical Corp., New York, N. Y.

†Papanicolaou counterstains prepared by the Pharr, Wood, and Traut formulas are obtainable from the Gradwohl Laboratory Supply Co., St. Louis, Mo.

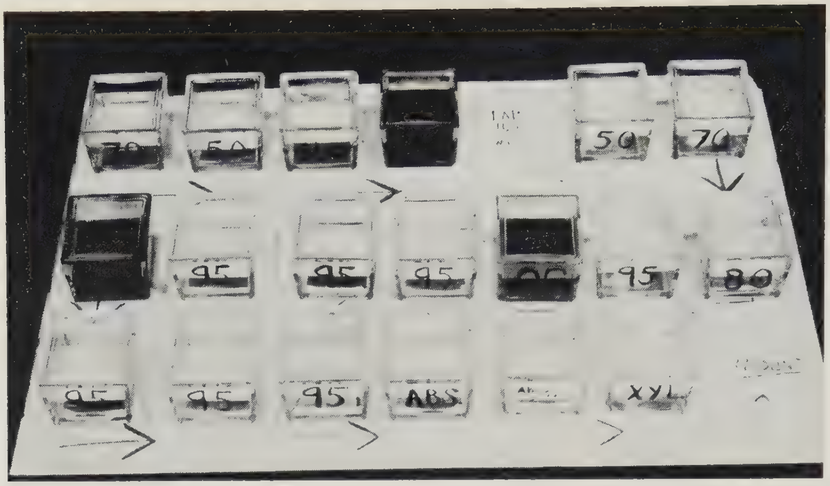

Fig. 590. Arrangement of staining dishes for Papanicolaou staining method.

consistent from one batch to another and have not precipitated during use.

Mayer hematoxylin:

Distilled water	1000	ml.
Hematoxylin	1	gm.
Ammonium or potassium alum	50	gm.
Sodium iodate	0.2	gm.
Citric acid, crystalline	1	gm.
Chloral hydrate	50	gm.

1. Dissolve the hematoxylin in the distilled water that has been heated to 55°-60° C. and rotate until all the stain is in solution.
2. Add the alum and sodium iodate, taking particular care that exactly 0.2 gm. sodium iodate has been weighed.
3. Add the citric acid next, followed by chloral hydrate. **The order of mixing must not be changed.**
4. Allow the solution to stand overnight before use.

The solution is stable for 6 wk.-2 mo. if the staining time is gradually increased from an initial 6 min. to 8 min. after prolonged use.

Occasional filtering may be necessary to remove accumulated cellular debris.

Staining procedure—Pharr, Wood, and Traut modified stains

1. Prepare slides and fix immediately in equal parts of ether and 95% ethyl alcohol for a minimum of 30 min.
2. Immerse in 70% ethyl alcohol for approximately 10 dips or until glossy.
3. Immerse in 50% ethyl alcohol for approximately 10 dips or until glossy.
4. Rinse in **distilled** water for approximately 10 dips or until glossy. This water should be changed after each use.
5. Stain with Mayer hematoxylin for 6-8 min., according to the age of the stain.
6. Wash in a gentle stream of running tap water for a minimum of 20 min.
7. Dehydrate in graded ethyl alcohol, 50%, 70%, 80%, and 95%, immersing for 10 dips in each.
8. Stain in orange G staining solution 1½ min., agitating occasionally.
9. Immerse for 10 dips each in 3 changes of 95% ethyl alcohol; the third 95% alcohol rinse solution should always be clear.
10. Stain in EA staining solution 1½ min., agitating occasionally.
11. Immerse for 10 dips each in 3 changes of 95% ethyl alcohol; the third 95% alcohol rinse solution should always be clear.
12. Dehydrate in absolute ethyl alcohol, immersing for 10 dips.
13. Immerse in a mixture of equal parts of absolute ethyl alcohol and toluene, 10 dips.
14. Clear in 2 changes of toluene, immersing for approximately 10 dips in each.
15. Mount in rapid drying mounting medium.*

Note: If the local tap water used in washing slides after staining by Mayer hematoxylin is not sufficiently alkaline, i.e., approximately pH 7.4, the lithium carbonate method for alkalinizing must be employed.

Prolonged standing in the alcohol rinses following staining with EA results in excess decolorization of both eosin and light green. The stained slides may stand in toluene for a short period but no longer than 1-2 hr.

Prevent water absorption and evaporation by keeping the staining dishes covered when not in use.

Staining tissue sections by modified Papanicolaou method

Tissue sections stained by the Papanicolaou method are of value in comparing cellular appearances in smears with their counterparts in similarly stained sections. The method is used primarily for preparation of material in cytology teaching centers.

---

*Rapid drying mounting medium available as Eukitt from O. Kindler, Konradstrasse No. 25, 1 Br. Freiburg, Germany.

Procedure:

1. Remove paraffin in 2 changes of xylol, 5 min. in each.
2. Rinse in 2 changes of absolute ethyl alcohol, immersing 10 dips in each.
3. Immerse in 95% ethyl alcohol for approximately 10 dips.
4. Immerse in 50% ethyl alcohol for approximately 10 dips.
5. Rinse in distilled water for approximately 10 dips.
6. Stain with Mayer hematoxylin for 15 min. Note that the staining time is increased.
7. Continue with previously described staining procedure (p. 1766). The staining times in orange G and EA remain the same.

Note: It is preferable to stain paraffin sections by this method on the same day they are cut. Do not place cut sections on a heated drying rack before staining.

ADDITIONAL CYTOLOGIC STAINING METHODS

Other staining methods in addition to the Papanicolaou procedure have been recommended for cytologic examination. The standard hematoxylin and eosin method is preferred by many because of familiarity with its use in histologic preparations.

Polychrome method—Shorr[21]

The polychrome staining method described by Shorr for cytologic smears is rapid and to some extent differential. The Shorr method has a limited following in this country[22] but is more widely used by European investigators.

Shorr stain[23]:

Ethyl alcohol, 95% . . .	100	ml.
Biebrich scarlet, water-soluble	0.3	gm.
Orange G	0.1	gm.
Aniline blue, water-soluble	0.025	gm.
Fast green FCF	0.075	gm.
Phosphotungstic acid, c.p.	0.25	gm.
Phosphomolybdic acid, c.p.	0.25	gm.
Glacial acetic acid . . .	1	gm.

Procedure:

1. Following fixation in equal parts of ether and 95% ethyl alcohol, immerse slides in Shorr stain for 2 min.
2. Drain off any excess stain and rinse by dipping 10 times each into 80%, 95%, and absolute alcohol.
3. Clear in xylol and mount.

Cresyl violet method—Masin-Masin[24]

Masin and Masin[24] recommend cresyl violet staining in exfoliative gynecologic cytology and stress the simplicity and rapidity of the technic and its resulting clarity of morphologic cellular details.

Cresyl violet stain:

Cresyl violet (National aniline)	0.3	gm.
0.01M Acetate buffer, pH 4.0	100	ml.

Filter each time before use.

Procedure:

1. Allow ether-alcohol fixed slides to dry in the air. These may be kept for several months before staining.
2. Hydrate through 70% and 50% alcohol and distilled water.
3. Rinse in 1% acetic acid for 30 sec., agitating gently.
4. Rinse in 2 changes of distilled water.
5. Stain in freshly filtered cresyl violet staining solution for 3 min., agitating gently during the first 15-30 sec.
6. Drain and dehydrate briefly in 2 changes of acetone, 10 and 5 sec., respectively.
7. Clear in 2 changes of xylol, 5 min. each, and mount.

Additional staining methods that have been applied to cytologic specimens include (1) supravital staining by a wet film method,[25, 26] (2) the periodic acid–Schiff–PAS staining procedure,[27, 28] (3) silver stain method,[29] (4) the May-Grünwald Giemsa procedure,[30] and (5) the Feulgen reaction.[31]

ADDITIONAL MICROSCOPIC TECHNICS

Cytologic examination by microscopic technics other than the conventional light microscope have been introduced and have provided interesting and provocative findings. At present it appears that these technics may supplement rather than substitute for the routine Papanicolaou method.

Acridine orange fluorescence technic

Acridine orange dye, a basic fluorochrome, binds nucleic acids, and when the stained preparation is irradiated with ultraviolet light in the fluorescence microscope, 2 kinds of nucleic acids, deoxyribonucleic (DNA) and ribonucleic (RNA) acids, fluoresce at different wavelengths.

Acridine orange-stained fixed smears studied with the aid of the fluorescence microscope have recently been used as a screening technic in exfoliative cytology.[32-38] The time required for microscopic screening is reported to be considerably less than that needed to examine

Papanicolaou-stained smears. Acridine orange-stained smears can be restained by the Papanicolaou method when indicated.

The basic fluorochrome, acridine orange, differentiates RNA in the cytoplasm and nucleolus in shades ranging from brick to orange and red, and DNA in the nucleus is stained in shades of green and yellow. Increased basophilia (increased RNA concentration) is an expression of growth per se and is not a specific expression of malignancy. Proliferating benign cells often have the same degree of cytoplasmic basophilia as do malignant proliferating cells. It should be emphasized that degenerating or acidophilic **malignant** cells stain green, a further exception to a specific color reaction of malignant cells stained by the acridine orange fluorescence method.

Acridine orange staining—Masin-Masin[32]

Reagents:

1. Acridine orange stock solution.
    - Acridine orange . . . . 0.1 gm.
    - Distilled water . . . . . 100 ml.
    - (a) Store in a dark bottle and refrigerate.
2. Acridine orange staining solution.
    - Acridine orange stock solution . . . . 10 ml.
    - M/15 Phosphate buffer . . . 100 ml.
3. M/15 Phosphate buffer.
    - Sodium phosphate dibasic . . . . . . 10.4104 gm.
    - Sodium phosphate monobasic . . . . . 84.88 gm.
    - Distilled water . . . . 10 L.
    - (a) If the pH deviates from the required 6.0, correct by adding basic or acid component. The buffer is stable indefinitely at room temperature.
4. 0.1M Calcium chloride solution.
    - Anhydrous calcium chloride . . . . . . 11.1 gm.
    - Distilled water . . . . . 1000 ml.

Procedure:

1. Ether-alcohol-fixed smears can be air-dried and stored for several months before staining, if required.
2. Hydrate smears by passage through 80%, 70%, and 50% alcohols and distilled water for approximately 10 dips in each.
3. Immerse in 1% acetic acid for 5 dips.
4. Rinse in 2 changes of distilled water for approximately 10 dips each.
5. Immerse in acridine orange staining solution for 3 min.
6. Wash with a gentle stream of M/15 phosphate buffer from a plastic washing bottle for 1 min.
7. Wash with a gentle stream of 0.1M calcium chloride solution from a plastic washing bottle for 1 min.
8. Repeat M/15 phosphate buffer wash as described.
9. Repeat 0.1M calcium chloride wash as described.
10. Repeat M/15 phosphate buffer wash again.
11. Mount in M/15 phosphate buffer with a cover slip.

Note: All glassware used in the acridine orange staining procedure must be cleaned carefully and rinsed in alcohol or acetone to remove any absorbed stain.

Introduction of the acridine orange fluorescence technic for cancer detection has stimulated a controversial reception which is remarkably parallel to the early emphatic and opposing opinions expressed of the Papanicolaou smear method and is an indication of the potential importance of the fluorescence method. It appears that a cautious attitude should be adopted for the present pending more definitive investigations of the exact value, convenience, and reliability of the acridine orange fluorescence method.

Phase contrast microscopy

Wied[39-41] has made an extensive comparative evaluation of phase microscopy and the routine Papanicolaou method. He concludes that phase microscopy is the "second best choice" for routine cytologic examination. He cites the possibility for immediate microscopic examination as the major advantage and suggests utilization of phase microscopy as an additional technic employed in cancer detection and for hormonal evaluation of gynecologic specimens.

Interference microscopy

The principle of interference microscopy stems from the fact that a beam of light passing through a dense medium or object undergoes a retardation of its phase as compared with a reference beam.[42] Thus it is possible by means of interference microscopy to determine the dry weight of individual cells or cellular constituents. Hirst[43] has described interference microscopy as "phase microscopy in color." Although there has been some evidence that the per cent dry-weight content of the carcinoma cell nucleus and cytoplasm is less than that of the normal cell as indicated by Mellors[44] and also by Foraker,[45] the cost and complexity of interference microscopy preclude its use for routine examination.

Chapter 96

Cytologic examination of secreta from various sources

SAMUEL L. PHARR

The basic considerations related to technics for collection, preparation, and staining of cytologic specimens have been discussed. The reader is urged to familiarize himself with Chapter 95 before proceeding with specific methods for collecting and processing individual types of specimens.

GYNECOLOGIC CYTOLOGY

Smears obtained from the female genital tract greatly predominate among the types of specimens submitted for routine cytologic examination. A wide variety of methods can be applied; however, for best results selection of method of collection and preparation should conform to the recommendations made by the cytology laboratory to which the smears are to be referred. Selection of collection method may depend upon the purpose of the cytologic examination, whether for cancer detection or for evaluation of hormonal and inflammatory changes. The choice of method may also depend upon whether the sample is to be collected by a physician or, as in mass screening programs, by nonprofessional assistants, or even by the patient herself.

Preparation of patient

It is essential that the patient be advised not to douche, bathe, or use intravaginal medicaments (including contraceptives) for a 24 hr. period prior to specimen collection. At least 6 wk. should elapse following cauterization, curettage, or biopsy.[46] The speculum, when inserted before smear collection, must be introduced without lubricant; if necessary, a few drops of warm saline may be used to moisten the speculum.

Vaginal smear

Collection of pooled secretions from the posterior vaginal fornix, as originally described by Papanicolaou and Traut,[47] has remained the most widely used single method for cytologic detection of uterine cancer. Most authorities today, however, insist that both a vaginal pool smear as well as a cervical smear be collected from each patient. The vaginal pool smear should be collected through a speculum whenever possible and practical.

Methods of collecting vaginal smears

Pipet: A specially designed, slightly curved, blunt-end, glass pipet fitted with a rubber bulb is inserted, with negative bulb pressure, about 3-4 in. into the vagina. Secretion is aspirated gently for ½ min., moving the end of the pipet from side to side to assure collection of a good sampling of cells. A portion of the aspirate is placed on a clean glass slide bearing the patient's identity. The material is smeared and the slide is immediately placed in the fixative while still moist.

Spatula: Vaginal secretion may be obtained through a speculum by use of the special wooden spatula described by Ayre[48]* (see below) or by a common tongue blade. The smear is prepared by applying the material collected on the spatula directly to the slide. Immediate fixation, before any drying occurs, is essential.

Speculum blade: The secretion present on the posterior blade of a bivalve speculum after withdrawal may be used for the vaginal smear preparation. The gloved fifth finger (not covered by glove powder) is dipped into the secretion and is then

---

*Clay Adams, Inc., New York, N. Y.

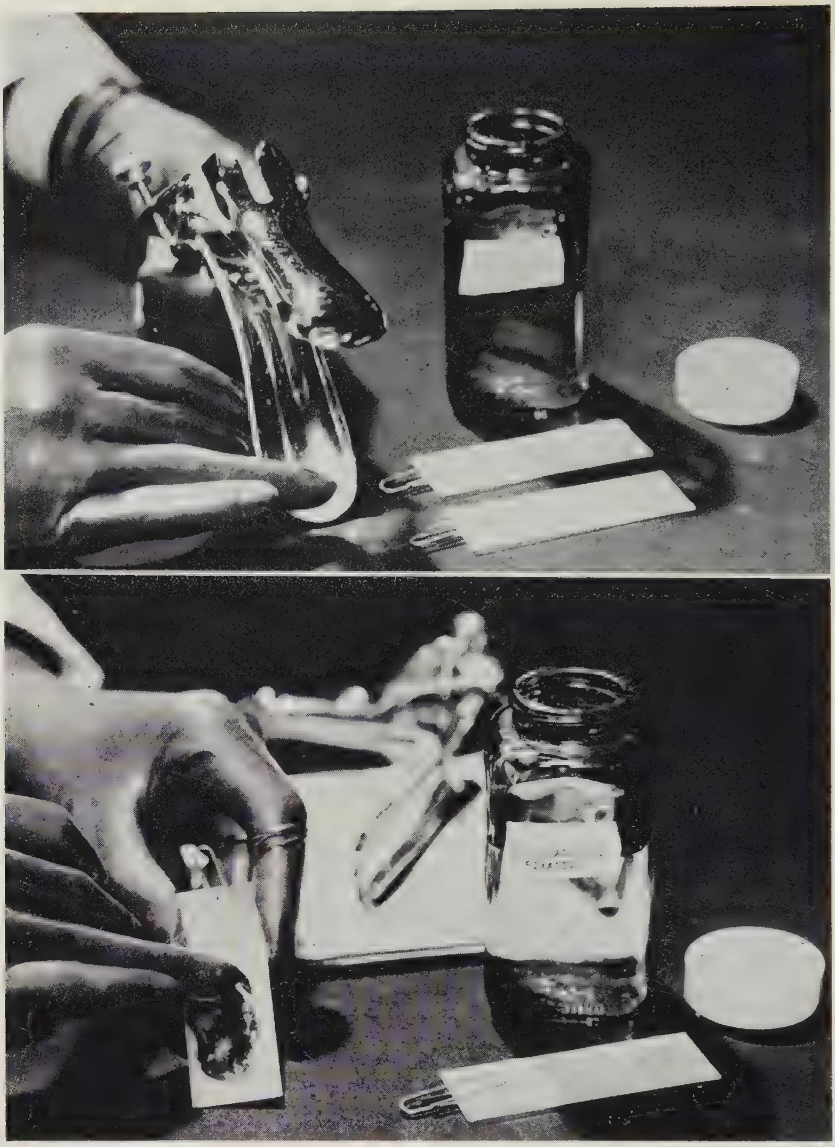

Fig. 591. Vaginal pool secretions collected by clean gloved finger (above) and quickly spread over slide (below).

quickly streaked lengthwise upon a clean glass slide, making 2 parallel strokes.[49] Fix smears immediately.

Cotton swab: An applicator stick tipped with nonabsorbent cotton may be used to obtain vaginal secretions from the posterior fornix through the speculum. The method has also been advocated as a method acceptable to the patient for self-obtained vaginal smear collection.[50]

Cervical smear

Collection of cellular material directly from the cervix increases the detection rate of early cervical cancer, but it is of very little value for detection of fundal carcinoma.[51] According to von Haam,[52] the most satisfactory method to date for cytologic examination of the female genital tract is accomplished by use of the vaginal smear and the cervical smear **together,** taken by a physician after visualization of the cervix by speculum.

Collection of cervical smears

Ayre spatula*: The cervical os is scraped 360° with a specially designed wooden spatula described by Ayre or by means of a common tongue blade that has been cut with curved scissors to fit the contour of the cervix.[53] It is important that the scraper fit the external os, which serves as a pivot for rotation. Collected material is rapidly streaked from the spatula onto a slide and immediately fixed.

Cotton swab: The entire portio vaginalis of the cervix is swabbed with a cotton-tipped applicator stick, introducing the applicator as far as possible into the external os. Material obtained in this manner is best smeared by a rapid rolling motion of the applicator tip on the slide. Murray[54] recommends use of cotton-tipped applicator sticks coated with collodion to produce slight abrasion during collection.

---

*Clay Adams, Inc., New York, N. Y.

Direct cervical imprint: A new approach reported by Nieburgs[53] and also by Nyklicek[55] employs a specially designed slide and slide holder whereby a direct impression smear of the cervix may be made, which maintains anatomic relationships and thus may assist in locating occult lesions.

Brunschwig-Draghi tampon: Under ideal circumstances smears prepared with the Draghi tampon* may be considered partially of cervical origin. The method of collection described by Brunschwig[56] and favorably evaluated by Papanicolaou[57] as a mass screening technic utilizes a specially designed tampon encased in a sheath of nonabsorbent nylon.

The tampon is inserted into the vagina by the patient through a cylindrical cardboard container with a narrower cardboard plunger. The tampon is removed after 5-30 min. and smears are prepared by quickly dabbing the distal end of the tampon upon the surface of a clean glass slide. The slide is placed immediately in the fixative. Papanicolaou[57] reported that smears of better quality are obtained when the tampon has remained inserted overnight.

Nieburgs[58] has modified the Brunschwig-Draghi method for use in mass screening whereby the patient also prepares the smears by pulling the withdrawn tampon through a box device† containing 2 slides. Two smears are automatically prepared. The smears are rehydrated before staining and need not be fixed at the time of preparation.

Endocervical smear: Much interest has been directed to collection of endocervical material and particularly to collection of the mucus plug from the external cervical os. It is believed that this material serves as an ideal reservoir for malignant cells when cervical cancer is present. The material may be conveniently and satisfactorily collected with a cotton applicator slightly moistened with physiologic saline, or a pipet or metal cannula may be used. Collection of the cervical mucus plug or endocervical aspiration should precede cervical scraping.

Combined cervicovaginal smear: Several methods have been reported which combine upon a single slide material originating from multiple female genital sites. Frost[59] has described a rapid and economic method which he reports to be suitable for routine usage. A drop of secretion obtained from the posterior vaginal fornix is mixed **on the slide** with material obtained by circumferential cervical scraping.

Wied[60] insists that collection of smears from 3 sites (vaginal pool, cervix, and endocervix) is required from each patient for complete and efficient evaluation. Wied and Bahr[61] reported a method whereby these 3 secretions are separately smeared upon a single, specially designed, partitioned slide—the **VCE slide.*** Specimens are not smeared until all 3 secretions have been obtained. The vaginal and cervical material remains as a thick drop on the collecting instrument, not subject to drying, until the scant endocervical material has been collected and smeared. Vaginal and cervical secretions are then rapidly smeared in the appropriate divided areas of the VCE slide. Speed in smear preparation and immediate fixation are essential. Wied introduced the 3-smears-on-1-slide method as a routine procedure at the Chicago Lying-In Hospital 5 yr. ago and reports that the method has achieved excellent acceptance and utilization by the attending staff.[62]

Intrauterine smears

Cytologic detection of fundal carcinoma is improved through examination of secretions obtained directly from the uterine cavity. The procedure is attended by definite risks, however, and present methods for collection of endometrial secretion do not permit routine usage. Cytologic examination of intrauterine smears should not be considered a substitute for curettage. This type of examination must never be performed during pregnancy. Endometrial cells are well preserved in smear preparations made directly from the uterine cavity in sharp contrast with their often degenerative appearances in cervical and vaginal smears.

Rakoff[63] stated in 1960 that his accuracy in detecting cases of endometrial cancer improved from 66 to 92% by including endometrial aspiration smears in addition to cervical and vaginal smears in selected cases. In a series of 63 patients with uterine carcinoma, Cuyler et al.[64] examined endometrial aspiration smears and were able to diagnose 84.1% as positive or suspicious.

Reports of additional intrauterine smear examinations have been made by Hect[65] and by Reagan and Sommerville.[66]

Endometrial aspiration: A number of instruments have been designed for collection of secretion from the endometrium. These include various types of metal cannulas, polyethylene tubing, and a number of abrasive devices. For specifications and sources of instruments see Nieburgs,[67] and for full details of intrauterine technics see Romberg.[68]

Endometrial lavage: Morton et al.[69] described a lavage method in 1957 for obtaining representative samples from the endometrial cavity. A small quantity of sterile saline is injected into the uterine cavity and the return flow is then aspirated from the posterior vaginal fornix.

In a series of 797 lavages obtained from 673 patients, the investigators accurately diagnosed uterine cancer in 24 of 26 (92%) histologically proved cases. In 11 cases, however, the authors erroneously interpreted benign endometrial cells as suspicious or positive.

*Available as VCE cytologic slides from Glasco Hospital Products, Chicago, Ill.

PULMONARY CYTOLOGY

The introduction of the Papanicolaou smear technic in 1943[70] for cancer diagnosis coincided closely with the development of serious concern among clinicians over the increasing incidence of lung cancer. There was no delay in investigating the reliability of cytologic examination of sputum and bronchial secretions for lung cancer detection. Wandall,[71] in a report published in 1944, was able to identify malignant cells in the sputum of 84 of 100 patients with primary carcinoma of the lung. In 1946 Herbut and Clerf[72] accurately diagnosed 47 of 57 cases (82%) of carcinoma of the lung by examining bronchoscopically obtained secretions. Farber et al.[73] in 1948 reported an accuracy of 80% and emphasized the necessity of examining multiple specimens from each case. Additional studies reported by Woolner and McDonald,[74] Liebow et al.,[75] and by McKay et al.[76] were in close agreement with the previously reported accuracy and sensitivity of pulmonary cytology in detecting lung cancer.

Several factors are responsible for the failure of pulmonary cytology to have achieved more widespread clinical usage. The continued necessity of examining multiple sputum specimens, the tediousness of the microscopic examination of tenacious mucus, and the paucity of therapeutic successes have conjunctly discouraged the application of pulmonary cytology to large segments of the population. Nevertheless, there is a sizable number of investigators at present whose investigations have established highly reliable morphologic criteria for recognition of pulmonary malignancy and other pathologic chest conditions.[77-87]

The **specimen** may consist of sputum which has been spontaneously expectorated or of bronchial secretion obtained by aspiration or lavage through the bronchoscope. An additional method of collection has been proposed to induce sputum production in asymptomatic individuals by aerosol inhalation of a hypertonic saline solution containing propylene glycol[88] or nebulized SO_2.[89]

Sputum

Thorough instructions to the patient are essential to achieve cooperation and understanding. Failure to clarify instructions often results in obtaining nasal secretion, postnasal drainage, saliva, or an admixture rather than a true sample of lower respiratory secretion. Whenever possible, the patient should be verbally instructed by a member of the cytology laboratory staff; the conventional instruction to "spit in the bottle" does not suffice. Allegedly a fairly large proportion of patients do not raise sputum; however, if the raising of sputum is insisted upon with sufficient firmness, an amount enough for cytologic examination can almost always be collected.[90]

When verbal instruction to each patient is impractical, distribution of written instruc-

INSTRUCTIONS TO PATIENTS FOR SPUTUM CYTOLOGY STUDY*

Sputum is the material that originates from deep in the chest and can be obtained only by deep cough.

Saliva is the watery fluid in the mouth and is **not** desired in this test.

Postnasal drainage is the thick material that may drain down from the nose and collect in the back of the throat, especially during the night in sleep. This material, if present, must be cleared from the throat and **discarded** before coughing to collect sputum for the cytology study.

Instructions:

1. In the morning, before breakfast, clear your throat and **discard** any material that is present.
2. Breathe deeply 8 to 10 times and cough deeply. Collect the sputum obtained in this way in the container provided. Repeat this procedure several times during the first hour after you awake. Even a small amount of material is suitable for this study, provided it has been raised from deep in the chest.

---

*Sputum cytology is a special test which requires a fresh morning specimen of sputum to be collected on 5 separate days.

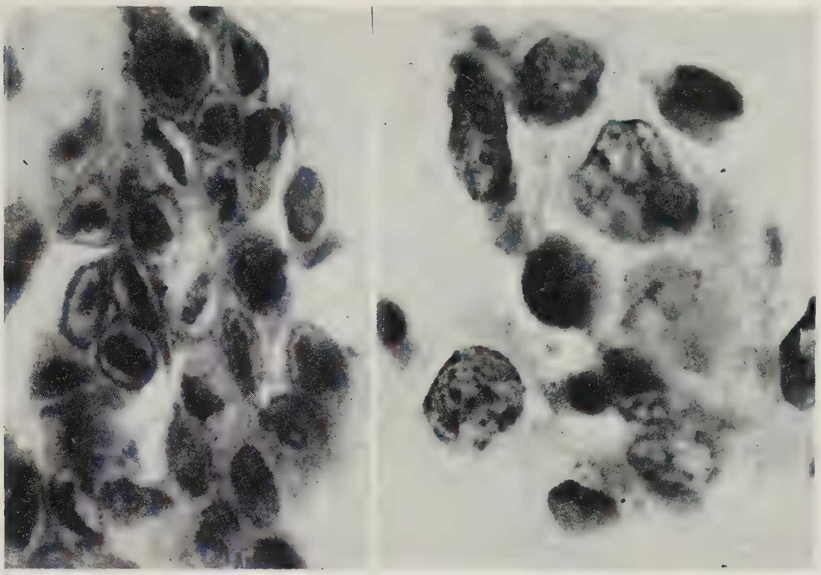

Fig. 592. Cell groups in sputum. Left, dyskeratosis suggesting bronchial squamous metaplasia. Right, hyperkeratinized malignant cells consistent with squamous carcinoma.

tions similar to the accompanying chart is beneficial.

Collection of the sputum specimen into a wide-mouthed glass bottle with a suitable cap or cover is preferred to use of a disposable cardboard carton. The latter is convenient but is less efficient for transferring the specimen to another container for selective smearing or for concentration. The sputum specimen raised upon awakening is best suited for cytologic examination; that raised by spontaneous cough is more likely to yield positive results. Particular effort should be made to obtain the sputum raised during the first hour following bronchoscopic examination.

Smears of sputum should be prepared as soon as possible after its collection; a delay of 4-6 hr. is permitted provided sufficient mucus or saliva is present to delay drying. Papanicolaou[91] recommends collection of sputum in a bottle containing 70% alcohol as a preservative. The resulting hardening of the sputum by alcohol, however, causes difficulty in smear preparation and also in obtaining adhesion of the material to the slide during fixation and staining.

Bronchial aspiration or lavage

The relative merits of cytologic study of secretions obtained by bronchoscopy versus sputum have been widely discussed.[72, 74, 75, 92-96] The reported accuracy of cytologic examination of bronchial aspiration ranges from 30%[75] to 95%.[96] In a series of 500 patients

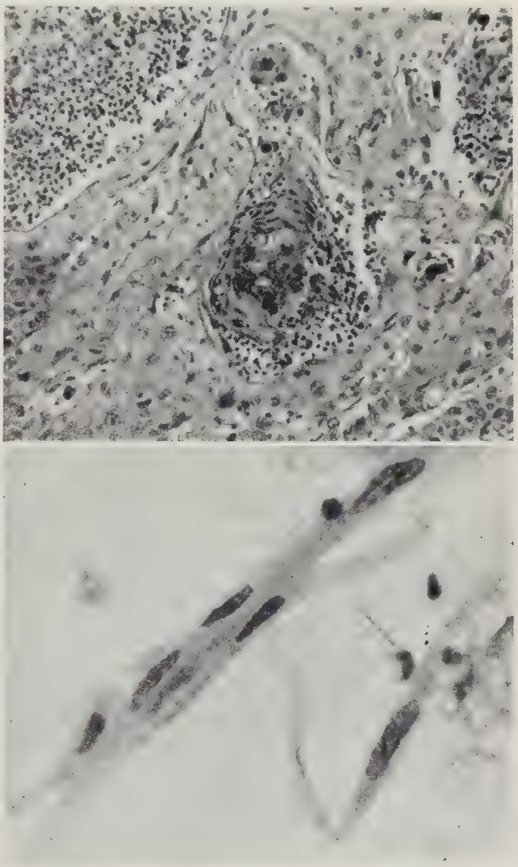

Fig. 593. Above, tissue section, well-differentiated squamous carcinoma of lung with pearl formation. Below, malignant "spindle" cells, assumed to originate from pearl formation.

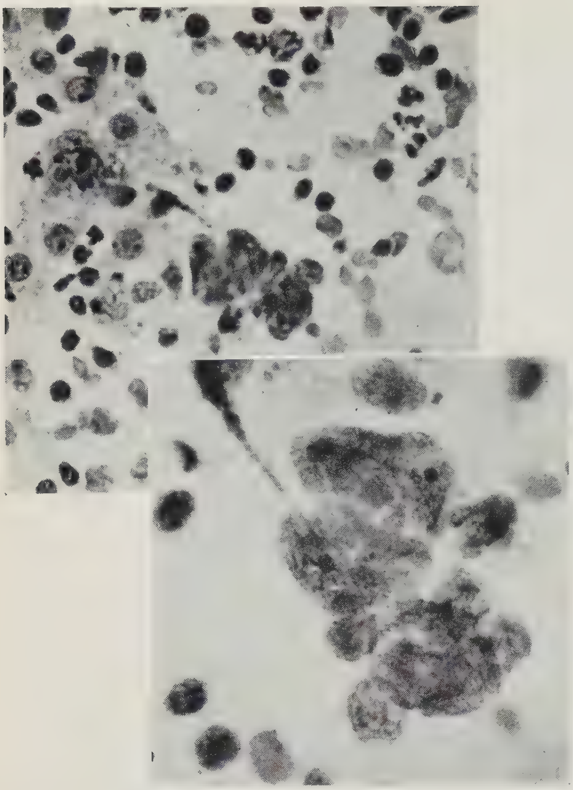

Fig. 594. Dorothy Reed cells in bronchial aspiration in a case of Hodgkin's disease with pulmonary involvement. (Specimen courtesy Dr. Bernard Pierson, Nancy, France.)

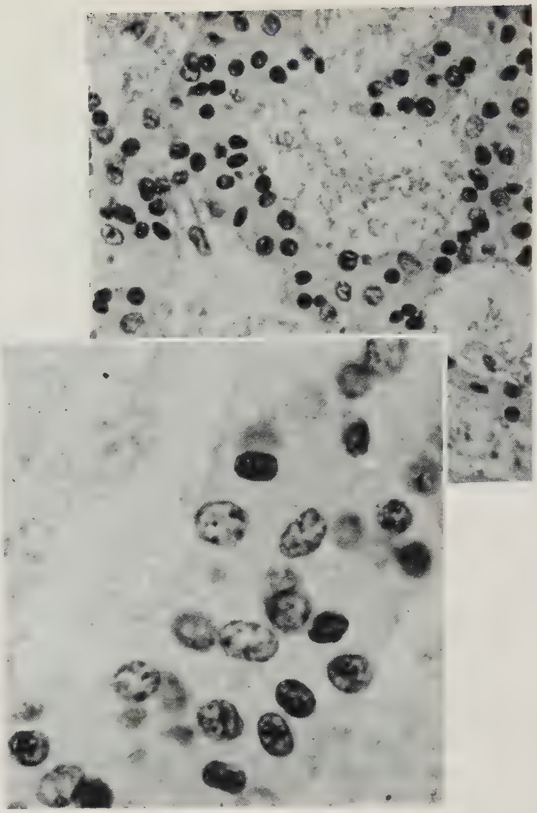

Fig. 595. Sheets of uniform cuboidal cells in bronchial aspiration from a patient with bronchial adenoma. (Specimen courtesy Dr. Bernard Pierson, Nancy, France.)

with bronchial tumors Pierson was able to diagnose 478 (95%) on the basis of bronchial aspiration alone. A repeated bronchial aspiration was required for diagnosis in only 43 of the 478 patients. There were 2 false positive cases among the total series of 4000 cases. Pierson attributes his unusually successful results to the teamwork of bronchoscopist and pathologist for specimen collection. Pierson personally attended bronchoscopy in the majority of cases in his series and insisted upon the following **requirements for specimen collection:** (1) precise location of aspiration with respect to the suspicious area or areas, (2) a slightly traumatizing procedure, and (3) a prolonged aspiration of at least 1 min. from each area examined. It is of further interest to note that Pierson's accuracy dropped by 15% in his examination of specimens referred to him from sources outside his hospital.[97]

Cahan and Farr[98] in 1950 described a method for obtaining secretions or washings from the trachea and main bronchi without bronchoscopy. The procedure can be performed in ambulatory patients.

A small catheter is passed to the trachea and Pontocaine is instilled as the catheter passes to the carina and main bronchi. Two ml. portions of physiologic saline are instilled and reaspirated from various areas and collected for cytologic examination.

The procedure may be useful as a means of obtaining pulmonary secretion from patients who do not raise sputum and whose clinical findings do not warrant bronchoscopy.

METHODS FOR CONDUCTING PULMONARY CYTOLOGIC EXAMINATION

The 3 methods for conducting cytologic examination of sputum and bronchial secretions are (1) direct smear preparations from selected areas of the specimen, (2) cell block preparations, and (3) digestion and concentration of specimens.

Direct smear method

The necessity of examining multiple sputum specimens is a consequence of the many items of chance involved in the collection and preparation of sputum specimens. In spite of giving thorough instructions to patients for collection of sputum, many submit upper respiratory secretions instead of sputum. In addition, no infallible method has been found to identify the types of sputum particles which may harbor malignant cells.

Three smears are prepared from each specimen of sputum or bronchial secretion. An attempt is made to select 3 different types of material from each specimen, with particular interest in searching for bloody strands of mucus, cheesy particles, or tissue fragments. The specimen should be poured into a Petri dish and inspected over a dark background with an adequate overhead light source.

Direct smears are prepared by introducing a pea-sized fleck of carefully selected sputum upon a clean glass slide, using a plain, untipped applicator stick. Excess material clinging to the selected portion of sputum can be severed by "sawing" it against the sharp glass edge with the applicator stick. The isolated portion of sputum can then be streaked across ⅔ of the surface of the slide or, preferably, teased apart and spread to an even thickness with a pair of applicator sticks.

Koss[99] advises use of a small nasal curet or a specially designed shallow spoon* for isolation and transfer of selected sputum particles from specimen to slide. He also advocates use of a "crush" preparation of material between 2 slides, presumably a method preferred for preparation of alcohol-fixed sputum specimens.

Cytologic smears of sputum are often made too thin rather than too thick; either extreme is undesirable.

Immediately after preparation each slide is placed in a fixative solution consisting of equal parts of ether and 95% ethyl alcohol. A paper clip inserted on the identified end of each slide prevents smears from sticking together in the fixative. Place slides in fixative gently and avoid striking container bottom forcefully.

Sputum smears should remain in the fixative for a minimum of 1 hr. before staining.

Accuracy, direct smears: Examination of a single sputum specimen by the direct smearing method is inadequate for lung cancer detection. Farber and Pharr[100] cite their experience of detecting only 45-50% of cases of pulmonary cancer when only 1 sputum sample is examined. A study of 3 separate specimens increases this accuracy to 65%, and a study of 5 separate specimens raises it to 90%. Thus, although cytologic examination of 5 separate sputum samples from each case requires considerable time and effort from trained personnel, study of fewer specimens is of limited clinical value.

Cell block

Some investigators prefer to examine sputum and bronchial secretions by preparing block sections according to the usual histologic technic. According to Hunter and Richardson,[49] the method has the following distinct advantages:

1. Cell dimensions following fixation and embedding in paraffin are the same as those in the more familiar tissue sections.
2. Cell grouping, when present, is not broken up.
3. The small area presented for microscopic examination precludes the necessity for previous screening by a cytotechnician.

More recently, Richardson et al.[101] investigated the results of the simultaneous use of smears and cell blocks in 2613 specimens of various body fluids; approximately ½ the cytologically positive specimens were sputum or bronchial washings (283 of 578 positive specimens). The authors concluded that carefully prepared smears are essentially a better diagnostic medium than cell blocks because of better preservation of cellular detail. They stress, however, that the highest degree of accuracy was achieved by utilizing smears as the principal diagnostic method and supplementing them with cell block preparations of the residual material remaining after smear preparation. With this dual method the authors were able to detect 12% additional cases through cell blocks of residual sputum and gained 19% accuracy by examining cell blocks of residual bronchial washings.

Procedure[101]:

1. Fix specimen in a solution of 13 gm. picric acid in 1000 ml. 70% alcohol for 4 hr. or more.
2. After fixation dehydrate and embed in paraffin.
3. Place 9-12 cut sections on 3-4 slides, stain, and mount.

Bothereau[102] recommends 12-24 hr. fixation in Allen fluid for cell block preparation of body fluids.

Allen fluid[102]:

Picric acid, saturated aqueous solution	75 parts
Formalin, c.p.	15 parts
Glacial acetic acid	10 parts
Urea	1 part

Sputum concentration

Attempts to concentrate the cellular content of sputum and bronchoscopically obtained secretions by mucus digestion have been reported by various investigators[103-109] who have

---

*Available from United Surgical Supply Co., Port Chester, N. Y.

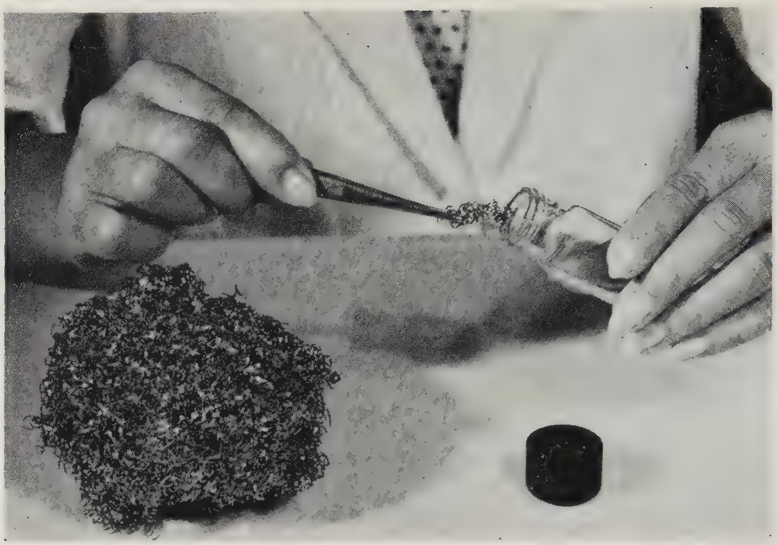

Fig. 596. Strand of metal coil added to sputum before agitation; shreds mucus strands and increases the surface area for effective mucolysis by trypsin solution.

used proteolytic or mucolytic enzymes such as hyaluronidase, lysozyme, papain, trypsin, and chymotrypsin.

The method to be described was developed personally and has been in use for more than 5 yr. A specially selected trypsin product and balanced electrolyte solution as diluent are used with mechanical agitation. Results have consistently been dependable, and there has been no evidence of cellular alterations due to the digestion process either in normal cells or in any type of malignant cells. Cellular grouping is not disjoined, and tinctorial reactions are not altered.

Advantages of tryptic concentration of sputum:

1. Examination of 2 sputum specimens per case is sufficient to obtain reliable cytologic results and is equivalent, if not superior, to examination of 5 or more specimens by the conventional direct smearing method.

2. A sampling from mixed sputum sediment following concentration is representative of the entire specimen, rather than a random selection; thus in each smear the cellular distribution is representative of the cellular population of the entire specimen.

3. Microscopic examination is facilitated by the uniformly thin distribution of smeared cells. Lysis of mucus and the absence of overlying and crowded cells permit improved visualization of cellular and nuclear detail.

4. Risk of laboratory infection is reduced by the method of processing the specimen, and the unsavory task of selecting and smearing sputum is eliminated.

5. Microscopic examination of the homogenized sediment provides a valid index to the relative number and appearance of benign cells and may be of clinical significance in evaluation of nonmalignant chest conditions.

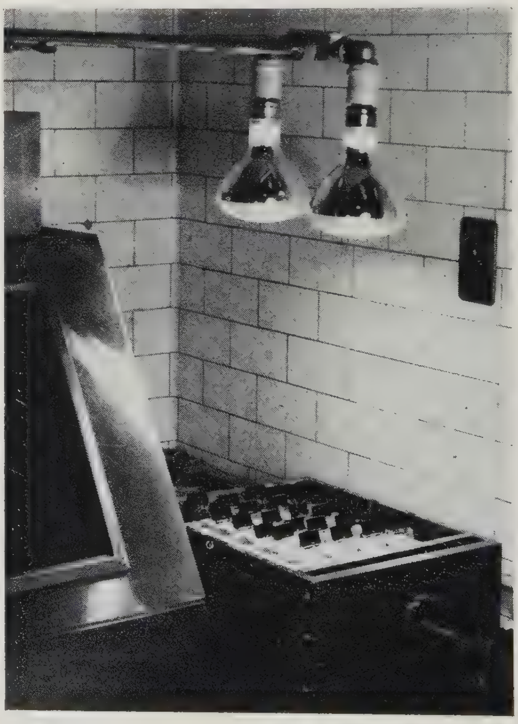

Fig. 597. Successful digestion of mucus by trypsin requires use of forceful agitation and simultaneous heating to 37° C.

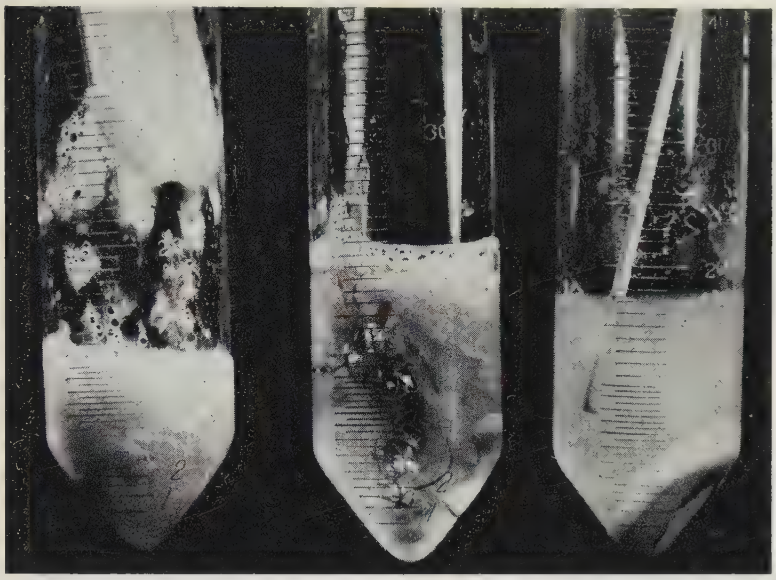

Fig. 598. Tryptic concentration of sputum. Left, tenacious sputum sample before treatment. Center, same specimen after addition of trypsin solution and metal coil. Right, same specimen following agitation and centrifugation. Note separation of sediment into distinct layers; the uppermost "buffy" layer is almost entirely bacteria.

The examiner is able to comment meaningfully on purulence, eosinophilia, and polymorphonuclear ratio and to judge semiquantitatively the content of macrophages, columnar cells, erythrocytes, and other elements in sputum samples.

6. Concomitant bacteriologic and mycologic laboratory examinations can be performed on the sediment processed for cytologic study with a resulting sensitivity that is equivalent, if not superior, to that of standard methods of study.

Concentration of the specimen requires approximately 60 min. Although this is considerably longer than the few moments needed to prepare direct smears, no attention from the worker is required during 45 of the 60 min. In addition, multiple specimens can be processed at the same time.

Reagents:

1. Crystalline trypsin.*
2. Isolyte-E, without dextrose.†
3. Celloidin-ether-alcohol fixative.
   (a) Add 1.5 ml. thick celloidin to each liter of equal parts of ether and 95% ethyl alcohol.
4. Papanicolaou staining solutions.‡ The Pharr, Wood, and Traut modified counterstains and modified staining method are particularly well suited for staining concentrated sputum sediment smears (pp. 1765 and 1766).

Equipment:

1. Box type shaking machine.
   260-270 strokes/min., 1½-2½ stroke amplitude. Rotator types not sufficiently forceful for use.
2. Pair of 250-watt infrared heat lamps.
   Mount on adjustable stand over shaking machine.
3. Stainless metal sponge, ribbon gauge.
4. 50 ml. round-bottomed centrifuge tubes with screw cap.*
5. Pasteur capillary pipets, 9 in. length.†

Procedure: The technic that follows applies to processing specimens of 10 ml. volume or less. Larger samples are divided into approximately 10 ml. portions and processed separately.

1. Measure 10 ml. Isolyte-E for each specimen; e.g., for processing 8 specimens, measure 80 ml.
2. Weigh 10 mg. crystalline trypsin for each specimen; e.g., for 8 specimens, weigh 80 mg.
3. Mix trypsin and Isolyte-E immediately before procedure is begun. **Caution:** There should be no lengthy delay after this point.
4. Add 10 ml. enzyme-electrolyte solution to each specimen, mix with a tongue blade, and transfer to a centrifuge tube, draining the entire liquid portion.
5. Add a 1 in. strand of metal ribbon cut from a scrubbing sponge and cap the tubes.

---

†Scientific Products; Cat. No. 67771.

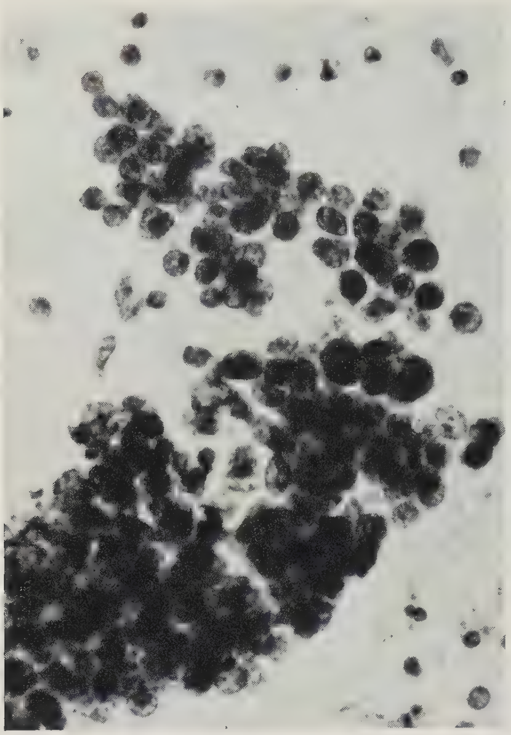

Fig. 599. "Oat cells" in tryptic concentrated sputum smear.

6. Place the tubes in a shaking machine at a 45° angle and agitate for 30 min. Overhead heat lamps are placed at a fixed distance to maintain a temperature of 35°-40° C. within the tubes during digestion.
7. Following digestion, remove the metal coil from each tube and discard. Without delay recap the tubes, balance, and centrifuge for 15 min. at 2500 r.p.m. Allow the tubes to come to rest without braking.
8. Pour off the supernatant fluid with a single rapid inversion and allow the tubes to drain for a full minute.
9. Mix the sediment **thoroughly** and prepare cytologic smears by the pull-apart method, previously described (p. 1760).

Concomitant laboratory uses of tryptic concentrated sputum: The use of trypsin as a digestant of sputum for isolation of acid-fast bacilli was described by Haynes[110] in 1942. The previously described tryptic digestion method was designed to preserve cellular detail but has also proved to be an efficient means for concentrating bacteriologic and mycologic components of sputum.

A top buffy layer is present in the sediment of most tryptic concentrated sputum specimens, and this has been found to contain a superconcentration of bacteria and light, amorphous debris. Material collected by loop or pipet from the buffy layer prior to mixing of the sediment for cytologic smear preparation is an excellent source of bacteria for bacteriologic examination by smear or by culture. Mycologic smears and cultures can be obtained from the mixed sediment.

Following is a résumé of laboratory examinations of tryptic concentrated sputum:

1. Acid-fast stain—1 slide from buffy layer.
2. Gram stain—1 slide from buffy layer.
3. Papanicolaou stain—2 or more slides from mixed sediment.
4. Fungus stain—1 slide from mixed sediment.
5. Tubercle bacilli culture—inoculate from buffy layer or from treated mixed sediment.
6. Pyogenic culture—inoculate from buffy layer.
7. Fungus culture—inoculate from mixed sediment.

GASTROINTESTINAL CYTOLOGY

Many malignant lesions of the gastrointestinal tract occur in locations which are accessible to cytologic examination by use of specialized technics. Although the methods employed for collection of gastrointestinal cytologic specimens are relatively simple, safe, and applicable to ambulatory patients, they are nonetheless time-consuming procedures and often demand patient selection on the basis of clinical symptoms or findings.

Esophagus

Rubin[111, 112] states that cytologic examination of esophageal secretion appears to be the most accurate of all gastrointestinal cytologic procedures. He and associates were able to detect 46 of 47 (97.9%) cases of malignant lesions of the esophagus by a lavage technic. In 3 additional reports by Gephart et al.,[113] Raskin et al.,[114] and Klayman[115] accuracy in detecting malignant lesions of the esophagus ranged from 90.5 to 95%. Imbriglia and Lopusniak[116] have reported cytologic detection of carcinoma in situ of the esophagus in 1 case, and Koss[117] reports an additional case detected cytologically as "approaching in situ carcinoma."

Rubin[111] has emphasized that the best results can be expected when the same physician is responsible for specimen collection and microscopic interpretation. He also indicated the need for familiarity with special clinical situations, such as vitamin B_{12} or folic acid deficiency, prior radiation, inflammatory disease, and others, to avoid false positive diagnoses of malignancy.

Lavage[111]

The patient should fast for 12 hr. before the cytologic examination. A 48 hr. delay is required after barium ingestion. In the case of a severely obstructed esophagus, a clear liquid diet may be necessary for several days preliminary to lavage.

If no obstruction is encountered, a Levin tube is passed into the stomach with the patient in the seated position.

The gastric contents are then aspirated and discarded unless tissue fragments are present, in which case they are isolated and smeared.

The patient is cautioned to expectorate all saliva and mucus of respiratory or nasal origin during the procedure.

The patient then drinks 100 ml. Ringer solution, which is recovered from the stomach.

With the patient in the supine position, the tube is withdrawn 5 cm. at a time.

At each level 50 ml. Ringer solution is vigorously instilled and reaspirated. If a questionable area has been previously localized by x-ray examination, special effort is made to lavage this area thoroughly.

Immediate centrifugation of the lavage specimen is essential, and smear preparation and fixation must follow without delay.

Abrasive cell collection

Various abrasive methods for esophageal cell collection during esophagoscopy have been described[118-121] and include use of a gauze sponge or specially designed abrasive instruments. Conflicting opinion exists regarding the reliability and advisability of employing such methods in cases of suspected esophageal cancer.[111, 113]

Stomach

The stomach is easily accessible for collection of cellular material. The reliability and accuracy of gastric cytology to detect up to 95% of cases of gastric cancer have been proved in a number of reports in which large series of patients have been examined.[122-128]

The methods described for obtaining gastric material for cytologic examination have varied widely from simple aspiration of fasting gastric contents to lavage by various solutions and use of abrasive instruments. Studies comparing the accuracy of various methods indicate that equally sensitive results are obtainable by each method, provided meticulous care is taken in performing the procedure.[129, 130] Rinaldo et al.[131] indicate that gastric cytology is especially useful for detection of cancer in the antrum, on the greater curvature, and in the fundus, and they note that it is in these areas that the radiologist most frequently fails.

Saline lavage[130]

Part I:

1. Have the patient fast overnight. In the morning, with the patient sitting upright on a bed or cot pass an iced No. 18 Levin tube orally 55 cm. into the stomach.
2. Aspirate and discard the gastric residuum.
3. Quickly and **forcefully** inject and aspirate 100 ml. isotonic saline. Then reinject and reaspirate, collecting in centrifuge tubes that are immersed in an ice-water bath.
4. Allow the tube to remain in place and inject 100 ml. fresh saline, repeating the procedure as described.
5. Repeat until 300-400 ml. fluid have been used.

Part II:

1. In the second part, introduce 500 ml. isotonic saline into the stomach.
2. Have the patient lie in each of the following positions for 2 min. each: on the right side, back, abdomen, and finally on the left side. Briskly massage the upper abdomen while the patient is supine.
3. Withdraw fluid when the patient has completed a 360° rotation. Approximately 400 ml. can be recovered.
4. Centrifuge the aspirate immediately and prepare and fix the smears without delay.

Comment: Ringer solution or a buffered solution may be substituted for isotonic saline. All authors have stressed the necessity of performing a vigorous and aggressive lavage and have emphasized the necessity of centrifuging the specimen and preparing smears as rapidly as possible after collection. Use of a bedside, portable centrifuge has been recommended.

Enzymatic gastric lavage

Two mucolytic enzyme solutions have been described for use as lavage solution in gastric cell collection. The purpose of each is to dissolve the mucous barrier which coats the luminal surface of the stomach and thus to permit recovery of cells trapped in the mucus and, more importantly, to permit shedding of cells directly from the surface of a gastric lesion.

Papain, a proteolytic enzyme derived from the fruit of the papaw, was used with a buffered solution for gastric lavage by Rosenthal and Traut,[122] and their method was reported in 1951. In 1955 Rubin and Benditt[132] introduced a similar lavage procedure which utilized another enzyme, α-chymotrypsin.

No superiority in results has been conclusively indicated for either method. The preparation of α-chymotrypsin lavage solution has been greatly simplified by use of a commercially prepared capsule containing a measured quantity of enzyme.*

---

*A capsule containing 7 mg. crystalline α-chymotrypsin available as Cyto-Lav from Armour & Co., Kankakee, Ill.

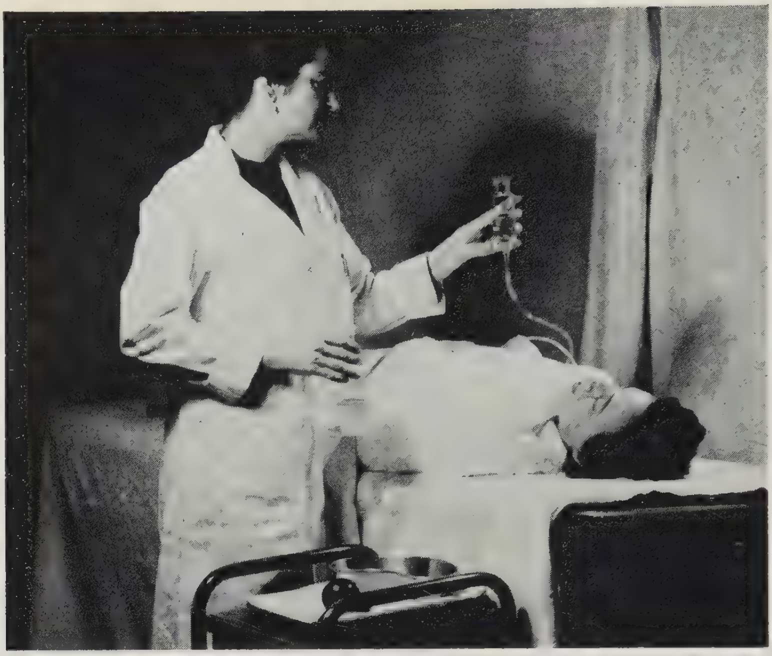

Fig. 600. Five hundred milliliters papain solution are instilled into stomach slowly.

Papain lavage—Rosenthal-Traut[122]

Reagents:

1. Papain buffer solution.

Dibasic sodium acid phosphate	350 gm.
Hydrochloric acid, concentrated	33 ml.
Distilled water	5 gal.

   (a) The pH is 7.3.
   (b) The buffer will keep indefinitely.

2. Papain gastric lavage solution.
   (a) For each lavage place 500 ml. papain buffer solution in a mechanical stirrer such as a Waring blendor and add 3 rounded teaspoonsful of powdered papain.
   (b) Mix 3-5 min. During the last 1 min. add 1 heaping spoonful of powdered activated charcoal.
   (c) Filter. The first few drops will contain charcoal; return these to the funnel. The remaining filtrate should be sparkling clear and amber.
   (d) Papain lavage solution can be kept 24-48 hr. before use if refrigerated.

Method: Preparation of the patient and intubation conform to previous instructions for conducting saline lavage. At least 2 wk. should elapse after gastric hemorrhage before the test is made.

1. Aspirate and discard fasting gastric contents.
2. Dissolve ¾ teaspoon cysteine hydrochloride (activator) in 500 ml. papain lavage solution immediately before use.
3. Instill 500 ml. activated papain lavage solution into the stomach by tube.
4. Request the patient to lie down and to rotate position frequently during the next 10 min. Gentle massage may be applied in the area of the stomach.
5. After 10 min. withdraw the lavage solution by gravity flow and centrifuge as soon as possible.
6. Underlay 2-3 ml. serum or plasma in the specimen before centrifugation to ensure adhesion of smeared sediment.
7. Make 4-6 smears by the pull-apart method.

Alpha-chymotrypsin gastric lavage

Reagent:

1. Sodium acetate buffer, pH 5.6.

Sodium acetate, crystalline	13.6 gm.
Glacial acetic acid	0.6 ml.
Distilled water	1000 ml.

   (a) Prepare the buffer in small quantity and refrigerate.

Method—Rubin et al.[112, 132]: Patient preparation and intubation are the same as previously described for saline lavage.

1. Prepare the α-chymotrypsin lavage solution immediately before use by adding the contents of a Cyto-Lav capsule* containing 7 mg. crystalline α-chymotrypsin to 500 ml. sodium acetate buffer.
2. Instill into the stomach the entire 500 ml. or as much as will be tolerated by the patient. Ask the patient to rotate himself through 360° during the next 10 min.

The solution should not remain in the stomach longer than 10 min. and should be withdrawn and centrifuged as quickly as possible. No more than 10 min. should elapse between withdrawal of fluid and fixation of smears.

---

*A capsule containing 7 mg. crystalline α-chymotrypsin is available as Cyto-Lav from Armour & Co., Kankakee, Ill.

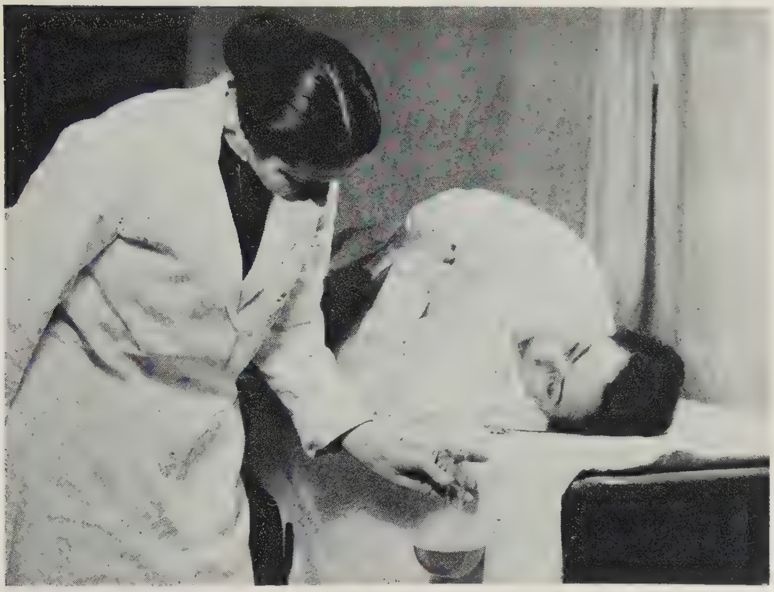

Fig. 601. At the end of 10 min. solution is recovered by gravity flow.

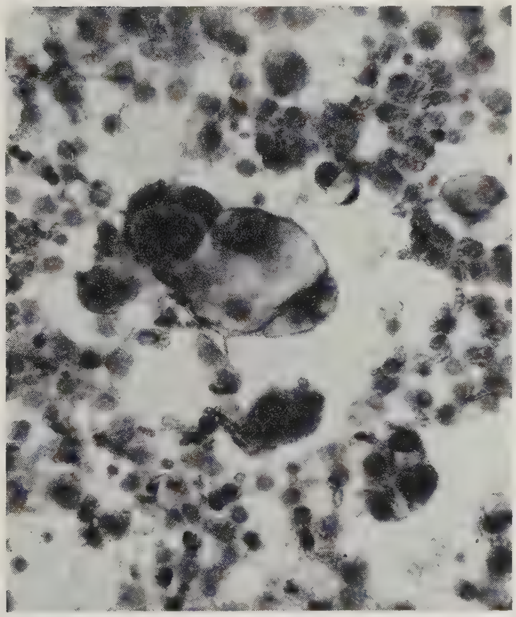

Fig. 602. Several groups of malignant cells in papain gastric lavage smear. Diagnosis was adenocarcinoma of stomach.

Abrasive methods for gastric cell collection

Sponge biopsy: A number of methods have been described for gastric cell collection, which depend upon mechanical irritation and abrasion of the gastric mucosa. The first method was described by Gladstone[133] in 1949. The method utilizes a Levin tube, along the lower portion of which 12-15 pieces of synthetic cellulose sponge are wound.

1. Pass the tube into the stomach and, with the patient on the right side, massage the abdomen to bring the sponges into contact with the gastric mucosa.
2. After withdrawal, fix the sponges in 10% formalin, embed in paraffin, and section according to standard histologic technics.

Gladstone has described similar applications of his sponge biopsy method for cell collection from cervix, rectum, bronchus, oral cavity, and skin.

Gastric balloon: The gastric balloon method of gastric cell collection was described by Panico et al.[134] in 1950. The instrument is a specially designed, inflatable gastric balloon covered externally with a wide-meshed silk net.*

1. Pass the balloon orally into the stomach, and then inflate and draw it to the cardia. Peristaltic action returns the balloon to the pylorus in 5-10 min.
2. Repeat the procedure each 10 min. for 30 min.; then deflate and withdraw the balloon.

Cellular material is obtained by vigorous rinse of the balloon and net in Ringer solution.

Centrifugation of rinsing fluid and smear preparation must follow without delay.

Cooper and Papanicolaou[135] report an overall diagnostic accuracy of 97.1% with the

---

*The entire apparatus can be purchased from Dr. Arthur O. Dahlberg, Walbrook Road, Scarsdale, N. Y. Full directions are given with the instrument.

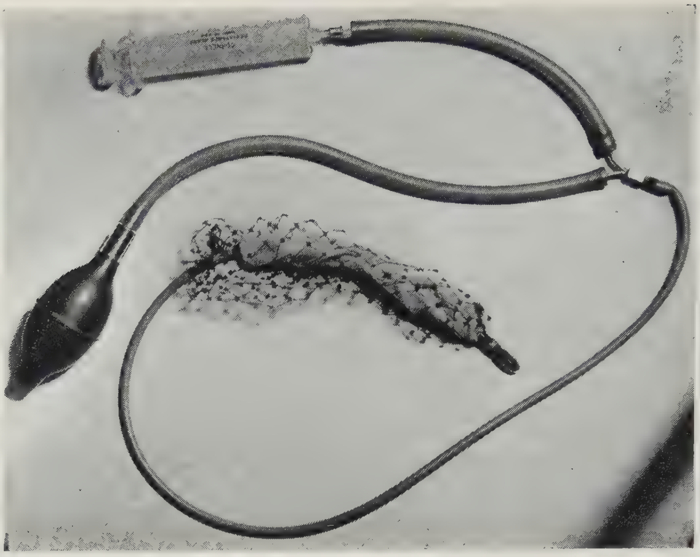

Fig. 603. Inflatable gastric balloon apparatus of William A. Cooper, Frederick G. Panico, and George N. Papanicolaou.

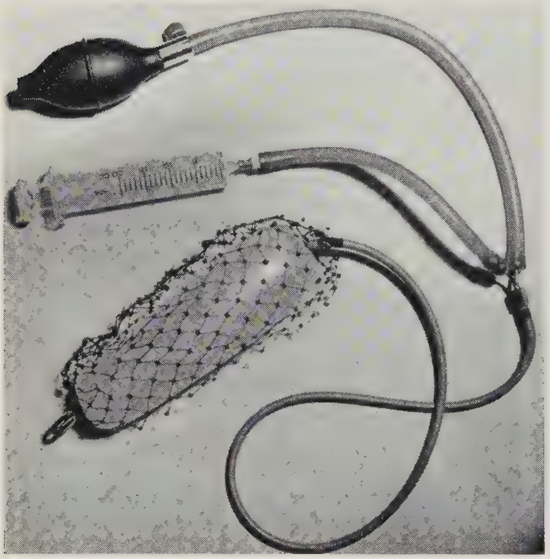

Fig. 604. Inflatable gastric balloon apparatus, showing the balloon partially inflated.

abrasive balloon technic. Other investigators[128, 136, 137] have found the technic to be prohibitively time-consuming and not tolerated well by patients. Koss[137] states that the abrasive balloon method is preferable to lavage only in cases of advanced gastric tumors with necrotic surfaces.

Abrasive brushes: Two abrasive brush instruments for gastric cell collection have been described. The first was reported by Ayre and Oren[138] in 1953. This is a retractable, biwinged brush which is spread open after passage to the stomach.

1. Rotate the brush as the tube is withdrawn from the pylorus to the cardia. Close and retract the brush and then withdraw the tube.
2. Prepare cytologic smears from material obtained by squeezing the brush from its base to tip between 2 slides.

Willner et al.[139] state that an unsatisfactory number of false positive diagnoses of malignancy are associated with gastric cytologic examinations obtained by the Ayre brush method and attribute the difficulty to misinterpretation of benign sheets of gastric mucosal cells. Nieburgs[140] has described a modified Ayre brush composed of retractable loops of nylon fibers.

Duodenum and pancreatic and biliary systems

Bowden and Papanicolaou[141] examined secretions obtained from the duct of Wirsung at the time of performing pancreatoduodenectomy in a small series of patients. They reported that they could usually identify exfoliated malignant cells in the fluid in cases of primary infiltrating carcinoma of the pancreas and in cases of carcinoma of the common bile duct or duodenum secondarily invading pancreatic parenchyma.

Cytologic examination of secretions obtained by duodenal drainage has remained of limited clinical value, however, because of the specialized skill that is required for specimen collection. Duodenal secretion is often scanty and its microscopic interpretation is difficult.[123, 142]

In a series of 356 duodenal drainages, Raskin et al.[143] were able to detect 33 of 55 cases (60%) proved to have carcinoma of the pancreas, bile ducts, gallbladder, or primary or secondary duodenal carcinoma. A similar accuracy has been reported by other investigators.[112, 144-146]

Colon and rectum

Cytologic examination of colonic washings is valuable for detection of malignant lesions beyond the reach of the sigmoidoscope. Rigorous preparation by cathartic and enemas is essential. An assumption that diagnostic malignant cells are removed during cleansing enemas is not substantiated by the reports of highly successful cytologic studies of colonic and rectal washings.[123, 147-150] Raskin et al.[123] obtained positive cytologic examinations in 36 of 38 cases (95%) with proved colonic malignancy. In 10 of the 36 patients with positive cytologic findings the initial barium enema examination failed to disclose evidence of malignancy.

Procedure—Koss[151]

1. Give the patient 2 oz. mineral oil or castor oil by mouth 12 hr. prior to examination.
2. On the morning of the procedure, administer cleansing enemas until returns are clear. Collection of cytologic material may be delayed 1-2 hr.
3. Instill 500-1000 ml. warm Ringer solution with the patient in the left decubitus position. Massage of the colon and rotation of the patient are helpful in obtaining better cytologic material.
4. Collect the fluid after 3-5 min., centrifuge immediately, and prepare and fix smears without delay.

SEROUS FLUIDS

The accumulation of fluid within the pleural, peritoneal, or pericardial cavities is indicative of a pathologic process. With the rare exception of mesothelioma, the presence of malignant cells in serous fluid indicates metastatic involvement. The appearance of serous effusion is often the first indication of a primary malignancy elsewhere and, as a result, considerable interest has been directed to its examination by the cytologic method.

Monographs by Whiman[152] and Spriggs[153] and a number of descriptive articles have been published which give detailed accounts of cellular morphology in both benign and malignant effusions.[154-161]

Serous fluids should be collected into an anticoagulant solution and rotated throughout collection. Addition of an anticoagulant agent after the specimen is collected will usually not prevent clotting of sediment following centrifugation. Any standard anticoagulant used for blood collection may be used and in the amounts required for the same volume of blood. Sodium citrate is economical and satisfactory; approximately 10 ml. 3.8% sodium citrate are used for each 100 ml. fluid collected. Ethylenediamine tetraacetate (EDTA) is highly recommended for use as an anticoagulant in serous fluids because of its excellence in preserving cellular morphology and in preventing the formation of fibrin. The dipotassium salt is preferred to the disodium salt for cytologic usage.

An aliquot of 100-200 ml. is the minimum requirement for cytologic examination. Addition of an adherent agent is not required. Following centrifugation, particular effort should be made to collect material from the top buffy layer for smearing; this layer is especially conspicuous in specimens of bloody effusion and is a rich source of malignant cells. The pull-apart method of smear preparation (p. 1760) gives excellent results.

When absolutely necessary, a serous fluid specimen may be refrigerated overnight before processing; however, artifactual changes, such as vacuolization and cytolysis, may provoke uncertainty in the microscopic examination. Collection of the specimen directly into an equal volume of 50% alcohol or 10% aqueous formalin has also been advocated.

The cell block technic is often employed as

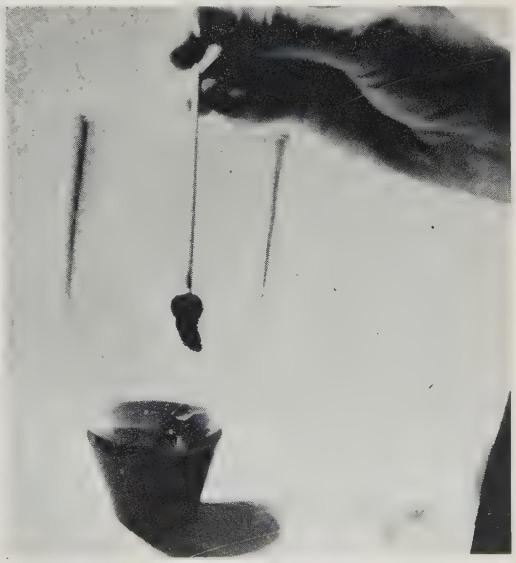

Fig. 605. Clotted serous fluid sediment caused by failure to collect specimen into anticoagulant.

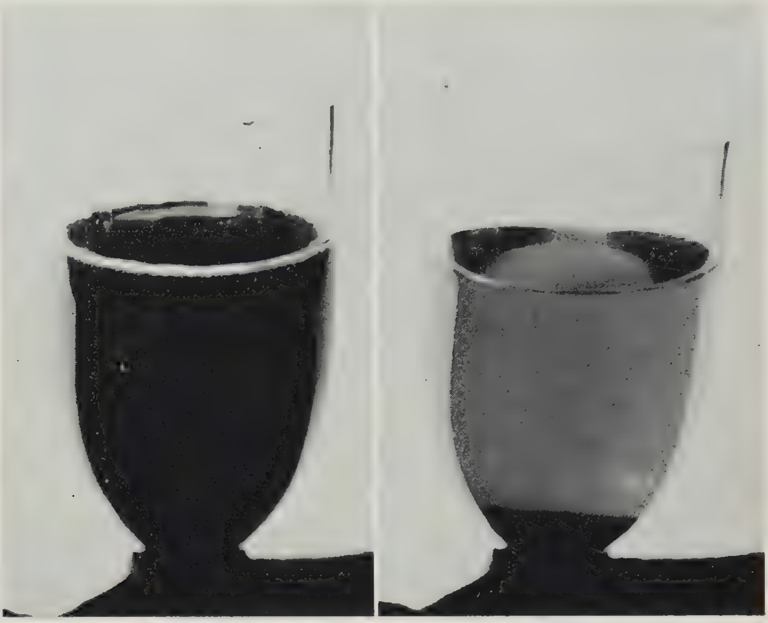

Fig. 606. Bloody pleural fluid before (left) and after (right) centrifugation. Note top "buffy" layer which is a rich source of malignant cells.

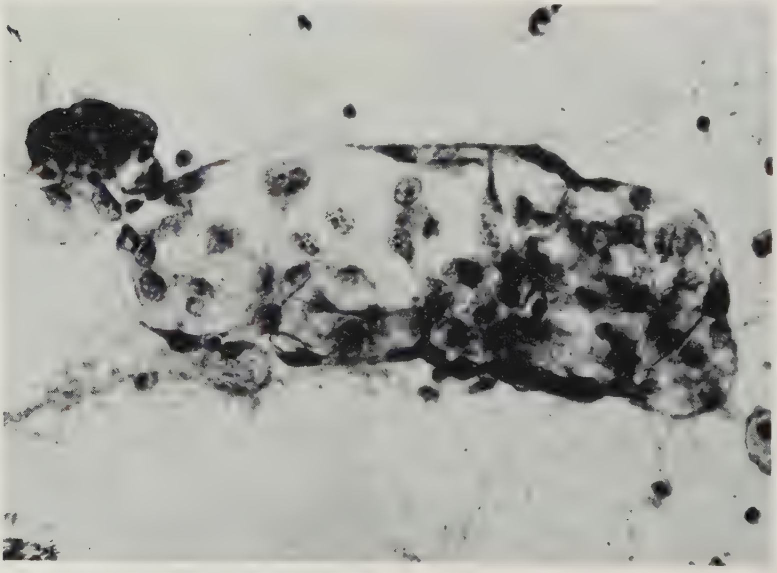

Fig. 607. Large, glandular group of malignant cells in ascitic fluid. The site of the primary was not determined.

an additional method of examining serous fluid sediment.[160, 162]

Rapid examination of serous fluid sediment can be performed through use of supravital staining. Foot and Holmquist[163] described their results with supravital staining by an alcoholic solution of neutral red and Janus green on a warm stage. A 5% solution of toluidine blue or brilliant cresyl blue in physiologic saline may also be used.

1. Place a drop of serous fluid sediment on a clean glass slide and mix with an equal volume of freshly filtered supravital staining solution.
2. Cover the wet smear with a cover glass and examine after 2-5 min.

The method is purely one of interest to the cytologist; the final diagnosis should await examination of the permanent Papanicolaou-stained smears.

Ceelen[164] and Foot,[165] in separate studies, investigated the use of the periodic acid-Schiff (PAS) staining reagent for differentiating benign mesothelial abnormalities from malignancy. Foot's application of Mowry alcian blue periodic acid-Schiff stain can be applied to smears previously stained by the Papanicolaou method.

URINARY SEDIMENT

Voided urine from males is suitable for cytologic examination; a catheterized specimen should be obtained from females. The first morning specimen is the most cellular, but cells are greatly distorted because of prolonged retention in the bladder. It is perhaps advisable to collect both an early morning specimen and one later in the day. In either case the specimen must be centrifuged and smears of the sediment prepared and fixed as rapidly as possible after collection.

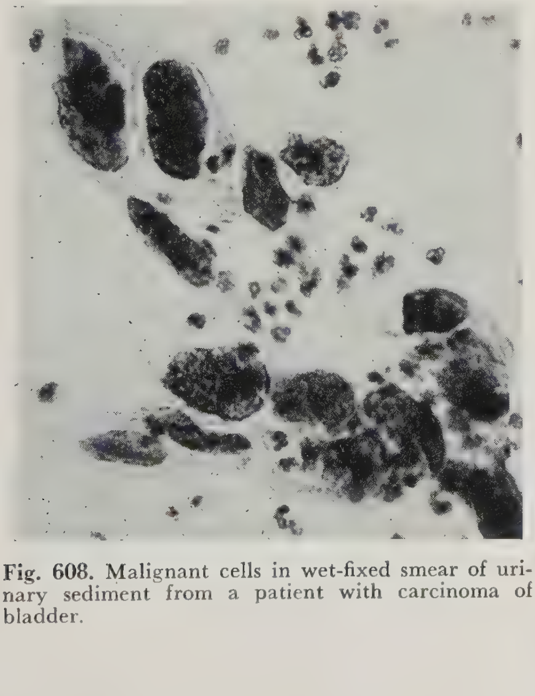

Fig. 608. Malignant cells in wet-fixed smear of urinary sediment from a patient with carcinoma of bladder.

A significantly large proportion of urinary cells is detached during fixation and staining resulting in a large number of unsatisfactory smears and false negative diagnoses. The reported incidence of unsatisfactory urine smear examinations has ranged from 20 to 30%.[166-168] Feeney et al.[169] reported in 1958 that insufficient cytologic evidence of malignancy was observed in 58% of cases with known urinary tract cancers.

A variety of methods has been proposed to improve adhesion. Partial to complete drying in the air has been suggested, followed by rehydration with sodium lauryl sulfate (see rehydration method, p. 1763). Solomon et al.[170] compared results obtained by immediate fixation in ether-alcohol, air drying with rehydration, and air drying without rehydration. They found, as was expected, that air-dried smears showed appreciably better adhesion but poorer cellular preservation than wet fixed ones. They found no appreciable difference between rehydrated smears and those that were not rehydrated. They advocate simple air drying before staining and report that results are suitable for reliable evaluation. Rofe[171] also advises use of the air drying method but recommends addition of a small amount of 8% glycerin solution at pH 7 to protect the cells from distortion due to drying.

The Millipore filter* has been applied to collection of cells suspended in urine. The method was first described by Seal in 1956[172] for collection of cells in serous fluids. A specially designed filter membrane of great porosity is used. The pore size is exceptionally uniform and is available in diameters ranging from 10 to 5μ. Fluid passes through the membrane rapidly; formed elements larger than the pore diameter are retained on the membrane and adhere to it. The entire membrane (4.7 cm. in diameter) is then stained by hematoxylin and eosin or by the Papanicolaou method. The membrane is rendered transparent in xylol before mounting. A detailed account of the Millipore filtration method for processing urine and special instructions for staining the membrane are contained in reports by Solomon et al.,[173] Merritt et al.[174] and Harpst et al.[175]

---

*Millipore Filter Corp., Watertown, Mass.

BREAST SECRETION

Spontaneous nipple discharge is collected with a cotton-tipped applicator stick and is quickly spread with a rolling motion onto a clean glass slide. The smear must be placed in the fixative without delay. If the secretion is scant, restrict the smear to a small area of the slide to avoid drying before fixation. If secretion is obtained from both breasts, identify smears as left and right.

In the case of localized lesions of the breast which produce discharge on pressure, the secretion can be collected directly on the slide after expressing material from this area. The pull-apart method of smear preparation (see methods of smear preparation, p. 1760) is well suited for smearing breast secretion.

Detailed accounts of cytologic findings in benign and malignant breast secretions have been reported.[176-179]

PROSTATIC SECRETION

Secretion expressed from the prostate by massage is collected directly upon a clean glass slide. It is advisable to have the patient hold the slide to assure recovery of the secretion. Cytologic examination of urine voided after prostatic massage is advisable, particularly if the massage was unproductive.

Highly accurate results have been reported. In a series of 100 patients with proved prostatic cancer, Peters and Frank[180] reported positive or suspicious cytologic evidence of malignancy in 95. Riaboff,[181] on the other hand, states that in his experience cytologic examination of prostatic secretion from asymptomatic individuals is of quite limited value. The necessity for thorough familiarity with cellular appearances in benign and malignant conditions has been emphasized.[182-184]

ORAL SMEARS

The cytologic method has been applied successfully to the detection of cancer of the oral cavity. The method is particularly valuable when used routinely to investigate all lesions of the oral or oropharyngeal mucosa, regardless of how insignificant the lesion may appear.

Cell collection is obtained by moderately forceful scraping of the lesion with a tongue blade or similar dull instrument. When present, superficial necrotic material and pus should first be removed. The material that can be obtained is often scant; therefore care must be taken to smear the secretion quickly over a small area of the slide. Fixation must follow without delay.

Sandler[185] in 1961 reported 91% agreement in cancer diagnosis between cytology and biopsy in a cytologic study of 452 abnormalities of oral mucosa. In 7 cases multiple biopsies were required to confirm the cytologic diagnosis of cancer; 1 case required 5 biopsies. Montgomery and von Haam[186] reported a 93% accuracy in diagnosis of oral malignancy by smear examinations; other investigators[187-189] have reported similar success.

Oral smears for determination of sex genotype

In 1949 Barr and Bertram[190] noted that the nuclei of neurons of female cats possessed single, small, densely staining, crescent-shaped masses of heterochromatin attached to the nuclear membranes. These masses were absent in the male. Subsequent studies disclosed that similar dimorphism distinguished the nuclei of human male and female subjects. Almost all tissues of the body have been examined for sex chromatin determination with consistent confirmation of Barr and Bertram's observation. Cell collection from the oral mucosa is convenient and suitable for demonstration of the sex chromatin.

The determination of genetic sex has been applied to establish the true sex of hermaphrodites and has also been of interest in studies of teratomas. A nucleus possessing the sex chromatin may be described as chromatin-positive, whereas one without is said to be chromatin-negative.

Normal values are as follows[191]:

Normal males: 0-4% of nuclei are chromatin-positive.

Normal females: 20-80% of nuclei are chromatin-positive.

Procedure:

1. Use a tongue blade, glass slide, or metal spatula for cell collection.
2. Draw the instrument firmly over the oral mucosa and smear evenly on a clean slide the milky fluid that collects.
3. Confine the smear to a small area of the slide, if scanty material is obtained, and place in a fixative immediately.
4. Collect at least 4 smears, repeatedly scraping the same area of oral mucosa.
5. Oral smears for sex genotype determination may be stained by the Papanicolaou method, by hematoxylin and eosin, or by the Guard stain, the latter specifically designed for demonstrating the sex chromatin.

Guard stain for sex chromatin[192]:

Staining solutions:

I. Biebrich scarlet stain:

Biebrich scarlet (Harleco)	1 gm.
Phosphotungstic acid, c.p.	0.3 gm.
Glacial acetic acid	5 ml.
Ethyl alcohol, 50%	100 ml.

II. Fast-green FCF stain:

Fast-green FCF (Harleco)	0.5 gm.
Phosphomolybdic acid, c.p.	0.3 gm.
Phosphotungstic acid, c.p.	0.3 gm.
Glacial acetic acid	5 ml.
Ethyl alcohol, 50%	100 ml.

Guard procedure:

1. Following ether-alcohol fixation, transfer slides to 70% alcohol for 2 min.
2. Stain in Biebrich scarlet staining solution for 2 min.
3. Rinse in 50% alcohol.
4. Differentiate in fast-green FCF solution for approximately 4½ hr. Check under a microscope at hourly intervals. Differentiation is complete when all the cells and nuclei are green, with the exception of pyknotic nuclei which will remain bright red. The sex chromatin stains pink to red.
5. Rinse in 50% alcohol for 5 min.
6. Pass through 70%, 95%, and absolute alcohol, 2 min. each.
7. Clear in 3 changes of xylol, 2 min. each, and mount.

CEREBROSPINAL FLUID

The volume of cerebrospinal fluid that can be withdrawn for cytologic examination is small and often contains few cells. McCormack et al.[193, 194] described a wet-film method for cytologic examination of cerebrospinal fluid sediment, which permits microscopic examination of scanty sediment by addition of a drop of toluidine blue staining solution. The method follows.

Wet-film examination of cerebrospinal fluid—McCormack et al.[193, 194]

Reagents:

1. Stock toluidine blue solution.

Toluidine blue	1 gm.
Ethyl alcohol, 95%	20 ml.
Distilled water	80 ml.

   (a) Grind the stain in a mortar with the alcohol and add the water slowly.
   (b) Store in a glass-stoppered bottle.

2. Toluidine blue staining fluid.

Toluidine blue stock solution	10 ml.
Equine serum	10 ml.

   (a) Centrifuge the mixture. The supernatant fluid constitutes the staining solution.
   (b) Add a few crystals of thymol and store in a refrigerator. Stable for several months.

Procedure:

1. Centrifuge freshly collected cerebrospinal fluid for 10 min. at 2000 r.p.m.
2. Decant the supernatant fluid and add 1 drop of toluidine blue staining fluid to the sediment and mix.
3. Transfer a drop of the stained sediment to a glass slide and cover with a cover glass.

NOTE: After wet-film examination, place the cover slips in acetic acid-alcohol fixative (97 ml. 95% ethyl alcohol, 3 ml. glacial acetic acid). Then stain the slide and cover glass by the Papanicolaou method and remount.

BONE MARROW

Bone marrow is a frequent site for metastasis of primary tumors elsewhere, especially carcinoma of the breast, lung, thyroid, kidney, prostate, gastrointestinal tract, and malignant melanoma. Hyman[195] has reported that only 57% of patients whose bone marrow contained cytologic evidence of malignancy had diagnostic lesions detected by skeletal x-ray survey. On the other hand, he reported that in a control group of 100 patients in whom marrow aspirates were negative for tumor cells, 30% had positive skeletal surveys for tumor involvement.

It appears that both bone marrow aspiration and skeletal roentgenologic survey are of complementary value in the total evaluation of the patient. Berkheiser[196] demonstrated malignant cells in 12 of 246 unselected, consecutive bone marrow aspirations. In a larger series of 1100 consecutive marrow aspirations, Amy and Jaimet[197] report that 24% were positive for malignant cells.

For reasons of ease and safety the iliac crest is preferred for obtaining marrow aspiration. Rubinstein[198] reports that the iliac crest is involved at least as often as other bones, once blood-borne metastasis has occurred.

King[199] has described a method that utilizes TELFA* to concentrate marrow elements.

Procedure—marrow aspiration, smears and sections:

1. Aspirate no more than 2 ml. from the sternum, iliac crest, or other preferred sites into a 20 ml. syringe that has just been rinsed with 10% EDTA (dipotassium ethylenediaminetetraacetate).
2. Immediately disconnect and withdraw the needle.
3. Rotate the syringe to prevent clotting.
4. Place 0.5 ml. of aspirate in a Petri dish and carefully select marrow elements on the end of a wooden applicator stick. Allow fluid blood to soak into the wood for about 30 sec.
5. Gently touch the applicator stick to the surface of precleaned glass slides, making rows of 5 to 6 touch patterns that cover ½ to ¾ of the slide.

---

*Curity, Bauer & Black Division, Chicago, Ill.

6. Routine cover slip or slide preparations may be prepared, as desired.
7. Combine the remainder of the material in the Petri dish and syringe and drop into the center of a 2 in. square pad of TELFA. Erythrocytes and serum are rapidly absorbed in the cotton pad, while marrow elements remain on the surface of the TELFA.
8. Separate the TELFA from the pad and place in Bouin fixative for 1 hr.

The marrow elements concentrated on the TELFA form a firm button which can be processed for routine paraffin sectioning.

CANCER CELLS IN THE CIRCULATING BLOOD

Malignant tumor cells were reported in circulating peripheral blood by Thiersch[200] in 1865, by Ward[201] in 1913, and by Pool[202] in 1934. More recently, reports by Engell[203] in 1955 and by Sandberg and Moore[204] in 1957 stimulated the interest of cytologists, clinicians, and surgeons to investigate the frequency with which metastatic cancer could be detected by blood examination and to relate the finding to its prognostic significance.

Engell[203] examined serially sectioned paraffin blocks of blood clots and identified tumor cells in 9.7% of patients with cancer and reported "atypical, tumorlike cells" in an additional 8.5%. Sandberg and Moore[204] precipitated erythrocytes by the addition of fibrinogen. They reported finding tumor cells in 38% of patients with advanced adenocarcinoma of various primary sites.

More methods have recently been described for separating tumor cells from normal hemic elements. Fawcett et al.[205] applied a flotation method for separation of erythrocytes in serous fluid. The method depended upon the difference in specific gravity of various dilutions of bovine albumin in saline. In 1954 McGrew[206] applied the method to isolation of cancer cells in circulating blood. In 1959 Seal[207] reported a modification utilizing a solution of blended silicones (SG 1.075) as a medium for separating erythrocytes and leukocytes under the silicone, and cancer cells and lymphocytes on the surface of the silicone. Seal also employed Millipore filtration for cell collection.

The significance of the presence of malignant cells in circulating blood is not yet clearly defined. The method of study does not appear to be of practical value for detection of early curable cancer, and the presence of tumor cells in circulating blood cannot be interpreted as signifying that metastatic spread has occurred. Engell[208] recently reported a follow-up study on patients in his earlier series who were found to have tumor cells in the circulating blood at the time of surgery. He states that, of the patients who have survived from 5 to 9 yr. after cancer surgery, 51% had tumor cells in the circulating blood at the time of the operation.

Chapter 97

Identification of benign and malignant cells

SAMUEL L. PHARR

Little experience is required to distinguish between typically normal and characteristically malignant cells. In the majority of cases, however, this distinction is not so clearly apparent, and accurate cytologic interpretation requires a careful and experienced appraisal of borderline changes. Thorough familiarity with cellular appearances in each type of secretion must be obtained from a study of healthy individuals as well as from patients with a wide variety of pathologic but benign conditions.

NONMALIGNANT CELLS

Squamous epithelial cells

Squamous epithelium undergoes a continuous process of cell maturation and shedding; thus the secretions that have contact with a squamous epithelial lining (i.e., the oral and nasal cavities, esophagus, vagina, anus, and skin) contain large numbers of exfoliated squamous cells. The maturation pattern differs between skin and mucous membrane, and the influence of hormones or inflammatory processes may alter the maturation process, particularly in the vaginal mucosa.

The generally accepted terminology for the cell forms of squamous epithelium applies the terms "parabasal," "intermediate," and "superficial." It should be kept in mind that ascribing a name to a form of squamous epithelial cell is merely a means of indicating its relative stage of maturity and has no relationship to the identification of a specific cell type.

Basal (squamous epithelial) cells: For practical purposes the basal cells are **not** encountered in cytologic preparations. The basal zone of squamous epithelium rests upon the basement membrane and consists of a single layer of undifferentiated cells which are not ordinarily exfoliated.

Parabasal (squamous epithelial) cells: These are spherical or ovoid cells which measure approximately 15-30μ in diameter and which originate in the deep layers of squamous epithelium directly above the single germinal layer. The cytoplasm is ordinarily basophilic and has a smooth, distinct boundary. Parabasal cells when seen in groups appear polygonal rather than round and may show intercellular bridges. The nucleus is usually single, centrally placed, and of uniformly round dimensions. Fine chromatin granules are evenly distributed throughout the nucleus, and a small nucleolus may be present.

Intermediate (squamous epithelial) cells: These cells are somewhat larger than parabasal cells and range in size approximately from 20 to 40μ in diameter. The increased size results from the swelling and elongation of cells in the intermediate layers of squamous epithelium. Smooth irregularity in the cytoplasmic contour is often present. The cytoplasm of intermediate cells is most often basophilic but may be acidophilic. The nuclei of intermediate cells vary from the size of parabasal nuclei to small, moderately degenerative pyknotic forms; the more usual form lies somewhere in between. When inconsistency between nuclear maturity and cellular flattening is observed, it is advisable to accept the over-all shape of the cell rather than the nuclear characteristics as the most dependable criterion for relating the cell to its appropriate cell layer.

Superficial (squamous epithelial) cells: These are the mature cells that are shed from the outermost few layers of squamous epithelium. In cytologic smear preparations superficial cells are large, often with a diameter of 50-60μ. The thin, filmy, transparent cytoplasm is frequently curled or overturned, and its boundary may be frayed or may blend into the background material. The cytoplasmic staining reactions of superficial squamous epithelial cells provide the artistic play of colors that is characteristic of Papanicolaou-stained smear preparations and may accept a pale basophilic stain or, more frequently, the acidophilic pink, yellow, or orange staining components. Typically, the nucleus of the superficial cells is a small condensed mass of chromatin with an intact nuclear membrane; frequently, however, the nucleus may be absent or karyorrhectic.

Columnar epithelial cells

Respiratory tract: Portions of the nasopharynx and larynx, as well as the entire length of trachea, bronchi, and bronchioles to their terminal portion, are lined by respiratory epithelium. This is composed of tall, pseudostratified, ciliated columnar cells with a varying distribution of nonciliated, secretory goblet cells interspersed. The cells that line the terminal bronchioles are a lower, ciliated cuboidal form; otherwise there are no distinguishing characteristics for identifying the precise area from where columnar cells have been shed. Exfoliated columnar cells vary markedly with their state of preservation, with the method of specimen collection, and as a result of various respiratory diseases. Relatively few columnar cells may be observed in specimens raised spontaneously from the respiratory tract and, when present, often show degenerative changes incurred during their passage and expectoration. Denuded nuclei, as well as swollen or shrunken nucleated forms, may be present within the same specimen. Specimens collected by aspiration or lavage from the respiratory tract, on the other hand, contain well-preserved columnar cells in groups and in single cell distribution.

The nuclei of columnar epithelial cells are basally placed in a clear or finely reticulated cytoplasmic column of variable length and shape. The cytoplasm of ciliated forms tends to conform to the width of the nucleus distally to its ciliated free surface. Variability is seen in the length and the degree of constriction of the proximal extension of cytoplasm by which each cell is attached to the basement membrane. The average diameter of columnar nuclei is approximately 6μ; however, a nuclear diameter of twice this size may be observed in some benign respiratory diseases. In well-preserved forms the chromatin is moderately coarsely granular and evenly distributed throughout the nucleus. The nuclear membrane is prominent and of uniform thickness.

The secretory cells of respiratory columnar epithelium possess no cilia. Cytoplasm is more abundant than in ciliated columnar cells and contains distinct interlacing vacuoles of variable size. The goblet form is usually present,

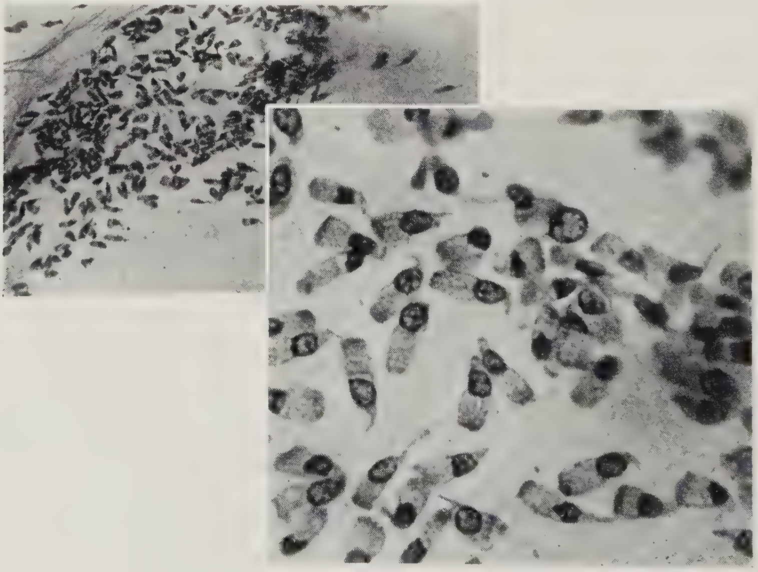

Fig. 609. Typical tall, ciliated, bronchial columnar epithelial cells obtained by bronchoscopic aspiration.

as well as secretory cells which are less distended by mucus. Cytoplasmic boundaries may be frayed or indistinct, and the nucleus is often opaquely pyknotic and compressed peripherally into a triangular shape.

Female genital tract: The abrupt junction of squamous to columnar epithelial lining is somewhat variable in anatomic location but generally occurs at the level of the external os. A second, less striking transition is found in the area of the internal os, marking the junction between endocervix and endometrium. In tissue sections the endometrial mucosal surface is lined by a single layer of tall, clear, secretory columnar epithelial cells with patches of cells possessing cilia. The columnar cells that form the endometrial mucosa are lower, often rounded, and more densely packed in a pseudostratified layer. Small groups of ciliated cells are also scattered among the secretory cells. The nuclei of endometrial cells are less uniform in size than those of endocervical cells and are more hyperchromatic. These histologic differences are reflected to some extent in cytologic appearances and assist in the differential identification of endocervical and endometrial cells. Considerable uncertainty may be experienced, however, in cytologic identification of intermediate forms. Large clusters of endometrial stromal cells are quite characteristic and are present in smears collected during the first 10 or 12 days of the cycle. The oviducts are similarly lined by secretory and ciliated columnar cells; however, they lack distinctive characteristics to permit precise identification in cytologic smear preparations.

Gastrointestinal tract: The transition between the stratified squamous epithelial tissue of the esophagus and the columnar epithelium of the stomach occurs abruptly at the cardiac junction. The surface epithelium of the stomach is composed of a single layer of tall, uniform columnar cells. No ciliated epithelium is present throughout the gastrointestinal tract. Cytologic specimens obtained from the stomach by aspiration of contents or by lavage may contain relatively few gastric mucosal cells. Sheets of gastric columnar cells may be seen in specimens obtained by forceful lavage or by abrasive instrumentation, and in smears they are often seen *en face* in honeycomb arrangement. The cytoplasm is delicately reticulated and is stained faintly yellow or yellow-pink in the Papanicolaou method. Single gastric mucosal cells may be degenerative as a result of partial digestion by gastric secretion. Cells from the upper and lower respiratory tract may be deposited in the stomach through swallowing and can be recovered in the cytologic gastric specimen.

The distinctive cell forms that line the gastric glands (zymogenic, parietal, mucous neck, and argentaffin cells) cannot be identified with certainty in cytologic smear specimens. Occasionally cells with intensely orangeophilic cytoplasmic granules are seen which are suggestive of Paneth cells; their presence in gastric secretion may result from intestinalization of gastric mucosa.

Cells collected from the mucosal surface of the duodenum are essentially identical to those of the gastric mucosa. At present (1963), the cytologic method is not applicable for studies of the jejunum and ileum.

The epithelial lining of the colon and rectum is composed of uniform secretory columnar cells with many goblet cells interspersed. There is little difficulty in identifying normal epithelial cells because of their characteristic uniformity; however, there is often a paucity of well-preserved cells.

Transitional epithelium; urinary tract

The urethra, bladder, ureters, and renal pelvis are lined by a somewhat specialized stratified surface known as transitional epithelium. As implied by the term, the epithelial components are intermediate between stratified squamous and simple columnar epithelium. Transitional epithelial cells in cytologic preparations are characterized by marked variation in size and form and range from typical parabasal squamous to typical simple columnar type. The intermediate forms are often strikingly enlarged, with a proportional enlargement of nucleus. Multinucleation is frequently present. The added pleomorphism resulting from cellular changes in benign pathologic conditions makes this area one of the most challenging for cytologic examination.

Mesothelium

The pleural, peritoneal, and pericardial cavities and the synovial cavities of the joints are lined by a single-layered mesothelium. Under normal circumstances these spaces are moistened by a thin layer of serous fluid in insufficient quantity to collect for cytologic examination. It is not meaningful, therefore, to describe the normal appearance of exfoliated mesothelial cells. The complexity of cellular appearances attendant to the accumulation of fluid in benign pathologic conditions precludes inclusion of a generalized morphologic description of cellular appearances here.

Reticuloendothelial cells

Wandering phagocytic cells of the reticuloendothelial (RE) system are a constant finding in all types of specimens examined by the cytologic method. They are perhaps the most variable morphologic forms which are encountered. Their number and morphologic features vary from site to site and in the presence of various pathologic conditions. Although purely academic, it may be impossible at times to distinguish between atypical forms of histiocytes and parabasal squamous epithelial cells. More importantly, bizarre histiocytes frequently present characteristics that may closely resemble those found in malignancy. It is indeed fortunate for the cytologist that RE cells occur and function as single cells, thus directing conservative evaluation of abnormalities observed in single cells, when no groups with similar changes can be found.

A generalized description of RE cells is of little benefit for identifying unusual forms. The nucleus is most frequently eccentric; multinucleation, lobulation, and constrictive nuclear distortion are commonly observed. The cell size and cytoplasmic structure of RE cells often reflect their function, environment, and state of activity; thus a variety of terms are applied—i.e., monocyte (blood-borne), histiocyte (in tissue), macrophage (free in secretion), lipophage (containing fat inclusions), and histiocytic syncytium (an elaborately multinucleated RE cell).

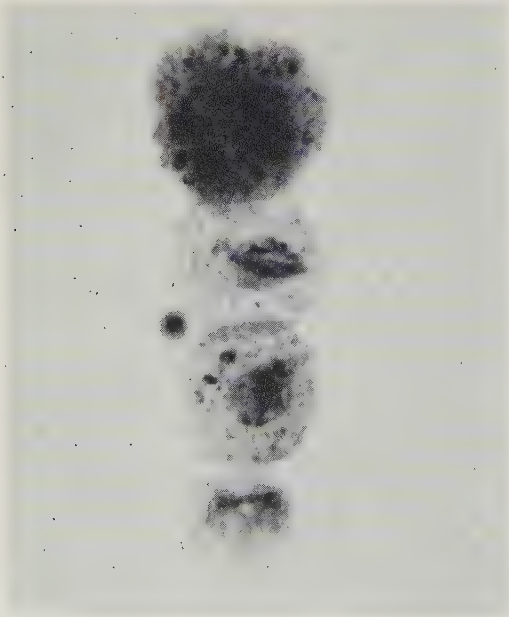

Fig. 610. Pulmonary macrophages in sputum. Note that uppermost cell is filled with phagocytosed material.

Miscellaneous benign cells and structures

Polymorphonuclear leukocytes (including eosinophils), erythrocytes, lymphocytes, monocytes, and plasma cells are recognized in cytologic smear preparations, but they are less specifically stained by the Papanicolaou procedure than by conventional hematologic staining methods. The proportion and types of blood elements offer a useful clinical indication of the status and degree of infection. In addition, the consistency in size of blood elements provides the cytologist with a convenient and familiar reference point for evaluating cell size. Staining intensity of leukocyte nuclei is often used to appraise the over-all nuclear staining quality in cytologic smears.

Bacteria and fungi are easily recognizable in cytologic smears, but more appropriate methods of study are usually required for precise identification. *Trichomonas vaginalis* and *Candida albicans* can be readily identified in Papanicolaou-stained vaginal smears, and to a more limited extent cytologic examination of smears of various secretions may disclose other parasites or their ova.

CYTOLOGIC IDENTIFICATION OF MALIGNANCY

Malignancies that arise in an epithelial surface can be detected at an early stage by the cytologic method; thus diagnostic cytology is primarily applied to detection of epithelial malignant tumors—carcinomas. At present (1963), utilization of the cytologic method is quite limited for the detection of malignant tumors that arise in the underlying connective tissue, muscle, bone, or in other areas where erosion into a draining passage occurs late in development (lymphoma, sarcoma, etc.).

The variety of cellular appearances in carcinoma is infinite, and the possible range within a single tumor extends from cells that cannot be distinguished from the typical normal cells of the organ to tumor cells whose changes exceed the imagination. It is not possible to describe or to identify a cancer cell as a specific entity. A cytologic opinion of malignancy results from an accumulation of definable cellular and nuclear characteristics which are known to be present in proved cases of cancer. The categorized features of malignant cells are seldom, if ever, diagnostic as a single observed entity. For example, marked nuclear enlargement per se can be a meaningless finding in the absence of additional nuclear structural abnormalities of chromatin pattern, nucleolus, or nuclear membrane. Likewise, observation of a single abnormal cell possessing abundant evidence of malignancy requires conservative judgment if no supportive evidence of cellular abnormalities can be found in the same specimen.

Criteria of malignancy

Nuclear abnormalities

Cytologic evidence of malignancy is derived almost entirely from observations of **nuclear** abnormalities. Changes in the nucleus of a cell must always, however, be appraised in relationship to its cytoplasm and particularly with regard to the interrelationships of adjoining cell nuclei within a group.

Nuclear hypertrophy: Increase in nuclear size indicates that a relative relationship must be established. In the case of well-differentiated tumors the nuclear volume of its component cells can be compared with the normal nuclear size seen in its benign counterpart. In undifferentiated or poorly differentiated malignant forms there may be no relationship to benign cell types; thus significance must be applied to an arbitrary nuclear diameter. A nuclear diameter greater than 20μ can be

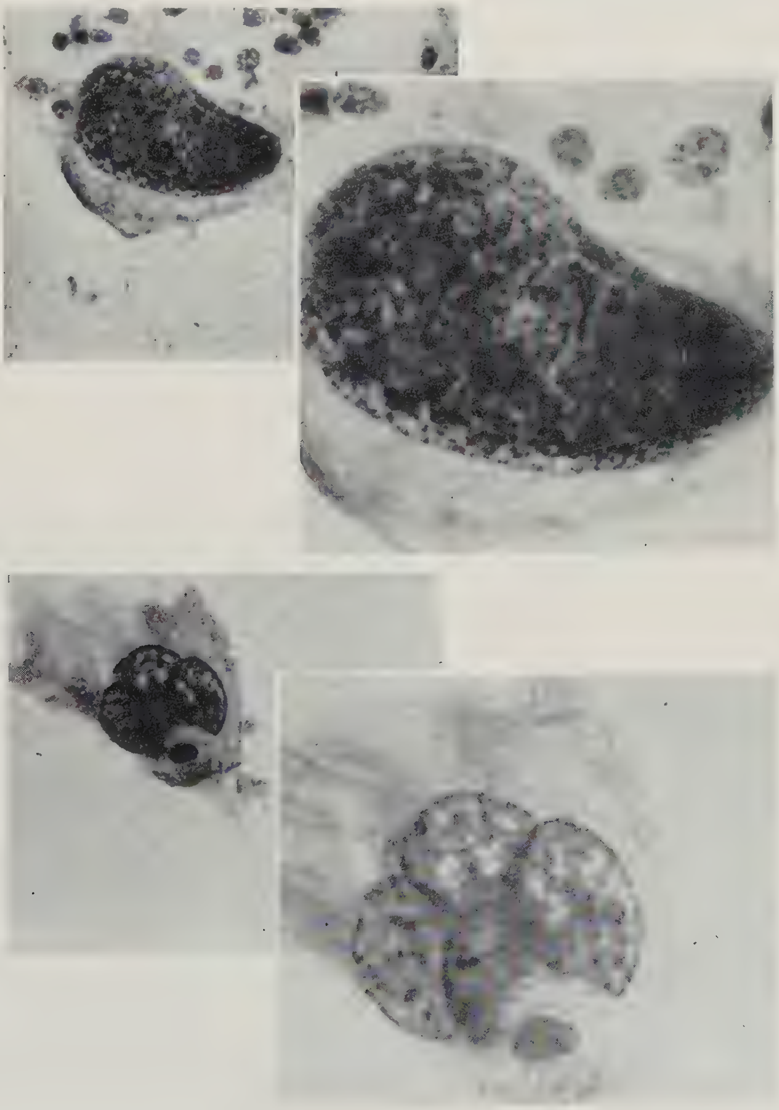

Fig. 611. Examples of single, malignant cells. Above, cells from pleural effusion. Below, cells from sputum. Note enlarged nuclei with dense, irregular chromatin.

interpreted as presumptive evidence of abnormality but is not an a priori indication of malignancy. Although nuclear hypertrophy is a frequent manifestation of cancer, it must be emphasized that nuclear diameters greater than 20μ are observed in benign cells at times and that in some cases malignant cell nuclei may be ½ this size.

Chromatin abnormality: Two forms of chromatin abnormality may be present in malignant cells: hyperchromasia and irregular distribution.

Hyperchromasia: This is a frequent manifestation of malignancy and reflects an increase in the nuclear content of deoxyribonucleic acid (DNA). Nuclear hyperchromatism and hypertrophy are usually companion abnormalities in malignant cells, and these characteristics provide the basis for successful screening of cytologic smears at low-power magnification (10×). The significance of hyperchromasia is also relative to other findings, and it must be compared to the over-all staining intensity of familiar cell nuclei.

Irregular distribution: The pattern of chromatin distribution within the nucleus provides the most dependable **single** criterion for identification of malignant cells and is particularly significant when there is also an increase in nuclear size and in total chromatin content. Abnormality in chromatin pattern within a malignant cell nucleus is frequently characterized by massive condensation and irregular distribution throughout the nucleus. Areas of clearing, formed by chromatin clumping, assist in distinguishing hyperchromasia from complete nuclear opacity resulting from overstaining or advanced nuclear degeneration.

Nuclear shape: The shapes of malignant cell nuclei often depart from the usual round or oval forms of benign epithelial cells. Jagged, sharp protrusions of nuclear contour are quite suggestive of malignancy when present in enlarged nuclei with chromatin abnormalities. Lobulation, pseudopod projections, or smooth constrictive irregularities of the nuclear contour may also be significant observations. Prominence of the nuclear membrane, particularly when irregularity in thickness is present, is an important consideration.

Multinucleation: Multinucleation can be interpreted as supportive evidence of malignancy only when the nuclei are of abnormal size and structure. Anisonucleosis of multinucleated cells further strengthens the opinion of malignancy.

Mitoses: Although an increase in mitotic activity is a frequently observed characteristic present in histologic sections of malignant tumors, mitotic cells are rarely encountered in cytologic smear preparations (with the exception of serous fluids, where they may be abundant in **both** benign and malignant conditions). The paucity of mitotic cells in exfoliated secretions appears to be due to the lack of dividing forms in the superficial desquamating tumor surface. Demonstration of mitotic figures and particularly "abnormal mitoses" in secretions other than serous fluids can provide strong supportive evidence of malignancy. However, it must be related to other cellular abnormalities present in the same specimen.

Cytoplasmic abnormalities

Nucleus-cytoplasm ratio: The relationship of nuclear volume to total cell volume, like nuclear hypertrophy, is a relative appraisal. For differentiated malignant cells a relationship is established to the nucleus/cytoplasm (N/C) ratio observed in the corresponding benign counterparts. In well-differentiated, keratinized malignant squamous cells the volume of cytoplasm may exceed that of the nucleus and yet be significantly altered, since only a small pyknotic nucleus is normally present in a benign, keratinized squamous cell. Likewise, cytoplasmic volume of hypervacuolated adenocarcinoma cells may greatly surpass nuclear volume. In less differentiated

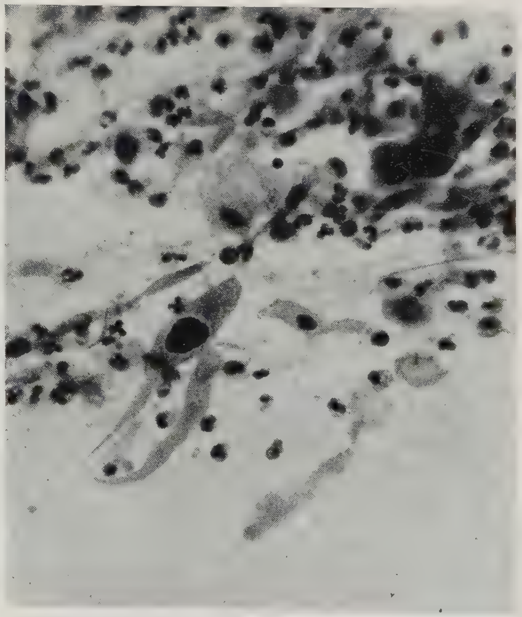

Fig. 612. Malignant "tadpole" cell in vaginal smear from patient with squamous carcinoma of cervix.

malignant cells, however, this ratio is generally reversed, with nuclear predominance.

Differentiation: Identification of tumor cell type stems from a critical appraisal of cytoplasmic structure and form. It must be emphasized that identification of tumor cell type cannot be made in every case and that it should always be a **secondary** step following the initial identification of malignancy based on nuclear abnormalities.

Squamous carcinoma: Hyperkeratinization of cytoplasm is regularly associated with well-differentiated squamous cell tumors and can be somewhat specifically identified in Papanicolaou-stained smear preparations by a brilliant orange, granular staining reaction. In addition to malignant nuclear changes seen in hyperkeratinized cells, a number of bizarre cytoplasmic shapes may be present, including the so-called spindle and tadpole forms. These pleomorphic cells may or may not be keratinized and often contain only minimal nuclear evidences of malignancy. Observation of such forms provides strong presumptive evidence of

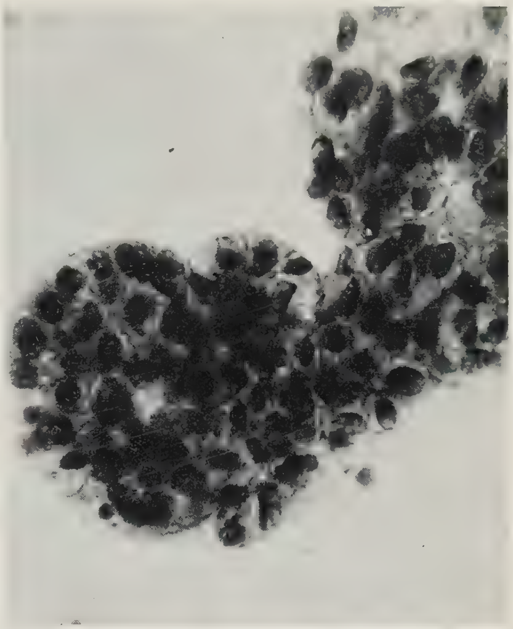

Fig. 613. Hypervacuolated malignant cells which form a glandular structure seen in vaginal smear from patient with endometrial adenocarcinoma.

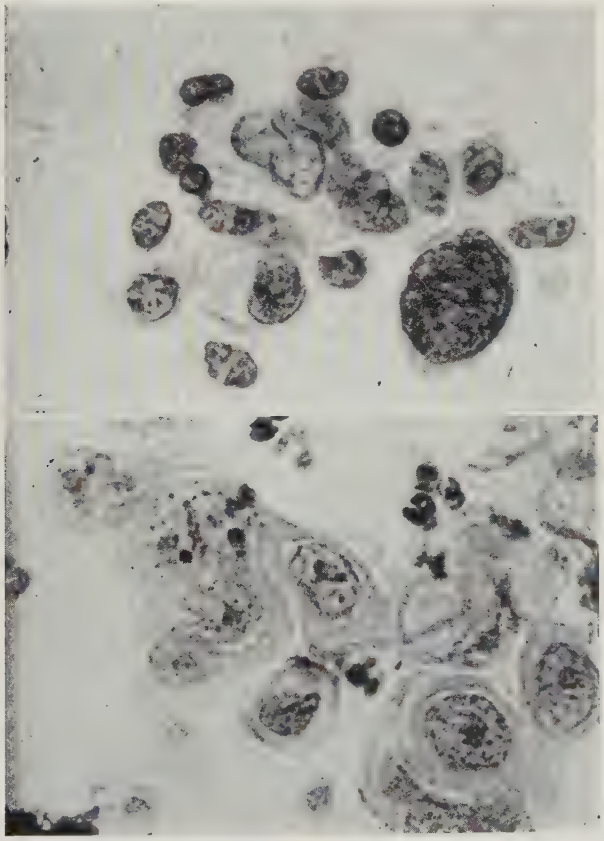

Fig. 614. Groups of malignant cells. Above, cells from cervical smear. Below, group of cells from urine.

squamous cell carcinoma only after malignancy has been established upon firm nuclear grounds.

Adenocarcinoma: Adenocarcinoma is evidenced by demonstration of hypervacuolated cytoplasm in malignant cells which form a glandular, unit structure—an **acinus.** Vacuolization within a single cell, regardless of its extensiveness, cannot be interpreted as evidence of adenocarcinoma. Multiple vacuoles are seen in adenocarcinoma cells and are often of enormous size. Distinct septae are present, and the nucleus is usually distended to the cell periphery.

Abnormalities in cell groups

The decrease in mutual adhesiveness of malignant tumor cells produces abundant shedding and provides the most important basis for conducting diagnostic cytologic examinations. At times, however, fragmentation of tumor may extend to its individual cellular components, and thus cytologic identification of malignancy may be made difficult when there is a predominance of single tumor cells. This is particularly true in cytologic specimens from well-differentiated squamous cell carcinoma. Although it is not necessary to observe a large number of groups of malignant cells for a positive cytologic diagnosis, at least a few groups of joined malignant cells must be seen so that abnormality in intercellular relationships can be evaluated. These abnormalities consist of marked variation in nuclear size and shape, discrepancy in maturation, and changes in polarity and parallelism.

Marked variation in nuclear size and shape: Anisonucleosis is a valid indication of malignancy only when the artifactual effect of nuclear shrinkage or swelling can be ruled out; thus for significance the chromatin pattern of adjoining nuclei must be similarly preserved. The nuclei of adenocarcinoma and undifferentiated cell groups tend to vary in size more than in shape, whereas those of squamous cell carcinoma vary in both size and shape.

Discrepancy in maturation: The tendency of normal epithelial tissue to mature at a rate that is uniform among neighboring cells is frequently lost or altered in epithelial malignant tumors. Abnormality of growth rate may also be observed in benign epithelium undergoing repair. Inequality in the rate of maturity can be assessed only in groups of cells that are distinctly joined to one another. The abnormality is characterized by variation in the degree of cytoplasmic maturation observed within a cell group. Discrepancy in maturation is most apparent in squamous cell carcinoma groups in which hyperkeratinized (orangeophilic) malignant cells are joined to immature (basophilic) and intermediate malignant cells. The significance of this finding depends upon the degree of accompanying nuclear abnormality.

Changes in polarity and parallelism: The tendency of malignant tumors to proliferate wildly and without the restraining influence of normal, orderly growth is most apparent in histologic sections. Unrestrained and disoriented growth pattern may be suggested in cytologic smear preparations, but the terms "polarity" and "parallelism" cannot be applied with accuracy, since there is no basement membrane or a similar fixed tissue structure from which to relate the direction and pattern of growth. The most convincing cytologic evidences of malignancy occur as a direct result of abnormal growth pattern and are reflected in the crowded positioning of malignant cells within a group. Mutual cellular and nuclear distortion results, and there is an impression of a loss of parallelism. Since crowding may result from mechanical distortion in smear preparation, the primary judgments of malignancy must be based on abnormalities of nuclear structure.

The importance that is contributed by finding groups of malignant cells cannot be minimized; it must be pointed out, however, that one of the most frequent sources of false positive cytologic diagnosis has resulted from placing a disproportionate emphasis upon structural characteristics present in cell groups, without first satisfying the **nuclear** requirements for a cytologic diagnosis of malignancy.

Section One

URINE ANALYSIS

Urine is an extremely complex solution of organic and inorganic substances offering a most convenient source of information which may be obtained quickly and inexpensively. As a result urine analysis is of basic diagnostic importance and an integral part of the examination of patients in all branches of medicine.

For the most part the constituents of urine are waste products of various metabolic processes and of ingested foods. Excessively large or small quantities of normally occurring substances or the presence of materials ordinarily absent in specimens of healthy subjects are often significant clues in the process of making a diagnosis or of following a therapeutic regimen.

Routine urine analysis generally refers to the determinations of specific gravity and acidity, the presence or absence of protein, sugar, and acetone, and a microscopic examination of the solid material. All other tests are considered to be more or less special, although some of these are performed so frequently that they too are essentially part of the routine analysis.

In the following chapters information is presented that covers all of the usually requested assays and, in addition, many of those that are requested rather infrequently. In keeping with the tradition established by the past editions of this text, material difficult to find elsewhere is included.

Chapter 98

General considerations

SAM FRANKEL

URINE PRESERVATIVES

It seems appropriate to discuss the various means available for preserving urine specimens at the beginning of the discussion since the quality of many of the subsequently described procedures is entirely dependent upon the state of the sample. Several potential changes may occur with improper preservation. The action of bacteria or mold spores will convert urea to ammonia, thereby altering the pH as well as the nitrogenous constituents. Glycolysis will cause loss of glucose and at the same time will increase acidity, thus invalidating the pH determination. Accompanying changes in pH will be precipitation of certain constituents, such as phosphates in alkaline solutions and urates in acid solutions.

Also to be considered are the constituents to be assayed, for in many cases a preservative suitable for some materials will interfere with others. A further complication is due to the various procedures available for the same type of assay since a preservative may interfere with one method but not with another.

Whenever possible the specimen should be freshly voided and immediately processed. For most practical purposes, however, there is always a time lapse before analysis is performed.

For routine urinalysis specimens are seldom collected under sterile conditions. Most preservatives are therefore primarily for the purpose of inhibiting bacterial or mold growth. Although some of the commonly used preservatives are most effective against contamination acquired after the specimen has been voided, it is good practice to provide some means of immediately closing the container.

Whether or not preservatives have been added to the empty container before collection, the specimen should be immediately protected by storing at cool temperatures. The drop in temperature will often cause certain constituents to precipitate and will also affect pH and specific gravity; therefore, rewarming to room temperature and thorough mixing should be part of the standard procedure.

The types of materials that have been recommended vary considerably and are often designed for the protection of a single constituent. Although a universal preservative has long been sought, no such material is yet available. Several suggested compositions, although suitable for routine analysis, do not apply in the case of special assays or for certain specimens containing unusual quantities of pathologic constituents.

Perhaps the most commonly used preservative is **toluol.** In this case a thin film of toluol floats on the surface of the specimen and is satisfactory for keeping out contamination although it is not very effective against bacteria or mold spores which are already in the sample. Another objection to toluol is that it enters pipets and has a certain nuisance value. This can be overcome by taking the bottom portion of the specimen contained in a separatory funnel although the time factor and lack of sufficient equipment would be a disadvantage when a large number of specimens are handled.

Chloroform, also frequently used as a preservative, has the advantage of producing a saturated solution so that it does inhibit growth in the specimen, but it does not form a surface layer so that contamination from outside is not prevented. Furthermore, chloroform has been reported to interfere with some of the tests for glucose such as the Fehling reduction test. **Formalin** also has the same advantages and disadvantages.

For 24 hr. urine collections, especially those to be assayed for ammonia, urea, or total nitrogen, a suitable preservative is 10 ml. concentrated hydrochloric acid. In this case, however, uric acid may be precipitated so that thorough mixing is required before this assay is performed.

For urine specimens that are being collected specifically for glucose analysis, such as in a glucose tolerance test or as an aid in regulating the insulin dosage of a diabetic, sodium fluoride or benzoic acid will inhibit glycolysis.

SPECIMEN COLLECTION

The first requirement for the collection of a valid specimen is a clean container that can be closed. Frequently the lids provided with many of the commercially available disposable containers are not used, thereby considerably increasing the chances of contamination.

In all cases, except for routine analysis, specimens should be collected at timed intervals. Because of variations in the excretion of various materials from one part of the day to the next, a 24 hr. specimen is necessary for any quantitative study. In certain cases, such as for clearances or enzyme excretion tests, timed specimens of 1 or 2 hr. are required. In other cases longer times are recommended. In every case, however, when quantitation is involved, time control is essential, and extreme care should be taken to guard against the loss of any portion of the sample.

EXAMINATION

Volume: Volume in 24 hr. is measured by pouring the urine into a 1000 ml. cylinder and reading the number of milliliters present. The **normal volume** of urine in 24 hr. is 750-2000 ml. or 25-65 oz. The average is 1500 ml.

Color: Record the color of the urine, for example, very pale yellow, light amber, dark amber, greenish, or brown. The color of the urine is dependent upon many factors. Normally, it is yellow or reddish yellow due to the presence of several pigments, especially urochrome. The intensity of the color depends upon the concentration of the urine. Dilute urines are usually pale, whereas concentrated urines are darker. Acid urines are usually darker than alkaline urines. The color may be greatly changed by the presence of abnormal pigments and by various drugs, as follows:

Blood: red or brown; smoky
Bile: yellowish or brown, turning greenish; yellow foam
Chyle: milky
Methylene blue: greenish blue
Phenols: olive green to brownish black, etc.

The color of urine is often affected by drugs, as follows:

Dark green: phenol, phenyl salicylate, creosote, and resorcinol
Red: antipyrine and trional (sulfonethylmethane)
Brown or black: pyrogallol
Yellow: phenacetin and picric acid; santonin changes from bright yellow to scarlet with the addition of sodium hydroxide

Red urine is also caused by eating beets.

Odor: Record as normal, aromatic, medicated, ammoniacal, putrid, strong.

Transparency: Record as clear, cloudy, turbid, or cloudy with sediment.

Freshly voided normal urine is clear or transparent but may be cloudy as a result of the presence of phosphates and pus. The phosphates disappear upon the addition of acid; pus does not disappear but may become gelatinous. Freshly voided urine may be cloudy from the presence of bacteria or may be comparatively clear with numerous shreds of mucopurulent material from chronic urethritis.

The transparency record is a factor only in dealing with fresh specimens because all specimens become cloudy due to bacterial growth and alkaline salt formations upon standing.

On cooling and standing, all specimens develop a faint cloud of mucus, leukocytes, and epithelial cells which settle to the bottom—the so-called nubecula. Acid urines may develop a white or pinkish sediment of amorphous urates, whereas alkaline urines may develop a heavy white sediment of amorphous phosphates. Urine containing pus shows a heavy mucoid, whitish sediment. Blood gives a reddish brown smoky sediment. Uniform cloudiness which cannot be removed by ordinary paper filtration is due to the presence of bacteria. Turbidity of urine is often due to the presence of fat or of spermatozoa.

REACTION

Dip a piece of blue litmus paper into the urine. If it turns pink, the urine is acid. If it does not change color, place a piece of red litmus paper in the urine. If it turns blue, the urine is alkaline. If neither the blue nor the red paper changes color, the urine is neutral. If the red litmus turns blue and the blue litmus turns red, the reaction is amphoteric.

Normal urine is acid in reaction with a pH ranging from 4.8 to 7.5 or a general average of 6.0. Urine may be neutral or alkaline as a result of the administration of alkalies. Diet may influence the reaction. Acid urine is usually present in acidosis, diabetes, starvation, diarrhea, etc. Alkaline urine occurs in alkalosis, severe vomiting, urinary infections, etc.

Determination of hydrogen ion concentration

The hydrogen ion concentration is determined with pH paper or with indicator solutions. For this method use fresh clear urine. Use the method outlined on pp. 20 and 21, and also see potentiometer measurement of the pH on pp. 22ff.

Nitrazine indicator for use in acidimetry and alkalimetry

Nitrazine* is a very sensitive indicator for use in acidimetry and alkalimetry, both for titration purposes and as an indicator of hydrogen ion concentration. It is especially useful in determining the reaction of urine, saliva, and other body fluids. The composition of food is perhaps the most important factor in determining the reaction of urine. The so-called alkaline tide occurs shortly after eating because of the increased alkalinity of the body fluids subsequent to the loss of acid for purposes of digestion.

Urine that has stood for some time becomes alkaline to litmus as a result of ammonia production due to the action of bacteria on urea. The alkaline reaction of urine of patients on a vegetable diet is due to the fact that vegetables and fruits, including acid fruits, contain acid salts of dibasic or other organic acids. These acids are converted to carbonates and have an alkaline reaction because they form some free alkali by hydrolysis. Part of the carbonic acid is lost to the body through the lungs, leaving the associated strong base together with some of the very weak carbonic acid to find their way into the urine.

Alkalinity of the urine can be raised by the ingestion of sodium bicarbonate.

Nitrazine changes color within approximately the same range as litmus, but since the indicator is more sensitive and the color changes are much more definite, differential readings can be made over smaller pH intervals.

Another advantage of Nitrazine is that the readings are made within 1 or 2 min. after applying a drop of the solution to the paper. When the Nitrazine test solution is used, the reaction is immediate and permanent.

The color values on Nitrazine paper observed when read in 60-120 sec., with the solution applied with glass rod, are as follows:

pH 4.0	bright yellow
pH 4.5	yellow, slightly duller (lemon yellow)
pH 5.0	mustard yellow
pH 5.3	light olive yellow
pH 5.5	olive yellow
pH 5.7	olive green with yellow cast
pH 6.0	olive green
pH 6.2	bluish cast to olive green
pH 6.4	slightly stronger bluish cast to olive green
pH 6.5	dark green
pH 6.6	blue gray
pH 6.8	dark blue gray
pH 7.0	gray blue
pH 7.3	deeper blue
pH 7.6	same
pH 8.0	same

Hydrion pH test papers

Hydrion wide-range pH test paper* is another method of determination of reactions. There are 5 types of Hydrion paper, showing changes at the following pH values: Hydrion A, pH 2-4-6-8-10; Hydrion B, pH 1-3-5-7-9-11; Hydrion C, 11-12; Hydrion D, 12-13; and Hydrion E, 13-14. These papers are dispensed in rolls in a special container for turning out a piece of the paper when its use is indicated. The paper is also furnished in strips in a vial.

Hydrion pH buffers are also supplied in vials. Each buffer when dissolved in 100 ml. distilled water gives a solution of the indicated pH. The manufacturer supplies the complete set of 55 standards in a permanent wooden case, pH 1.2-12.0 in steps of 0.2 pH unit.

Anachemia papers

A variety of test papers† is available in a wide range type from pH 1.0 to pH 12.0 as well as an acid range of pH 0.0 to pH 5.0 and alkaline to pH 14.0. In addition, 20 fractional range types are made, thus making available an indicator allowing accuracy to within 0.3-0.1 pH unit by use of overlapping papers. (See p. 1837 for combination of pH with sugar and protein tests.)

TITRATABLE ACIDITY OF URINE IN TERMS OF N/10 SODIUM HYDROXIDE

Folin method

Procedure:

1. Place 10 ml. urine in a beaker.
2. Add 6 gm. finely pulverized neutral potassium oxalate and 1-2 drops of phenolphthalein indicator.
3. Shake the mixture vigorously for 1-2 min.
4. Titrate with N/10 sodium hydroxide solution from a buret until the solution turns a faint permanent pink.
5. Read from the buret the number of ml. of N/10 sodium hydroxide used.

Calculation: Assume the vol. 24 hr. specimen is 1200 ml. and the number of ml. of N/10 NaOH used is 6. A 10 ml. aliquot of the specimen was titrated.

Titer × N × 24 hr. vol./aliquot = mEq./24 hr.
6 × 0.1 × 1200/10 = 72 mEq./24 hr.

SPECIFIC GRAVITY

Consult pp. 1893-1897 for concentration and dilution tests which utilize specific gravity determinations.

Pour the urine into a cylinder. Place a urinometer in the urine, spinning to prevent its floating to the side. Read the specific gravity from the stem of the urinometer.

The urinometer is always calibrated for use at a certain temperature. If the specific gravity is taken at any other temperature, one unit of the last order must be added to the reading for every 3° above the normal temperature, and subtracted for every 3° below the normal temperature.

Example: The urinometer is calibrated for a temperature of 15° C. The specific gravity of the urine at 18° C. was 1.022. True specific gravity is 1.022 + 0.001 or 1.023.

In the event that there is an insufficient amount of specimen, 1 ml. may be weighed on an analytical balance. At normal room temperature the weight of 1 ml. is sufficiently close to specific gravity to be acceptable.

The **normal specific gravity** of the first morning specimen is from 1.015 to 1.020. In diseased conditions it may vary from 1.001 to 1.060. The Exton* immiscible balance is useful to determine the specific gravity of drops of urine when only very small amounts are available, as in ureteral catheterization. The method and construction of the instrument are based on the principle of suspending the urine in an immiscible medium of the same specific gravity which is then determined by the usual methods, making possible rapid manipulations with minimal loss of material. A cylindrical mixing chamber is partially filled with a mixture of petroleum ether and carbon tetrachloride with a specific gravity of about 1.012. The side thistle tube is filled with petroleum-ether and the carbon tetrachloride is kept at hand in a drop bottle. A drop of urine is immersed in the mixture, which is then easily and rapidly varied by means of the stopcock and dropper, so that the urine remains suspended near the middle. The specific gravity of the mixture is then taken by means of the Exton hydrometer; this gives the specific gravity of the urine.

SOLIDS

The amount of solids in 1000 ml. may be roughly calculated by means of the Long coefficient, which is 2.6. Multiply the last two figures of the specific gravity at 15° C. by 2.6 to obtain the solids.

Example:
Specific gravity at 15° C. was 1.016.
16 × 2.6 = 41.6 gm. in 1000 ml. urine.

The output of a normal adult is about 60 gm. It must be remembered that the output of urinary solids is influenced by body weight, diet, exercise, age, metabolism, and state of kidney function.

Chapter 99

Chemical examination

SAM FRANKEL

SUGAR IN URINE

Glucose or dextrose exists in every normal urine in small quantity. It is assumed, however, in ordinary laboratory tests that the presence of sugar in the urine is a pathologic condition or the result of disturbed physiology.

At times other monosaccharides are found, such as fructose, pentose, and galactose. Also of interest are certain disaccharides which consist of 1 molecule of glucose (dextrose) and 1 molecule of either glucose or some other hexose, e.g., lactose, which consists of 1 molecule of glucose and 1 molecule of galactose. Different sugars in urine have different clinical significance.

A large sugar content in urine causes a high specific gravity, even though the color of the urine may be light and the daily output increased.

Pathologically, sugar is present in the urine in undue quantity. This condition is called glycosuria. It is a common incident in the disease known as diabetes mellitus. Glycosuria is also found in other diseases, e.g., in connection with certain poisons, such as morphine, carbon monoxide, mercuric chloride, etc. After prolonged hunger, glucose has been found in the urine.

Alimentary glycosuria: Alimentary glycosuria is a condition caused by undue ingestion of sugar and other carbohydrates by healthy individuals. Excessive ingestion of glucose may so overload the blood stream with blood sugar that the threshold point may be reached.

Renal glycosuria: Renal glycosuria has at times been called renal diabetes. In this condition there is usually a pathologic amount of sugar in the urine without any corresponding rise in blood sugar such as is seen in diabetes mellitus. Furthermore, there are no apparent symptoms of diabetes mellitus.

The following standards have been established in making the diagnosis:

1. Fasting blood sugar is within normal limits, and a normal glucose tolerance curve is expected.
2. Glucose should be present in appreciable quantity in all urine specimens, whether voided in the fasting state or postprandially.
3. Carbohydrate utilization should be normal, as evidenced by the respiratory quotient and serum inorganic phosphate after glucose ingestion.
4. Fat metabolism should be normal, ketosis being more likely to develop during fasting rather than after overeating.
5. Moderate doses of insulin should have little or no effect on the glycosuria.

Bland[1] reviewed the literature and reported 4 cases that conformed in every particular. He called attention to the fact that many persons with melituria of some type are treated for diabetes mellitus and that real damage may be done by such treatment. Since these patients are losing sugar steadily in the urine, it would seem only sensible that a liberal carbohydrate diet is indicated. Certainly, insulin treatment can be of no value in the treatment of renal glycosuria and may do considerable harm. These patients frequently complain of ease of fatigue and malaise, which symptoms may well have their origin in a low carbohydrate intake.

Renal glycosuria is characterized by a low renal threshold for sugar. Urinary sugar is present because of incomplete reabsorption of sugar by the proximal convoluted tubules of the kidneys. The reason for this abnormality is not well understood, although it is known that certain drugs, such as phlorhizin, will interfere with the phosphorylation mechanism known to be present in the tubules. All of Bland's cases had low renal thresholds as proved by the presence of glycosuria with a normal or subnormal level of blood sugar. It has been postulated that a deficiency of tissue phosphatase may be the abnormality producing consequent interference with the phosphorylation mechanism in the renal tubules on which sugar reabsorption depends. Another possible etiology was that suggested by Thomas and Southworth,[2] who conjectured that the renal threshold is under hormone control. Comparison is made with diabetes insipidus in which the hormone of the posterior pituitary exerts its well-known effect on the renal tubules. The renal glycosuria of pregnancy fits this conception in that there exists in pregnancy a hormonal imbalance. In Bland's second case the renal glycosuria developed after a series of streptococcal infections. He suggested that this may be more than coincidental. The widespread vascular lesions apparently produced by repeated hemolytic streptococcal infections may well produce changes in the blood supply to the renal tubules, which, in turn, could alter the tubular physiologic function.

In reference to treatment, a liberal and varied diet should be given with perhaps some emphasis on carbohydrate intake. The patient should be advised that his condition is benign and be reassured that his prognosis is good. Insulin is certianly not indicated. Somogyi[3] has shown that a low carbohydrate intake and ill-advised use of insulin may produce increased hepatic glycogenolysis with each episode of hypoglycemia, thus leading to increased hepatic fat and protein metabolism, with consequent increase in ketone production. Thus, clinical ketonuria may be induced in the absence of glycosuria. In such an instance insulin is clearly contraindicated.

Bland's study included determinations of both arterial and venous blood sugars in the glucose tolerance tests in order to prove adequate removal of glucose by the tissues from the arterial blood. Serum phosphorus determinations were simultaneously made to study the absorption of the glucose and the phosphorylation mechanism.

Pentosuria: In this condition there is a constant excretion of pentose in the urine regardless of the diet. In pentosuria it is believed that there is a disturbance in metabolism and that it is not a precursor of diabetes mellitus. It is essential to differentiate pentosuria from glycosuria because the pentosuric patient must not be subjected to the rigid dietetic control or insulin treatment of the diabetic patient. Tests to be described later (p. 1815) serve to differentiate pentosuria from glycosuria and fructosuria.

An abundance of levulose or fructose is noted at times. These cases of levulosuria or fructosuria are seen after the ingestion of large amounts of fruits. In other words, it is an alimentary condition rather than a metabolic condition. Tests later to be described serve to differentiate fructose from glucose. The Seliwanoff test (p. 1815) is the best test for this purpose.

Alkaptonuria: Alkaptonuria is a condition in which homogentisic acid is present in the urine. In this condition the urine becomes dark after prolonged standing due to oxidation processes. The urine becomes dark brown to brown black, which may be seen on clothing where the condition exists. It is seen frequently in small children. The addition of 10% sodium hydroxide results in a brownish black ring at the surface which gradually penetrates downward. Ferric chloride causes a transitory blue color with each drop, and reduction of silver lactate and of ammoniacal silver nitrate proceeds rapidly at room temperature. With Millon reagent a lemon yellow precipitate occurs. With heat this precipitate becomes red. The ammoniacal silver nitrate solution results in the production of a black color when added to alkaptonuric urine.

Millon reagent: Metallic mercury, 1 part; fuming nitric acid, specific gravity, 1.420, 2 parts. Dilute with an equal part of water and after a few hours decant.

Ammoniacal silver solution: Silver nitrate, 26 gm. dissolved in 200 ml. water. Add ammonia. A brown precipitate will form; add more ammonia until this precipitate is redissolved. Make the volume up to 1 L. with distilled water.

This condition is evidently an anomaly of protein metabolism and is probably inherited. It appears to be a rare recessive character in the mendelian sense. Its mode of incidence is remarkably similar to that of albinism, but its presence is not as strikingly apparent as is that condition. This error in metabolism is present from birth and persists throughout life.

TESTS FOR SUGAR IN URINE

The many tests available for the detection of sugar in urine utilize several different principles. Monosaccharides will reduce certain metals in alkaline solution with the aid of heat which is the basis of the Trommer, Benedict, and Fehling tests. Glucose, being fermentable, will produce carbon dioxide in the presence of yeast which has been used not only as a method of identification but also for quantitation. Physical properties, such as the rotation of polarized light, have also been used but are not particularly suitable for the routine laboratory. Caramelization, the principle of the Somogyi assay, offers a simple method of obtaining quantitative results.

Differentiation of sugars found in urine

1. Fermentation is a quality of glucose and fructose.

2. Typical crystalline form of osazone of glucose or fructose differentiates these sugars from lactose.

3. To distinguish between glucose and fructose, the Seliwanoff test (p. 1815) is used, or a polariscopic examination may be made.

4. The presence of pentoses is indicated by a positive reaction with Bial reagent (p. 1815).

QUALITATIVE TESTS FOR GLUCOSE IN URINE* (REDUCTION TESTS)

Benedict method

Reagents:

1. Benedict qualitative solution.
    (a) Dissolve 17.3 gm. copper sulfate, c.p., in 100 ml. distilled water with heat in a small Pyrex beaker.
    (b) In a 1000 ml. Pyrex beaker dissolve 173 gm. sodium citrate, c.p., and 100 gm. anhydrous sodium carbonate, c.p. (if crystalline sodium carbonate is used, 200 gm. are substituted for the 100 gm. of the anhydrous), in about 600 ml. distilled water, with heat.
    (c) Filter solution (b). Add the copper sulfate solution slowly and with constant stirring to the mixture of sodium citrate and sodium carbonate, until all has been added. Rinse the residue in the small beaker into the solution, using a few ml. of distilled water. Cool and dilute to 1000 ml. with distilled water.

Procedure:

1. Place 5 ml. Benedict qualitative solution in a test tube.
2. Add 8-10 drops urine and mix.
3. Place the test tube in a cup containing equal parts boiling water and calcium chloride.
4. Allow the contents of the test tube to boil for 2 min.
5. Let stand until cool.

If glucose is present in the urine, there will be a brick red precipitate. If glucose is present in a very large amount, the entire contents will assume a brick red color. Very small quantities of sugar, as low as 0.015-0.020%, will yield a precipitate. Phosphates yield a white precipitate. The degree of reaction is judged by the amount of precipitate.

Benedict solution, although less susceptible than Fehling solution to reduction by other urinary constituents such as uric acid or creatinine, is however promptly reduced by alkaptonic acids or the conjugated glycuronic acids or by an excess of preservatives such as chloroform, chloral (trichloracetaldehyde), and formaldehyde. When the urine of a patient shows reduction in the first examination, use further tests to determine whether the substance is sugar and the kind of sugar.

Streptomycin in concentration as low as 200 μg/ml. reduces alkaline copper reagents such as Benedict solution. With drug levels greater than 700 μg/ml. it is possible that the reaction obtained with the Benedict reagent may be interpreted incorrectly as a positive test for glycosuria.

Unless the urine contains enough reducing substance to reduce the Benedict solution in the heating time specified, it is not clinically significant. Remove the protein from the urine by acidifying with acetic acid, boiling, and filtering.

Fehling method

Reagents:

1. Fehling solution I.
    (a) Dissolve 34.639 gm. crystallized copper sulfate, c.p., in about 300 ml. distilled water with gentle heat.
    (b) Dilute to 500 ml. with distilled water.
2. Fehling solution II.
    (a) Dissolve 173 gm. sodium potassium tartrate (Rochelle salt) and 100 gm. potassium hydroxide, c.p., in about 300 ml. distilled water.
    (b) Dilute to 500 ml. with distilled water.

Procedure:

1. Mix equal parts of solutions I and II in a test tube.
2. Dilute this with 2 or 3 times the amount of water and boil for a few seconds.

If the mixture remains clear after boiling, the solutions may be used. Continue the boiling, adding the urine to be tested drop by drop. If sugar is present, a yellow precipitate will form. If sugar is present in large amount, the first few drops will yield a precipitate. If the quantity of sugar is small, urine is added until an equal volume has been used. If no precipitate forms, the specimen contains no sugar.

---

*"In two- to four-plus specimens a yellow film usually adheres to the inside of the tube and defies removal by soap, brush, or cleaner. It will disappear as if by magic if you drop a pinch of dry bicarbonate of soda into the wet tube, moisten the test tube brush and swish it around in the tube, add a little water, and swish it several times more, rinse, and dry. . . ." Medical Economics: Cleaning of test tubes used in sugar analysis.

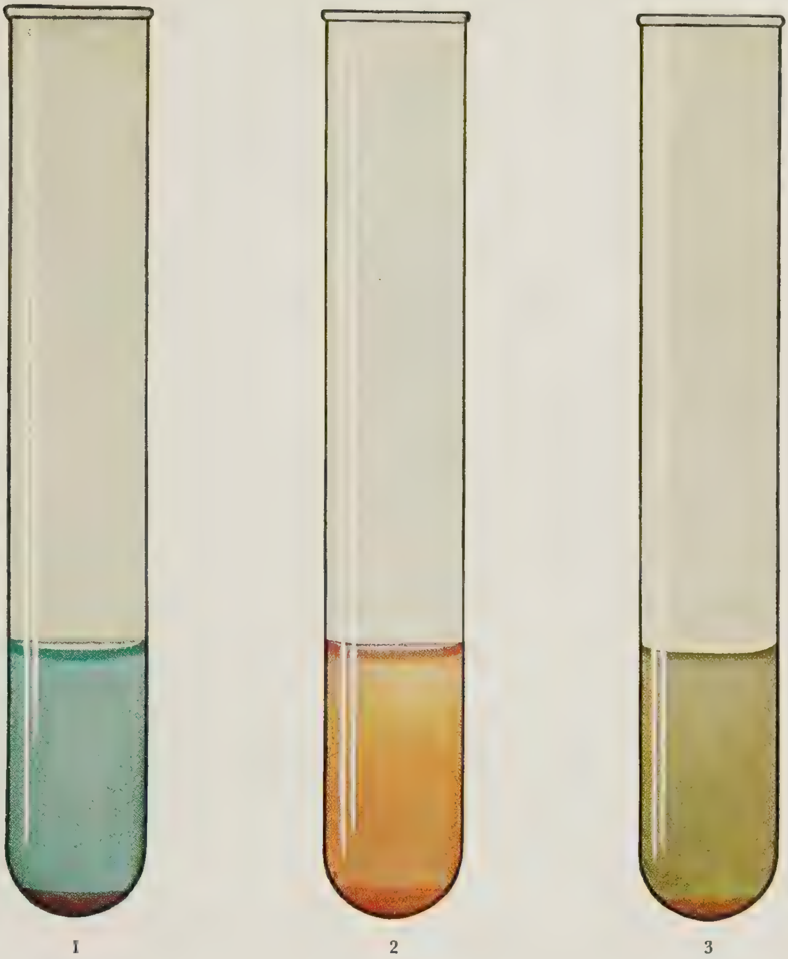

Fig. 615. Benedict test for sugar. **1,** Green—showing only a trace of sugar. **2,** Red—showing a large amount of sugar. **3,** Yellow—showing a small amount of sugar. (From Gradwohl, R. B. H., and Blaivas, A. J.: The newer methods of blood and urine chemistry, St. Louis, The C. V. Mosby Co.)

Nylander method

Reagent:

1. Dissolve 5 gm. Rochelle salts (sodium potassium tartrate) in 100 ml. 10% solution of sodium or potassium hydroxide.
2. Warm and add 2 gm. bismuth subnitrate.
3. Cool and filter through filter paper.

Keep in a dark bottle.

Procedure:

1. Place 5 ml. urine in a test tube.
2. Add 0.5 ml. Nylander reagent.
3. Heat for 3-5 min.
4. Allow to stand for a few moments before reading.

A black color indicates the presence of sugar. A brown color is indicative of a trace of sugar. If the solution turns black after cooling, the reaction is due to substances other than sugar. Phosphates yield a white precipitate. If albumin is present in large amount, remove it by boiling and filtration, since it gives the same reaction as sugar.

Moore-Heller method

1. Place in a test tube 2 parts urine and 1 part 10% potassium hydroxide solution.
2. Boil the upper portion for 2 or 3 min.
3. If phosphates are precipitated in large amount, remove by filtration.

If sugar is present the following reactions take place:

1% or less of sugar yields a canary yellow color
1 to 2% gives a wine yellow color
2 to 3% gives a sherry color
3 to 4% gives a rum color
Above 4% gives a dark brown or black color

Phenylhydrazine test for sugar

1. Place 10 ml. urine in a test tube.
2. Add 0.4 gm. phenylhydrazine hydrochloride and 0.8 gm. sodium acetate.

3. Place the test tube in a water bath and boil for ½-1 hr.
4. Allow it to cool.

Within ½ hr. typical crystals of phenylglucosazone separate when sugar is present, which appear microscopically as fine bright yellow needles arranged in bundles, sheaves, or rosettes.

QUANTITATIVE ESTIMATION OF GLUCOSE IN URINE

Somogyi method

Somogyi[4] has approached the question of carbohydrate utilization or tolerance of diabetic patients along the line suggested by Naunyn and his school at the turn of the century. It is a method of preparing daily balance sheets of carbohydrate consumption and loss of glucose in the urine, the balance representing the amount of carbohydrate utilized in 24 hr. In cases in which insulin therapy is applied, Somogyi advises estimating the total glucose output for 24 hr. periods, running separate quantitative determinations on every sample of urine collected between insulin injections. The information thus obtained proved to be the best criterion for the adequacy of the insulin dosage. One of the advantages of this procedure is that it can be pursued for any length of time without hardship to the patient, whereas gathering of the equivalent information by serial blood sugar determinations is scarcely tolerable for days and nights in a row.

The basis of this method is the well-known change of color which takes place when sugars are heated in alkaline solution; the shade which develops in the reaction varies from pale yellow to dark amber, depending upon the concentration of sugar. Sodium carbonate is the alkali which satisfies the requirements of this test. Glucose quantities varying from 1-30 mg. in 5-6 ml. reaction mixture give maximum color intensities when the concentration of the carbonate is maintained within the range of 8-15%. The maximum color appears after heating alkaline glucose solutions in a boiling water bath for 8 min.; prolongation of the heating beyond 10 min. causes a gradual fading of the color. Boiling over an open flame for 1½-2 min. produces the same colors as heating in the water bath for 7-10 min.

Equipment:

1. Test tubes of 14 mm. inside diameter. All test tubes employed must be of identical diameter. A simple way to select uniform test tubes is to measure accurately 10 or 15 ml. portions of water into a series of tubes and to retain for use only those in which the water level is of the same height.
2. Pipets for measuring 0.5 and 5 ml. portions of fluid.

Reagents:

1. 10% anhydrous sodium carbonate.
   (a) Dissolve 10 gm. anhydrous sodium carbonate in about 50 ml. distilled water and dilute to 100 ml. with distilled water.

Procedure:

1. Introduce into test tubes 0.5 ml. portions of the urines to be analyzed; then add to every test tube 5 ml. sodium carbonate reagent.
2. Mix the contents, place the test tubes in a rack, and heat, immersed in boiling water, for 8 min. Racks accommodating 1-2 doz. (or more) test tubes are serviceable.
3. After 8 min. heating read the results by matching the colors against the standards in the comparator block.*

If the color of the unknown does not closely match any one of the standards but lies between 2 of them, estimate the intermediate value by interpolation. If, for example, the color shade of an unknown is halfway between the 3 and 4% standards, its sugar content is 3.5%; if it is between 3 and 4% but distinctly nearer the 3% standard, then it contains 3.2-3.3% of glucose, etc.

A source of error because of fading of the standards has been eliminated by Somogyi by devising permanent standards. The stock solution for permanent standards is a 0.01N iodine solution in absolute alcohol from which a series of solutions is prepared by dilution with absolute alcohol. The normality of the several diluted solutions is given in Table 358. An 0.008N alcoholic iodine solution is of the same color, shade, and intensity as the 6% glucose standard and thus takes the place of it; a 0.0058N iodine solution is a substitute for a 5% glucose standard, and so on, as given in Table 358.

Table 358. *Concentrations of alcoholic iodine solutions used as permanent standards*

Normality of iodine solutions	*Corresponding percentual glucose concentrations*
0.0004	0.5
0.0009	1.0
0.0018	2.0
0.0028	3.0
0.0043	4.0
0.0058	5.0
0.0080	6.0

Approximately 5 ml. portions of these iodine solutions are introduced into Pyrex test tubes of 14 mm. inside bore, and the tubes are then sealed. In this condition the standards remain unchanged without requiring any special precautions, as, for example, protection from light or changes in room temperatures. The

---

*Sets of permanent standards with a matching block were placed on the market by Aloe Scientific, St. Louis, Mo., and are available through laboratory supply houses.

Table 359. *Comparison of results of urinary sugar determinations by Somogyi method with true sugar values estimated by a copper-iodometric method*

	Gm. sugar/100 ml. urine	
No.	*Copper-iodometric method (p. 84)*	*Somogyi method*
1	0.21	0
2	0.42	0.3
3	0.31	0.5
4	0.41	0.3
5	1.2	1.2
6	1.3	1.3
7	2.1	2.0
8	2.6	2.5
9	3.0	3.0
10	3.9	4.0
11	5.0	5.0
12	5.0	5.0

permanence can be readily ascertained by comparison with standards freshly prepared with pure glucose solutions. The earliest permanent standards in Somogyi's laboratory after 2 yr. showed no deterioration.

In Table 359 one can see the results of the Somogyi method with true sugar values estimated by a copper-iodometric method.

This method is as rapid and simple as a properly executed qualitative test for urinary sugar, particularly when one is to carry out considerable numbers of determinations. When only occasional single determinations are to be made, however, preliminary heating of a water bath to boiling and heating of the reaction mixture for 8 min. may involve a waste of time. This difficulty can be overcome by the use of an open flame. Analysis is carried out as follows.

Procedure:

1. Measure into a test tube 0.5 ml. urine and 5 ml. carbonate reagent, drop in 2 small glass beads or quartz pebbles and a drop of paraffin oil (or a corresponding bit of paraffin wax).
2. Heat to boiling over an open flame and, turning the flame low, keep the liquid boiling **very gently** for 1½-2 min.

The color develops to the same shade as after heating for 8 min. in a boiling water bath and can be matched against the permanent standards.

A distinct advantage of the carbonate reaction is that it is more specific for sugars than are copper reagents. This quality comes mainly into play when dealing with concentrated urines, so frequent in hot summer weather, which may reduce appreciable amounts of copper without containing any abnormal amounts of glucose; with Somogyi's method such urines give negative results.

Somogyi further states that if the urine is abnormally dark colored or contains blood or bile, it must be decolorized preliminary to the analysis. To this end add about 2-3 gm. (roughly ½ tsp.) Lloyd reagent* to about 10 ml. urine in a test tube or a small flask, agitate the mixture gently for about 1 min. (or longer), and then filter through a dry filter paper. The nearly colorless filtrate is ready for analysis.

Note: Instead of preparing the permanent standards or purchasing a matching block, it is practical to run standard sugar solutions and to read them in a colorimeter, thereby establishing a standard curve. This would eliminate dependence upon artificial standards as well as permit closer approximations of those specimens that fall in between the standards.

Benedict method

Reagents:

1. Benedict volumetric solutions.
   - (a) Dissolve 18 gm. crystalline copper sulfate, c.p., in 100 ml. distilled water with heat in a small Pyrex beaker.
   - (b) In a 1000 ml. Pyrex beaker dissolve 100 gm. anhydrous sodium carbonate, c.p. (or 200 gm. of crystalline sodium carbonate), 200 gm. sodium or potassium citrate, c.p., and 125 gm. potassium sulfocyanate, c.p., in 600 ml. distilled water with heat.
   - (c) Filter. Add the copper sulfate slowly and with constant stirring to the above mixture. Rinse the residue of copper sulfate in the beaker into the solution with a few ml. distilled water. Transfer to a 1000 ml. volumetric flask, rinsing the beaker with a few ml. distilled water and adding the rinse water to the solution in the flask. Add 5 ml. 5% solution of potassium ferrocyanide. Cool and dilute to 1000 ml. with distilled water. Mix thoroughly; 25 ml. this reagent are reduced by 50 mg. glucose, 52 mg. fructose, 54 mg. galactose, or 67 mg. lactose.
2. To adjust Benedict volumetric solution:
   - (a) 1% glucose solution. Dissolve exactly 1 gm. glucose in distilled water in a 100 ml. volumetric flask and dilute to 100 ml. with distilled water. This solution is not stable.
   - (b) Place in a casserole 25 ml. newly made Benedict volumetric solution.
   - (c) Add a few gm. of sodium carbonate and a pinch of powdered pumice.
   - (d) Titrate as follows: Fill a buret with 1% glucose; record the reading on the buret; boil the contents of the casserole.
   - (e) Add 1% glucose drop by drop to the cas-

---

*A hydrated aluminum silicate, used extensively in urine analysis for clarification and also for adsorption of certain alkaloids; obtainable from Hartman-Leddon Co., Philadelphia, Pa.

serole, boiling constantly, until the copper sulfate is reduced to a gray color. Record the reading on the buret. Subtract the first reading from the second.

If more than 5 ml. of a 1% solution of glucose is used, the Benedict volumetric solution is too strong. Adjust as shown in the following example:

6 ml. of a 1% glucose solution were used.
6 ml. contain 60 mg. glucose.
60 : 50 :: x : 25
50x = 1500
x = 30 (vol. to which each 25 ml. solution must be diluted).
30 − 25 = 5 ml. water must be added to each 25 ml. Benedict volumetric solution. There are 975 ml. Benedict volumetric solution on hand.
975 ÷ 25 = 39
39 × 5 = 195 ml. distilled water to be added to a vol. 975 ml.

If the solution is too weak, adjust as shown in the following example:

Second reading 23.0
First reading 18.3
4.7

4.7 ml. 1% glucose were used to reduce 25 ml. Benedict volumetric solution.
4.7 ml. 1% glucose contain 47 mg. glucose.
47 : 50 : : x : 450
50x = 21,150
x = 423 mg. copper sulfate present in each 25 ml. Benedict volumetric solution. Each 25 ml. should contain 450 mg. copper sulfate. This solution lacks 27 mg. copper sulfate for each 25 ml. Benedict volumetric solution.
Vol. 975 ml.
975 ÷ 25 = 39
39 × 27 mg. = 1053 mg. or 1.053 gm. copper sulfate to be added to 975 ml. Benedict volumetric solution.

Procedure:

1. Place the urine in a graduated buret.
2. Place in a casserole of at least 200 ml. capacity 25 ml. Benedict volumetric solution, 5-10 gm. sodium carbonate, and a pinch of powdered pumice.
3. Heat the mixture in the casserole to boiling.
4. Add the urine from the buret drop by drop and very slowly, stirring constantly and boiling the mixture in the casserole throughout the entire procedure. Continue, adding the urine slowly until the last trace of the blue color disappears. This is the end point.
5. Read from the buret the number of ml. of urine used in the reaction.
6. Calculate the quantity of sugar present as follows: 25 ml. Benedict volumetric solution are reduced by 50 mg. glucose. The number of ml. urine used in the titration, therefore, contains 50 mg. glucose. Divide 50 by the number of ml. urine used in the titration, to obtain the number of mg. in 1 ml. urine. Multiply by 100 to obtain the number of mg. glucose in 100 ml. urine. Divide this figure by 1000 to obtain the number of gm. glucose in 100 ml. urine or the per cent of sugar present in the specimen.

Example:

2.5 ml. urine were used in the titration of the specimen.
50 divided by 2.5 is 20.
1 ml. urine contains, therefore, 20 mg. glucose.
100 ml. contain 100 × 20 mg. or 2000 mg. (2 gm.) sugar. The percentage of sugar present is therefore 2.

Fehling method

1. 10 ml. Fehling solution are reduced by 0.05 gm. sugar. Dilute 1 ml. Fehling solution with 4 ml. distilled water in a test tube and heat to boiling.
2. Add urine from a 1 ml. graduated pipet a drop at a time until all the blue color has been removed from Fehling solution. The number of ml. urine used in bringing about this reaction contained 0.005 gm. glucose.

If 0.1 ml. of urine were used in the reduction of Fehling solution, then 0.1 ml. urine contains 0.005 gm. sugar.

1 ml. contains 0.05 gm. sugar.

100 ml. urine contain 5 gm. The percentage of sugar in the urine is therefore 5.

Robert fermentation test

1. Place 4 oz. urine in each of 2 bottles: the first, a bottle of 12 oz. capacity; the second, of 4 oz. capacity.
2. Add a piece of fresh yeast* the size of a walnut to the urine in the 12 oz. bottle and cork; nick the cork for the escape of gas evolved by the fermentation of the sugar. Cork the smaller bottle tightly. Keep both bottles at room temperature.

The fermentation of the sugar will be completed within 24 hr. Take the specific gravity of urine in both bottles. The difference of the specific gravities indicates the number of grains of sugar per fluid ounce. Example:

If the specific gravity of the unfermented urine is 1.035 and of the fermented urine is 1.020, the urine contains 15 grains sugar/fl. oz. or 3%.

This method is not very accurate.

Einhorn fermentation saccharometer

An Einhorn saccharometer is a fermentation tube on a stand with graduations on the arm. It is necessary to have 2 such tubes and 1 test tube for a test.

1. Place 10 ml. urine in a test tube and add 1 gm. fresh yeast.* Shake thoroughly. Pour into the saccharometer, tilting it back until the fluid runs up into the arm, expelling all the air.
2. At the same time fill a saccharometer with normal urine.
3. Allow both to stand at room temperature for 24 hr.

The tube containing the normal urine should show no gas. A small bubble of gas may be disregarded. If the normal urine reacts correctly, the test may be read. Read from the arm of the fermentation tube the amount of sugar present. If the urine contains more than 1% of sugar, it must be diluted with distilled water before testing.

---

*Use brewer's or compressed yeast.

Urine of a specific gravity of 1.018-1.020 is diluted twice. Urine of a specific gravity of 1.021-1.028 is diluted 5 times. Urine of a specific gravity of 1.029-1.038 is diluted 10 times.

Millard-Smith micromodification

1. Place exactly 1 ml. Benedict volumetric reagent in a test tube.
2. Add 0.2-0.7 gm. anhydrous sodium carbonate and a pinch of powdered pumice.
3. Draw the urine into a Mohr pipet up to the 100 mark.
4. Heat the Benedict solution to boiling.
5. Add the urine from the Mohr pipet until reduction of the copper sulfate is complete, determined by the disappearance of the blue color. Urines containing more than 3% sugar should be diluted before titration.

Calculate the quantity of sugar present.

One ml. Benedict volumetric reagent is reduced by 2 mg. glucose. If 2 ml. urine were used, then 2 ml. urine contained 2 mg. glucose. One ml. urine contained 1 mg. glucose; 100 ml. urine contained 100 mg., or 0.1 gm. glucose, or 0.1%.

FRUCTOSE IN URINE

Seliwanoff reaction

1. To 10 ml. urine in a test tube add a small amount of resorcin and 2 ml. diluted hydrochloric acid and mix. Heat.

If fructose is present, the solution turns red and precipitates a dark sediment. The sediment is soluble in alcohol, giving a bright red color.

LACTOSE IN URINE

Rubner test

1. To 10 ml. urine in a test tube add 3 gm. lead acetate.
2. Filter off the precipitate and heat the filtrate for a few minutes. A yellowish brown color appears. At this point add ammonium hydroxide and continue heating.

If lactose is present, a brick red color appears in the solution, with a cherry red or copper-colored precipitate. The supernatant fluid becomes colorless after the formation of the precipitate.

Lactose may be found in the urine of women during lactation and in patients who have been on an exclusive milk diet for a long time.

MALTOSE OR ISOMALTOSE IN URINE

Maltose or isomaltose reduces copper solutions but not so strongly as glucose. Ten ml. Fehling solution are reduced by 0.0807 gm. maltose.

CANE SUGAR (SACCHAROSE) IN URINE

Pure saccharose (sucrose) does not reduce Fehling solution.

The finding of saccharose in the urine is of no clinical importance.

PENTOSES IN URINE

The more important pentoses found in urine are rhamnose, arabinose, and xylose. The pentoses reduce copper solutions, the reduction taking place more slowly than with other carbohydrates.

The presence of pentose may be only a temporary or alimentary disturbance due to the ingestion of large amounts of pentose-rich fruits, but it may be pathologic, especially in diabetes. The pentose which is most frequently present in the chronic form is arabinose.

Ten ml. Fehling solution are reduced by 0.0542 gm. pentose.

Fermentation test is negative.

Nylander solution yields a gray precipitate.

Bial orcinol test for pentoses

Bial reagent:

Hydrochloric acid, 30% . .	500 ml.
Orcinol	1 gm.
Ferric chloride solution, 10%	25 drops

Procedure:

1. Boil 5 ml. Bial reagent in a test tube.
2. Remove from the flame and add urine drop by drop until not more than 1 ml. urine has been used. A green color appears almost immediately if pentoses are present.

PROTEIN IN URINE

SIGNIFICANCE OF ALBUMINURIA

Tests for albumin in urine depend upon the visual demonstration of the precipitated protein. The question of what is or what is not pathologic has not entirely been settled. The problem as to which is the best test for protein is also the subject of much debate. The sulfosalicylic acid test is 16 times more sensitive than the Heller test when applied to dilute protein solutions, and when applied to urine the sensitiveness is 3 times as much.

Folin[5] evidently realized the danger of introducing too sensitive a test for routine work and advised a method of using sulfosalicylic acid which is 10-15 times less sensitive than the maximum which can be obtained.

An important question is the significance of small amounts of albumin in urine.

According to life insurance companies, albuminuria in amounts up to 0.03% does not prevent a person under 35 yr. of age and with a negative previous history and otherwise normal findings from being accepted as a standard risk. When, however, individuals with a minute trace of albumin give a history of previous renal disease, then, of course, this finding becomes of great significance.

Insurance authorities divide albumin groups dependent upon the amount of albumin found in various specimens. Daly further divides them into 2 other classes: **intermittent,** in which the albumin is found in ⅔ or less of the specimens examined, and **constant,** in which albumin is found more often. An estimate of the Medico-Actuarial Committee, published in 1938, states that in the class of the **intermittent small amounts,** there were 51,807 exposed to risk, 298 actual deaths against the expected death total of 232, or a mortality ratio of 128% of the expected; in the class of **intermittent moderate amount,** 5881 with 23 actual deaths against an expected death total of 17 deaths, or a mortality ratio of 132%. According to figures of insurance authorities, the mortality is fairly constant in the **intermittent** group, but this does not hold when the albumin is **constant.** In the **moderate amount** of **constant** albuminuria group there were 86 actual deaths against 52 expected, with a mortality ratio of 165%, and in the **large amount** category there were 50 actual deaths against an expected 17 with a mortality ratio of 289%. Expressed in other words, the **constancy** of albuminuria has a definite primary influence on mortality, the **amounts** only a secondary influence. However, the mortality ratio was higher at the older than at the younger ages of entry and increased as the duration of the policies advanced, according to Daly's figures. He states further that the concept of renal disease has changed. Formerly, albuminuria and hypertension were considered definite evidence of Bright's disease; now it is recognized that the hypertension usually comes first and the prime effect is on the cardiovascular system and only secondarily on the kidney. This is reflected in the mortality statistics of insured lives.

The presence of albumin in the urine does not necessarily mean disease of the kidney, for it may at times reflect the reaction to substances, toxic and otherwise, that originate within the body. Physiologic factors may cause transient albuminuria, such as orthostatic and lordotic albuminuria, which will be explained later. In the insurance world albuminuria is but a symptom; albuminuria is considered only from a statistical standpoint. Statistically, one can say that the constancy of albuminuria has a definite primary influence on mortality, the amounts only a secondary influence. However, as just stated, the mortality ratio, according to Daly, was higher at the older than at the younger ages of entry and increased as the duration of the policies advanced. The death rates from nephritis and heart impairment were 5 and 2½ times the normal, respectively.

Albuminuria may be classified clinically as follows:

1. **Febrile albuminuria,** which usually disappears with the fever.
2. **Toxic albuminuria,** which may be either chemical or bacterial: chemical poisoning by phenol, phosphorus, lead, mercury, arsenic, etc.; bacterial toxic albuminuria as is seen in bacterial diseases such as diphtheria, scarlet fever, meningitis, typhoid fever, etc.
3. **Albuminuria due to cardiovascular disease.**
4. **Nephrotic albuminuria;** for example, following leukemia, purpura, syphilis, diabetes, etc.
5. **Obstructive albuminuria** caused by ureteral obstruction from stricture, calculus, or pressure of tumors.
6. **Nephritic albuminuria** (will be fully discussed later; pp. 1817 and 1904).
7. **Neural albuminuria,** such as is seen in certain diseases of the central nervous system; such as epilepsy, brain tumor, cortical injuries, etc.
8. **Alimentary albuminuria,** which occurs in certain individuals from undue ingestion of protein material.
9. **Accidental albuminuria,** in which the albumin comes from other material containing albumin mixed with the urine; such as pus, blood, seminal fluid, etc.
10. **Physiologic albuminuria,** which occurs from violent physical exercise.
11. **Postural albuminuria** (described below).
12. **Benign albuminuria,** which occurs in childhood and adolescence, occurring also in cycles; hence frequently called "cyclic" albuminuria.

Albuminuria is frequently found in young men without any other indications of pathology. Statistical studies in young men with albuminuria disclosed very little difference eventually between the normal subjects, and those with albuminuria. In other words, transitory albumin is likely to be found in young men. College students have been examined, for instance, and have been found to have definite albuminuria in a certain percentage of certain groups. Examination from 5-10 yr. later revealed that in most cases the albuminuria had disappeared.

The past history of these young people must be taken into account in estimating the significance of albuminuria. Those with frequent colds or disturbances in the nose and throat were frequently shown to have albuminuria.

Many different names have been given to this transitory albuminuria of supposedly healthy people, such as orthostatic, postural, lordotic, juvenile, pubertile, cyclic, transitory, etc.

In relation to the so-called postural type of albuminuria, albumin frequently appears in the urine of young men only when they are in an erect posture. It was noted that most of these men with postural or orthostatic albuminuria showed in the standing position a well-marked lordosis, the deepest part of which was at the level of the first and second lumbar vertebrae. This disappeared when the patient reclined. Jehle proved that the production of a lordosis in the erect position accounted for the orthostatic nature of the albuminuria. If a person remained on his knees, a position in which lordosis is very marked, the albuminuria was very pronounced. If the patient, while standing, put one foot on a stool, thus eliminating the lordosis, the albuminuria disappeared. It seems undeniable that the cause of albuminuria in many young people is lumbar lordosis.

The albuminuria which most concerns us as an important diagnostic factor is that seen usually in nephrosis or nephritis. In diseases of the kidney there is an alteration in the secretory function to such an extent that leakage of protein occurs. The urinary protein in renal disease consists of serum albumin and globulin, which are eliminated from the blood plasma. Occasionally in renal disease a cloud forms after the addition of a few drops of 5% acetic acid to the cold urine. Proteins giving this reaction are known as the acetic acid body which does not coagulate on heating. Theoretically it is the result of the presence in the urine of serum albumin and chondroitin-sulfuric acid, which precipitates protein at a faintly acid reaction. In most forms of renal disease, albumin is far more abundant than globulin in the urine.

The amount of protein in albuminous urine varies greatly. The most copious albuminuria occurs in degenerative processes in the renal epithelium; especially great quantities of protein are found in the urine in syphilitic and other chronic nephroses. As much as 5% protein may be found in syphilitic nephrosis.

Regarding the transit of albumin from blood to urine, it seems that urinary proteins have different isoelectric points from the corresponding serum proteins; therefore these must undergo some modification in their transit through the kidney or in the urine.

Some have claimed that proteins are derived entirely from disintegration of the renal cells, but this is questionable. Everything points to the fact that the amount of protein derived from the tubular epithelium is evidently small in comparison with that coming from the blood.

The manner in which protein is excreted in the glomerular portion of the kidney has been the subject of much study. The increased permeability of the kidney to albumin is in line with the fact that the smallest molecular parts of plasma proteins alone pass into the urine. The serum albumins are of smaller molecular weight than the serum globulins, and albuminous urines almost always contain a much higher ratio of albumin to globulin than does the blood. We do not know, of course, what particular influence produces the increased permeability in the glomerular portion.

QUALITATIVE TESTS FOR ALBUMIN IN URINE

Heat test with acetic acid

1. Fill an ordinary test tube ¼ or ⅕ full of of urine.
2. Boil thoroughly.
3. Add 2 or 3 drops of a mixture of equal parts of glacial acetic acid and water.

If albumin is present, the urine becomes cloudy; the greater the cloudiness, the larger the amount of albumin.

The following reactions are possible:

1. If the urine is transparent and remains so, it is normal.

2. If the urine becomes cloudy after boiling but clears after the addition of acetic acid, phosphates are present. If the urine effervesces upon the addition of the acid, either calcium carbonate or ammonium carbonate is present.

3. If the urine becomes cloudy after boiling and remains cloudy or increases in cloudiness, albumin is present. If albumin is present in large quantities, flakes will form and precipitate. Slight cloudiness may be detected by comparison of the test with a test tube of the untested urine. If the 2 test tubes are held against a black background, the faintest cloudiness may be observed.

4. If the urine is cloudy, clears upon boiling, and remains clear after the addition of the acid, urates are present, especially sodium urate.

5. If the urine is cloudy and the cloudiness disappears upon warming but reappears and becomes more pronounced upon boiling with the addition of the acid, urates are present in excess.

6. If the urine is cloudy and remains unchanged by boiling and the addition of the acetic acid, microorganisms are present.

Purdy modification of the heat test with acetic acid

This test is made to eliminate the possibility of nucleoalbumin and mucin.

1. Filter the urine and fill a test tube about ⅔ full of the filtered urine.
2. Add ⅙ its volume of saturated aqueous solution of sodium chloride.
3. Add 5-10 drops 50% acetic acid.
4. Gently heat the upper inch or so of the mixture for ½ min.

If albumin is present, it appears as a cloud in the upper, boiled portion of the test tube. It must be examined in a good light. Even the minutest traces of albumin may be detected by this test.

Heller test

1. Place a small quantity of pure nitric acid in a test tube.
2. Stratify a small amount of urine on the nitric acid.

A white ring at the point of contact indicates the presence of albumin. Urates appear in a ring above the point of contact. Uric acid and urea are recognized by their crystalline nature. Mucin is precipitated but is dissolved by the nitric acid at the point of contact. Nucleoalbumin and albumoses are precipitated. Nucleoalbumin gives a fainter ring than albumin and is above the point of contact. Proteoses disappear upon heating and reappear upon cooling. They are also soluble in picric acid.

Potassium ferrocyanide test

1. Place 10 ml. filtered urine in a test tube and add 5 drops glacial acetic acid. A precipitate should be removed by filtration.
2. Add a few drops of a 5-10% solution potassium ferrocyanide. If a small amount of albumin is present, a faint cloudiness at once appears. If a large amount of albumin is present, a flocculence occurs. Proteose gives a cloudiness, which disappears upon heating.

Spiegler test—modified by Jolles

Reagent:

Mercuric chloride	10 gm.
Succinic acid	20 gm.
Sodium chloride	20 gm.
Distilled water	500 ml.

Procedure:

1. Filter the urine.
2. Place 5 ml. filtered urine in a test tube and add 1 ml. 30% acetic acid solution.
3. Stratify with 4 ml. Spiegler reagent.

If albumin is present, a white zone will be formed at the point of contact.

Sulfosalicylic acid test

1. Place 4 or 5 ml. urine in a test tube and add 2 or 3 drops 20% aqueous solution of sulfosalicylic acid and mix thoroughly.

Opalescence occurs if small amounts of albumin are present. If large quantities of albumin are present, a pronounced turbidity is noted. A heavy precipitate may accompany the turbidity. Proteose is precipitated but disappears on heating, reappearing on cooling.

Biuret reaction

1. Place the urine in a test tube and treat first with 10% sodium or potassium hydroxide solution and then with a 10% cupric sulfate solution. The copper sulfate is added drop by drop.

If serum-albumin and globulin alone are present, the mixture becomes pure violet. If albuminoses and peptone alone are present, it turns rose. If several of the albumins are present together, the urine assumes tints between violet and rose.

Do not add too much copper sulfate because its color will obscure a faint reaction.

Picric acid test

1. Filter the urine.
2. Place 5 ml. urine in a test tube.
3. Add an equal amount of saturated solution of picric acid.

If albumin is present, a precipitate forms, varying from a light cloud to a heavy flocculence, according to the quantity of albumin.

Proteoses are dissolved.

Roberts test

Reagent:

Saturated aqueous solution magnesium sulfate (made by adding 76.9 gm. magnesium sulfate to 100 ml. distilled

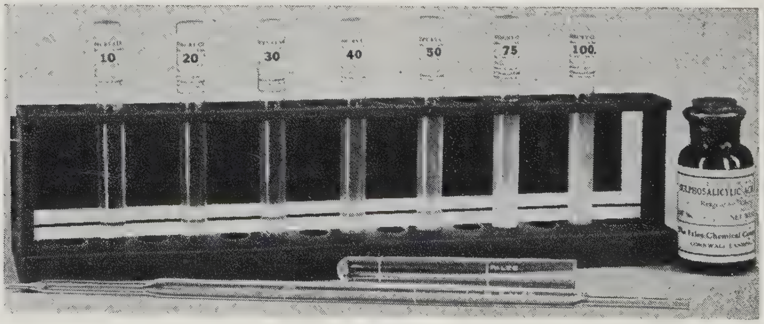

Fig. 616. Kingsbury-Clark albumin kit. (Courtesy Fales Chemical Co., Cornwall Landing, N. Y.)

water) . . . . 5 parts
Concentrated nitric
acid, c.p. . . . . 1 part

Procedure:

1. If the urine is cloudy, filter.
2. Place 1 ml. Robert reagent in a test tube.
3. Stratify 1 ml. urine on the reagent.

A white ring at the point of contact indicates albumin; the larger the ring, the greater is the quantity of albumin. Proteose also precipitates with this reagent but is soluble in picric acid. We highly recommend this test.

QUANTITATIVE TESTS FOR ALBUMIN IN URINE

Kingsbury-Clark method

The advantages of this test are as follows:

1. Uric acid and resin do not react with sulfosalicylic acid.
2. The mucinlike substances are not appreciably affected.
3. The definite amount of albumin is ascertained.

Procedure:

1. Pipet 2.5 ml. centrifuged urine into a test tube graduated at 10 ml. and add 3% sulfosalicylic acid (30 gm. dissolved and diluted to 1000 ml. with distilled water) to the 10 ml. mark.
2. Invert the tube to mix, allow to stand 10 min., and compare the turbidity with the permanent turbidity standards.
3. Record the value of the standard most closely matched, as the albumin content of the urine.

Seven standards are used, equivalent to 10, 20, 30, 40, 50, 75, and 100 mg. albumin/100 ml. urine. In case the specimen contains more than 100 mg. albumin it may be quantitatively diluted and redetermined. By multiplying the value found by the number of times the specimen has been diluted, the desired result is obtained.

A detailed description of the method will be found in the original paper by Kingsbury et al.[6]

A value of 50 mg. albumin/100 ml. urine obtained by this method corresponds to what is usually designated as a "trace" when the Heller or heat and acetic acid test is used.

Although the albumin standards are referred to as being permanent, this is not strictly true. After about 9 mo. the lighter standards tend to become more so and thus yield results which are somewhat too high. The entire set of standards should be replaced every 9 mo.

The principle of the method is that clarified urine is treated with sulfosalicylic acid, and the degree of turbidity is measured by comparison with standard turbidities.

The 7 standards, representing 10, 20, 30, 40, 50, 75, and 100 mg. albumin/100 ml. urine, are corresponding degrees of turbidity uniformly suspended in gelatin medium. Carefully matched test tubes are used to contain the standard turbidity masses to compare perfectly with the empty calibrated specimen test tube in which the test is conducted.

The urine should be filtered or centrifuged. Comparison of the test with the various standards is made with a special comparison rack, and the albumin content is recorded as the value of the standard it most closely matches in turbidity. The comparison rack is best located so that uniform north light enters through the rear, striking through the standards and viewed by the observer at an eye elevation of about 12 in. or so.

It goes without saying that the calibrated tubes in which the test is carried out should be of the same dimensions as the standards.* The standards, when not in use, should be kept in the daylight rather than in a dark cupboard to prevent taking on a dark green tinge. Exposure to undue heat will prove harmful to the standards.

Esbach method

Esbach reagent:

1. Dissolve 1 gm. picric acid, c.p., and 2 gm. citric acid, c.p., in distilled water.
2. Dilute to 100 ml. with distilled water.

Procedure:

1. Render the urine acid by adding a few drops diluted hydrochloric acid, testing with blue litmus paper after the addition of each small quantity; then filter. If the quantity of albumin is very great, dilute accurately with distilled water before making the test.
2. Fill the Esbach tube to mark U with urine.
3. Add Esbach reagent until the liquid stands at mark R. Take care to prevent the formation of bubbles. Close with a rubber stopper.
4. Mix by inverting several times and allow to stand in an upright position for 24 hr. Read from the tube the height of the coagulum, which will be the number of gm. albumin in 1000 ml. urine. To obtain the percentage, divide this by 10. If the urine has been diluted, multiply the final result by the dilution.

Purdy method

1. Place 10 ml. urine in a graduated 15 ml. centrifuge tube.
2. Add 2 ml. 50% acetic acid.
3. Add 3 ml. 10% potassium ferrocyanide.
4. Mix and allow to stand for 10 min.
5. Centrifuge at 1500 r.p.m. for 3 min.
6. Read off the volume of precipitate on the test tube.

Use Table 360 for calculations. The equivalent on Table 360 gives the number of gm. of dry albumin in 100 ml. urine. If the volume of the 24 hr. specimen is 1500 ml. and the precipitate in the centrifuge tube stood at 1.2, then the number of gm. of dry albumin in the 24 hr. specimen is as follows:

Equivalent to 1.2 in Table 360 is 0.25 gm./100 ml. In 1500 ml. urine there are 15 times 0.25 gm. or 3.75 gm.

If the amount of albumin is very large, dilute the urine accurately, and after calculation multiply the final result by the dilution.

Kwilecki modification of Esbach method

1. Place the urine in the Esbach tube to mark U.
2. Add 10 drops 10% solution of ferric chloride and mix.
3. Fill the tube to mark R with Esbach reagent and mix.

---

*These tubes, with the standards, can be obtained from the Fales Chemical Co., Cornwall Landing, N. Y.

Table 360. *Showing the relation between volume of precipitate after centrifugation and gravimetric percentage of albumin in the Purdy test*

4. Place in a water bath at 72° C. for a few minutes.

The result may be read at once.

Tsuchiya modification of Esbach method

Tsuchiya reagent:

Crystalline phosphotungstic acid	1.5 gm.
Concentrated hydrochloric acid	5 ml.
Alcohol, 95%	93.5 ml.

Use this reagent instead of the Esbach reagent in the Esbach tube and read after 24 hr.

LaMotte outfit for determination of albumin and sugar in urine

The LaMotte albumin and sugar outfit is very useful for simple, accurate, quantitative tests for albumin and sugar in urine. The Kingsbury-Clark sulfosalicylic acid method is used for the albumin determination, and the Benedict picrate method for sugar.

Urine is treated with sulfosalicylic acid solution, and the resulting turbidity is compared with prepared turbidity standards. The percentage of albumin in the urine is obtained from the value on the label of the tube with which a match is obtained.

The sugar determination involves treating the urine with picric acid in alkaline solution, and development of the color by heating in a water bath. Per cent of sugar is obtained by comparison with permanent color standards.

PROTEOSES IN URINE

Both deuteroproteose and heteroproteose are found in urine in pathologic conditions. They may be divided into 2 groups—**primary** and **secondary**. Primary proteoses are precipitated upon half saturation with ammonium sulfate and secondary proteoses upon complete saturation.

1. Acidify the urine with acetic acid and filter off any precipitate of nucleoprotein which may form.
2. Boil for several minutes.
3. Filter while hot to remove the albumin and globulin.

Test the filtrate by overlaying a saturated solution of trichloracetic acid. A white ring at the point of contact indicates the presence of proteoses. If the test is positive, the primary and secondary proteoses may be separated by half and complete saturation with ammonium sulfate.

BENCE JONES PROTEIN

Significance of Bence Jones protein: The presence of Bence Jones protein in the urine of a patient suspected of having multiple myeloma is supportive evidence of this disease but is not diagnostic. This protein is found in 35-65% of the cases of proved multiple myeloma.

The first reference in the literature to Bence Jones protein appeared in *Philosophical Transactions of the Royal Society* for 1848 in a paper presented by H. Bence Jones on "A new substance occurring in the urine of a patient with mollities ossium." His paper stated, "On the first of November, 1845, I received from Dr. Watson the following note, with a test tube containing a thick, yellow semi-solid substance. The tube contained urine of a very high specific gravity; when boiled it became highly opaque; on the addition of nitric acid it effervesces, assumes a reddish hue, becomes quite clear, but as it cools, assumes the consistence and appearance which you see: heat liquefies it. 'What is it?' "

At the present time, Bence Jones proteins should be regarded not as chemical entities but rather as a class of proteins whose physical state is altered in vitro by temperature changes. That there are multiple Bence Jones proteins is further supported by differences in (1) solubility, (2) electrophoretic mobility, (3) sedimentation velocity, and (4) serologic properties of constituent protein substances. Some investigators conjecture that a patient with multiple myeloma excretes this protein, that it is the result of tumor cell metabolites. Ellinger demonstrated these proteins in the blood, also in ascitic fluid. Yet it has been shown that in the presence of Bence Jones proteinuria, heat-coagulable serum proteins may be absent.

Martin and Mathieson[7] suggest the name pyroglobulinemia to indicate the presence of heat-coagulable globulin in the blood. This is in contrast to the cryoglobulins which are serum protein gels that appear on exposure to cold and redissolve on warming. Cold-coagulable globulins have been described in association with multiple myeloma and also in association with other conditions. The same applies to heat-coagulable globulins. The cases reported to date have, in the main, concerned victims of multiple myeloma, but Hammarsten and associates referred in their work to sera which are sensitive to heating as being found occasionally in chronic infections and in instances of hyperglobulinemia in otherwise clinically healthy persons. Martin and Mathieson reported 1 case of pyroglobulinemia associated with multiple myeloma, but in 4 cases this association did not obtain. In one of the latter cases the patient had lymphosarcoma. There is at times no correlation between the occurrence of pyroglobulinemia and Bence Jones proteinuria.

The evidence at hand favors the conclusion that Bence Jones protein is an extremely small globulin, or group of small globulins, with a molecular weight of approximately 40,000 to 50,000. Its small size may well account for its frequent occurrence in the urine as contrasted with the rarity with which it has been noted in the blood. It has been reported in the following conditions other than multiple myeloma: metastatic carcinoma of the bone, multiple sarcoma of the bone, senile osteomalacia, fibrocystic disease, comminuted fracture, tumor of the jaws, lymphocytic leukemia, myelocytic leukemia, polycythemia, adenocarcinoma of the stomach, carcinoma of the kidney, inactive pulmonary tuberculosis, and prostatitis.

The following is a scheme for processing urine suspected of containing Bence Jones protein, especially in the presence of other protein.[8]

Principle: Bence Jones protein has been described as a urinary protein which is soluble at room temperature and near the boiling point but which coagulates at temperatures beginning at 45°-60° C., reaching maximum insolubility at 55°-70° C.

Reagents:

1. Nitric acid, concentrated.
2. Hydrochloric acid, concentrated.
3. Acetic acid, 25%.
4. Sulfosalicylic acid, 50%.

Procedure:

1. Add 2 or 3 ml. of concentrated HNO_3 to a small test tube.
2. Gently overlay with a few ml. filtered urine.
3. After approximately 3 min. evaluate the precipitate according to the scheme recommended by Jacobson and Milner[8] (Table 361).

Table 361. *Degree of opacity related to protein concentration*

Degree of opacity	*Gm. %*	*Appearance*
1+	0.010-0.018	Not visible against a light background but barely visible when viewed obliquely against a dark background
2+	0.018-0.040	Visible obliquely but not from above
3+	0.040-0.40	Visible but not opaque from above
4+	Over 0.40	Opaque from above

4. If the above test is negative, Bence Jones protein is presumed to be absent. If positive, proceed with step 5.
5. Perform a ring test using concentrated HCl as in steps 1-3.
6. If negative, Bence Jones protein is absent, and the test is discontinued. If positive, proceed with step 7.
7. If the HNO_3 test is greater than 3+, the urine must be diluted with a **protein-free urine** to a concentration approximately 3+.
8. Adjust about 15 ml. urine (original or diluted) to pH 5 with indicator paper, using 25% acetic acid.
9. If a precipitate forms within a period of 5 min., filter and discard the residue (nucleoprotein).
10. Pipet 5 ml. of the urine or filtrate from step 9 into a test tube, place in a water bath, warm slowly to 70° C., and maintain this temperature for 15 min.
11. If no precipitate appears, Bence Jones protein is absent. If positive, proceed to step 12.
12. Raise the temperature to the boiling point for 10 min. If the precipitate dissolves upon shaking, Bence Jones protein may be present.
13. If the precipitate does not dissolve, add 0.5

ml. concentrated HNO_3 and maintain temperature of water bath at boiling point for 10 min. If the precipitate dissolves, Bence Jones protein may be present.

14. If the precipitate does not dissolve, repeat step 10, using another aliquot of the original or diluted urine.
15. Centrifuge and discard supernatant liquid unless the determination of the presence of proteoses or heat-coagulable proteins is desired.
16. Suspend the residue from step 15 in 5 ml. fresh, normal, protein-free urine.
17. Add 0.5 ml. concentrated HNO_3 and heat to boiling point for 10 min. as in step 13. If the precipitate dissolves, Bence Jones protein is present.
18. If the precipitate does not dissolve (pseudo Bence Jones protein), filter while **hot** into a test tube placed in the boiling water bath. Do not allow cooling to occur during this step.
19. Allow the filtrate to cool at room temperature. If the filtrate remains clear, Bence Jones protein is absent.
20. If a precipitate forms, add 0.5 ml. 50% sulfosalicylic acid. If the precipitate dissolves, Bence Jones protein is absent.

Notes: The following comments are numbered to conform to the step numbers in the procedure.

1. The nitric acid ring test is always positive when proteins are present in sufficient amounts.
5. The hydrochloric acid ring test is useful as an additional screening test.
7. It is necessary to adjust the protein concentration to 0.4 gm.% or less to maintain proper response to temperature. Normal urine must be used as the diluent since Bence Jones protein dissolves at boiling temperatures only in the presence of the proper amounts of salt and urea.
8. The proper adjustment of the pH is necessary to obtain maximal precipitation of Bence Jones protein at 70° C.
9. Nucleoprotein, which precipitates at pH 5 at room temperature, is a source of difficulty in that it obscures the presence of Bence Jones protein.
10. The temperature should be controlled to 70° C. with frequent stirring and a thermometer in the solution. Rapid temperature rise should be avoided since actual precipitation begins at about 45°-60°.
11. The appearance of a precipitate at 70° C. does not necessarily prove the presence of Bence Jones protein.
12. Albumin often obscures the re-solution of Bence Jones protein. Therefore, the fact that no apparent re-solution is noticed should not be taken to indicate the absence of Bence Jones protein.
13. It is important to add the proper amount of HNO_3 and to heat for the proper time to avoid hydrolysis and solution of non-Bence Jones protein.
18. Hot filtration is necessary to prevent precipitation and loss of Bence Jones protein. The steam from the water bath serves to heat the funnel used to separate the non-Bence Jones proteins.
19. Rapid cooling should be avoided to prevent the precipitation of urates which may be present. Bence Jones protein which begins to appear as a precipitate at about 70° C. does not redissolve upon further cooling.
20. Sulfosalicylic acid will dissolve urates and cause further precipitation of protein.

Remarks:

1. Fresh urine specimens should be used to avoid the possible conversion of other proteins to pseudo Bence Jones protein or the decomposition of Bence Jones protein which would change its properties.

2. Two other methods that do not depend upon the peculiar solubility-temperature relationship of Bence Jones protein have appeared in the literature.[8a, 8b] The first method utilizes differences in solubility in phosphate solution, whereas the other uses differential solubility in *p*-toluene sulfonic acid.

3. Bence Jones protein is considered to be a urinary rather than a serum component because of its rapid excretion, undoubtedly due to its relatively low molecular weight of about 40,000-50,000.

4. Although the presence of Bence Jones protein is considered to be characteristic for multiple myeloma, it is actually found in only about half of the cases.

5. The amount of Bence Jones protein excreted varies considerably, from trace quantities to 20-30 gm./day.

Qualitative test (presumptive)

1. Place 10 ml. urine in a test tube in a water bath with a thermometer and heat very slowly and gently.
2. Observe frequently. Turbidity will begin to occur at about 40° C., and precipitation will take place at about 60° C.
3. Now acidulate very slightly with acetic acid and raise the temperature to the boiling point (100° C.). The precipitate now partly or totally disappears. Filter while still boiling hot.

The precipitate returns as the tube cools. Precipitation at so low a temperature and dissolving at a higher temperature is typical of Bence Jones protein. It is this characteristic that differentiates it qualitatively from all other protein material occurring in urine.

Test the filtrate by overlaying a saturated solution of trichloracetic acid. A white ring at the point of contact indicates the presence of proteoses. If the test is positive, the primary and secondary proteoses may be separated by half and complete saturation with ammonium sulfate.

1. Precipitate the protein with nitric acid. This precipitate should disappear on boiling and reappear upon cooling.

2. Precipitate the protein with alcohol and col-

lect immediately by centrifuging. The precipitate should be soluble in water.

SPECIAL TESTS

Special urinary tests are described in the following discussion: indican, acetone bodies, bile, bile acids, urobilin and urobilinogen, uroresin, urinary phenols, hemoglobin, hematoporphyrin, coproporphyrins and uroporphyrins, screening test for porphobilinogen in the presence of urobilinogen and indole derivatives, drugs and occult blood.

INDICAN IN URINE

Indican is derived from indole, a product of intestinal putrefaction of albuminous substance. The indole is absorbed by the blood and is oxidized in the tissues to indoxyl, which combines with potassium sulfate and is eliminated in the urine. It is present in minute amounts in every normal urine.

Indican is increased following diets rich in protein and in cases of obstruction of the small intestine, also in intestinal indigestion and in diseases of the stomach associated with decreased hydrochloric acid, gastritis, and gastric cancer. It is also increased in diminished bile flow and in cases in which there is decomposition of proteins in other parts of the body, as occurs in peritonitis and empyema, and other pus collections.

QUALITATIVE TESTS FOR INDICAN IN URINE

Obermayer method

Obermayer reagent:

Fuming hydrochloric acid, c.p.	1000 ml.
Ferric chloride, c.p. . . .	3 gm.

Method 1:

1. Precipitate 20 ml. urine with 5-10 ml. 10% lead acetate solution and filter.
2. Add an equal volume of Obermayer reagent to the filtrate. Shake thoroughly.
3. Add 5 ml. chloroform. Shake thoroughly.

A **blue** coloration of the chloroform indicates indican. A **pink** color is due to the ingestion of iodides.

Method 2:

1. To 5 ml. urine in a test tube add 5 ml. Obermayer reagent.
2. Mix and add 15 drops chloroform. Shake and allow the chloroform to settle.

A **blue** colorization of the chloroform indicates the presence of indican. A **pink** color is caused by ingestion of iodides.

Jaffe method

1. To a small amount of urine in a test tube add an equal volume of hydrochloric acid, c.p.
2. Mix and add 10-15 drops chloroform.
3. Add drop by drop a strong fresh solution of calcium hypochlorite, shaking after the addition of each drop. A blue color appears if indican is present.

A 0.5% solution of potassium permanganate may be used in place of the calcium hypochlorite if preferred. Five drops of the potassium permanganate are used with 10 ml. urine.

Jolle method

1. To 10 ml. urine add 2 ml. 20% lead acetate solution, shake, and filter. To the filtrate add 0.5 ml. 10% alcoholic solution of thymol, 10 ml. Obermayer reagent, and 4 ml. chloroform.
2. Mix thoroughly.

The chloroform takes on a pronounced violet color if indican is present.

QUANTITATIVE ESTIMATION OF INDOXYL COMPOUNDS IN URINE

Sharlit method[9]—modified by Meiklejohn-Cohen[10]

Indican, which is indoxyl potassium sulfate, is the most familiar indole derivative in urine. Part of the indole excreted in urine may occur in a form which is responsible for the urorosein reaction (as yet no satisfactory quantitative method has been developed for the latter).

Reagents:

1. Potassium persulfate solution, 1%.
   (a) Dissolve 1 gm. potassium persulfate in enough distilled water to make 100 ml. solution.
2. Thymol 1% in 95% alcohol.
   (a) Dissolve 1 gm. of thymol in enough 95% alcohol to make 100 ml. solution.
3. Trichloracetic acid, 25%, in hydrochloric acid.
   (a) Dissolve 25 gm. trichloracetic acid in enough hydrochloric acid to make 100 ml. solution.
4. Thymol-free alcohol.

Preparation of urine for test:

1. Place 10 ml. unfiltered urine, preserved under toluene, in a 100 ml. volumetric flask. (It is not necessary to use fresh urine. Addition of a few ml. toluene to the urine when first voided is sufficient to maintain the values obtained by this method for at least 24 hr.)
2. Dilute to 100 ml. with distilled water.
3. Measure 5 ml. diluted urine (containing 0.5 ml. undiluted urine) into a 15 ml. graduated centrifuge tube.
4. Add 0.5 ml. 1% potassium persulfate solution, 0.5 ml. 1% alcoholic thymol, and 5 ml. 25% trichloracetic acid in concentrated hydrochloric acid.

Preparation of blank for test: Prepare a blank determination, using urine and reagents in the same quantities as in the test, but substituting **thymol-free alcohol** for the thymol-alcohol reagent.

High blank readings are sometimes obtained with the use of thymol-free alcohol. This is due to nonspecific substances which on oxidation by persulfate form colored products soluble in ethyl trichloracetate. Such substances might include urorosein and perhaps bile products. Preliminary treatment with basic lead acetate, as advocated by some workers, may sometimes result in a significant reduction in the colorimeter reading, due to the removal of such interfering pigments.

Procedure:

1. Mix the solutions well in their various test tubes.
2. Place the tubes in a boiling water bath until the ethyl trichloracetate has filtered out and the aqueous layer is essentially free from pigment. This requires about 20 min.
3. Centrifuge briefly.
4. Remove as much as possible of the supernatant aqueous layer, using a pipet.
5. Take up the trichloracetate layer together with the small volume of aqueous layer remaining in the centrifuge tubes in sufficient glacial acetic acid to bring the volume to the 5 ml. mark.
6. Transfer to special tubes for use in a Klett-Summerson photoelectric colorimeter. Thoroughly mix by pouring back and forth between the centrifuge tube and the colorimeter tube.
7. Read immediately in the photoelectric colorimeter, using a No. 540 filter.

Calculation: Subtract the logarithmic scale reading given by the blank determination from the reading of the unknown. Calculate the μg indican/ml. urine as follows:

$$\text{Colorimeter reading} \times \frac{0.38}{1000} \times \text{vol. urine} = 24$$

hr. excretion of indican (μg)

If the reading on the colorimeter is less than 0.200 or more than 0.400 optical density units, greater accuracy may be achieved by repeating the test, using appropriately greater or smaller amounts of urine.

Meiklejohn and Cohen[10] found that the factor necessary to convert colorimeter readings into terms of the amount of indican present varies somewhat over the range employed, or, in other words, when colorimeter readings are plotted against concentrations of indican, the resulting calibration curve is not absolutely linear, as required to fulfill Beer's law exactly. The differences between the factors for each concentration of indican are so small that for practical purposes one factor may be used throughout. The factor 0.38 is employed to convert colorimeter readings into terms of μg indican/ml. solution. This factor was obtained from the following equation:

$$\text{Factor} = \frac{\text{Indican in } \mu\text{g}}{\text{Colorimeter reading} \times \text{vol. indican sol.}}$$

$$\text{or } \frac{50}{262 \times 0.5} = 0.38.$$

5-Hydroxyindoleacetic acid[11]

Principle: The normal urinary metabolite of serotonin, 5-hydroxyindoleacetic acid, is diazotized and coupled, producing a purple product. In normal quantities the color is too faint to be seen.

Reagents:

1. 1-nitroso-2-naphthol, 0.1% in 95% ethanol.
   (a) Dissolve 0.1 gm. in 100 ml. 95% ethyl alcohol.
2. Nitrous acid.
   (a) Prepare 2.5% sodium nitrite ($NaNO_2$) by dissolving 2.5 gm. salt in 100 ml. water.
   (b) Just before use add 0.2 ml. sodium nitrite to 5 ml. 2N sulfuric acid.
3. Ethylene dichloride or ethyl acetate.

Procedure:

1. Into a test tube pipet 0.2 ml. urine. Always run a normal urine for comparison and to check the reagents.
2. Add 0.5 ml. nitrosonaphthol reagent and mix.
3. Add 0.5 ml. freshly prepared nitrous acid and mix.
4. Let stand at room temperature for 10 min.
5. Add 5 ml. ethylene dichloride or ethyl acetate and shake vigorously. If turbid, centrifuge.

Results: A purple color in the top layer is positive. A 24 hr. specimen containing 40 mg. shows a detectable color. One having 300 mg. is almost black.

ACETONE BODIES IN URINE

Diacetic acid, acetone, and β-oxybutyric acid are called the acetone bodies. Diacetic acid is formed first, and the others are derived from it. The chief source of these acetone bodies lies in abnormal catabolism of fats. For further particulars about these bodies, refer to Chapter 8.

DIACETIC ACID IN URINE

Gerhardt method

The urine must be fresh.

To a few ml. urine in a test tube add 10% ferric chloride solution drop by drop until no further precipitation occurs.

If diacetic acid is present, the urine will turn a Bordeaux-red color. If the diacetic acid is due to drugs, it does not disappear upon heating. True diacetic acid disappears upon heating and does not reappear upon cooling. If the reaction is dubious, acidulate some of the urine with sulfuric acid and shake up with ether. Remove the ether with a pipet and shake up with very dilute ferric chloride solution. If diacetic acid is present, a violet color results, which changes to a Bordeaux red upon further addition of ferric chloride.

Arnold method—modified by Lipliawski

Reagents:

1. Solution I.

Para-aminoacetophenone	1 gm.
Distilled water	100 ml.
Hydrochloric acid, concentrated	2 ml.

2. Solution II.

Potassium nitrite (KNO_2)	1 gm.
Distilled water	100 ml.

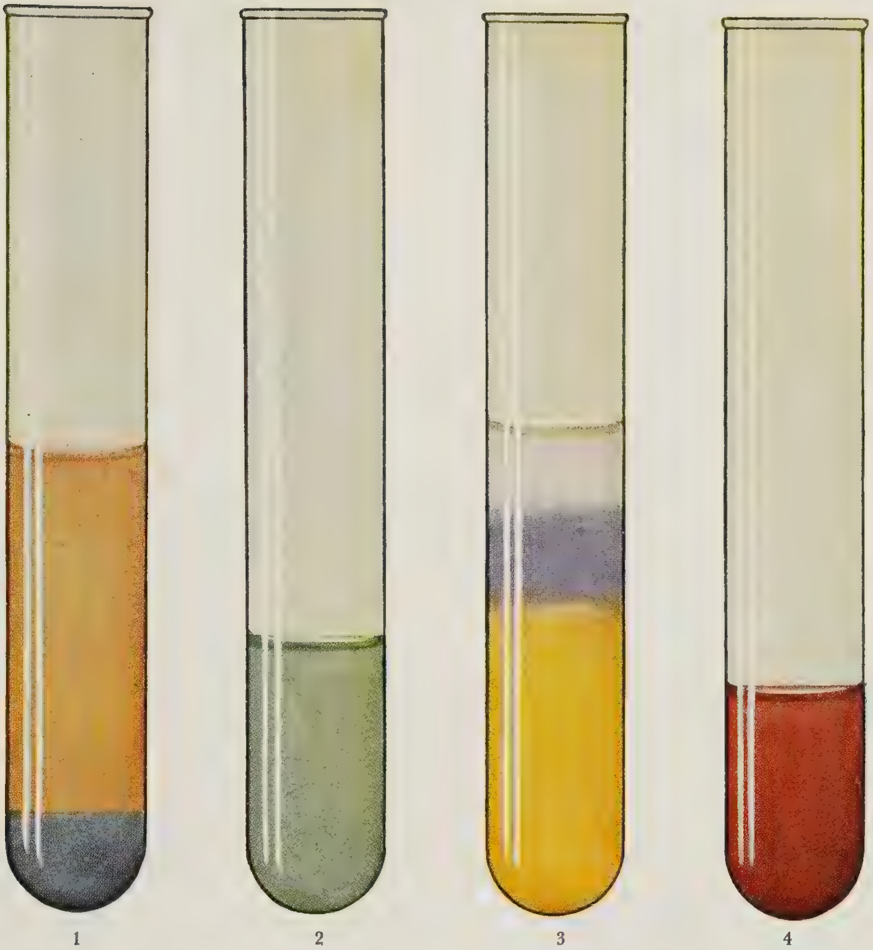

Fig. 617. Urine color reactions. **1,** Indican reaction. **2,** Benzidine test for blood. **3,** Acetone reaction. **4,** Diacetic acid reaction. (From Gradwohl, R. B. H., and Blaivas, A. J.: The newer methods of blood and urine chemistry, St. Louis, The C. V. Mosby Co.)

Procedure:

1. Place 6 ml. solution I in a test tube.
2. Add 3 ml. solution II.
3. Add an equal volume urine and 1 drop concentrated ammonia. Shake the mixture until it assumes a brick-red color.
4. Treat from 10 drops-2 ml. of this mixture (according to probable amount of diacetic acid present) with 15-20 ml. concentrated hydrochloric acid, 3 ml. chloroform, and 2-4 drops of a 10% aqueous solution of ferric chloride. Close the tube with a cork and shake gently for ½-1 min.

If diacetic acid is present, the chloroform becomes tinged with violet. If no diacetic acid is present, the color is yellow or light red.

ACETONE IN URINE

Legal method

1. Dissolve a few crystals of sodium nitroprusside in 2 ml. distilled water in a test tube.
2. To a few ml. urine add enough sodium or potassium hydroxide solution to render it distinctly alkaline.
3. Add a few drops of sodium nitroprusside solution.
4. Add a few drops of concentrated acetic acid.

A purple or violet-red color indicates acetone. Alcohol or acetic aldehyde and diacetic acid also appear red.

Jackson-Taylor modification of Legal test

1. To a few ml. urine add a few drops of a freshly prepared solution of sodium nitroprusside (a few crystals in 2 ml. water).
2. Mix thoroughly and add 1 gm. ammonium sulfate powder.
3. Mix and stratify on this 2 ml. ammonium hydroxide.
4. Allow to stand several minutes.

A purplish red or permanganate-colored ring at the point of contact indicates the presence of acetone.

Lieben iodoform test

1. Add a small amount of phosphoric or hydrochloric acid to 200 or 300 ml. urine, in the proportion of 3 ml. to 100 ml. urine.
2. Distill this mixture.

The tests are performed with the first 10 or 15 ml. distillate. To the distillate add a few drops of strong potassium hydroxide solution and a few drops of iodine and potassium-iodide solution. If acetone is present, a yellow precipitate of iodoform develops at once. This can be easily identified by the characteristic odor. Microscopically, there will be seen thin, yellow hexagonal plates or starlike groups of crystals.

Gunning modification of Lieben test

To prevent confusion with alcohol, Gunning suggests the addition of an excess of alcoholic iodine solution and some ammonia to the distillate or to the urine itself. Iodoform is deposited if acetone is present. The liquid often turns black at first, but as the nitrogen iodide settles and disappears, the yellow iodoform deposit can be recognized.

Do not warm the mixture during the period that it contains nitrogen iodide.

Frommer test

1. To 10 ml. urine in a test tube add 1 gm. potassium hydroxide. Do not wait for a complete solution.
2. Treat the mixture with 10-20 drops of a 10% alcoholic solution of salicylaldehyde.
3. Warm to 70° C.

An intense purplish red ring appears at the point of contact if acetone is present.

BETA-OXYBUTYRIC ACID IN URINE

Hart method

1. To 20 ml. urine add 20 ml. distilled water and a few drops of acetic acid. Boil, reducing the volume to 10 ml. This removes the acetone and diacetic acid.
2. Dilute to 20 ml. with distilled water.
3. Mix and divide the contents equally into 2 portions.
4. To one of the quantities add 1 ml. hydrogen peroxide. Warm gently and allow to cool.

Apply the Legal test for acetone to both tubes (p. 1825). Allow them to stand for a few hours.

If β-oxybutyric acid is present, the tube containing the hydrogen peroxide will show a red ring at the point of contact, whereas no reaction will be detected in the other tube.

BILE IN URINE

These tests depend upon the oxidation of bile pigments by acids with the formation of a series of colored derivatives like biliverdin (green), bilicyanine (blue), and choletelin (yellow). The most important pigment of this group is bilirubin.

Gmelin test

1. Place a small quantity of concentrated nitric acid containing a small amount of yellow nitrous acid in a test tube.
2. Stratify a small amount of urine on the acid.

A band of colored rings at the point of contact of the 2 fluids indicates the presence of bile. These rings are green, blue, violet, red, and yellow. Green is the most pronounced.

Rosenbach test

1. Filter the urine through pure white filter paper.
2. Apply a drop of nitric acid containing yellow nitrous acid to the inside of the filter. A band of colored rings will appear around the nitric acid if bile is present.

Ultzmann test

1. To 10 ml. urine add 3 or 4 ml. 25% potassium hydroxide solution and an excess of pure hydrochloric acid.

If bile is present, the mixture becomes a definite green color.

Maher test[12]

This qualitative test for bile in the urine was developed during the course of determinations of sulfonamide drugs in urine by the Maher-Camp modification of the Marshall method.[13]

1. Place 10 ml. urine in a test tube and acidify by the addition of 1 ml. 20% solution of *p*-toluenesulfonic acid. Ten per cent hydrochloric acid may also be used.
2. Two min. later add 1 ml. 0.1% freshly prepared solution of sodium nitrite.
3. Mix the contents of the tube well.

Development of a green color indicates the presence of bile, presumably by the oxidation of bilirubin to a green derivative. No other substances produce a similar reaction.

BILE ACIDS IN URINE

Hay test

In the Hay test advantage is taken of the fact that bile acids have the property of reducing the surface tension of fluids in which they are contained.

1. Cool the urine by placing it in a refrigerator for several hours.
2. Sprinkle upon the surface a little finely powdered sulfur (flowers of sulfur).

If the sulfur sinks at once, bile acids are present in the amount of 0.01% or more. If the sulfur sinks only after gentle agitation, bile acids are present in 0.0025% or more. If the sulfur remains floating, even after gentle shaking, bile acids are absent.

Oliver test

The Oliver test depends upon the principle that a precipitate is formed of a protein (peptone) and bile acids.

Reagent:

Peptone	8.33 gm.
Salicylic acid	1.12 gm.
Water containing 2 drops acetic acid	1000 ml.

Procedure:

1. Filter a small amount of urine (5 or 10 ml.) until perfectly clear.
2. If the urine is neutral or alkaline, acidify with acetic acid.

3. Dilute with water until the specific gravity is less than 1.008.
4. Place 2 ml. in a test tube.
5. Add 5 ml. reagent.

A positive reaction is indicated by a milky turbidity.

UROBILIN AND UROBILINOGEN IN URINE

It is claimed that urobilin is excreted as the chromogen urobilinogen, which is changed by light into urobilin within a few hours after the urine is voided.

Urobilinogen is increased whenever there is an excess of bilirubin formed through excessive destruction of erythrocytes, especially in pernicious anemia and malaria. When the liver cells fail to function properly, there is an increase, and for this reason the test has become of practical value as a **liver function test.**

A marked decrease or even total absence may occur in obstructive jaundice when the obstruction is complete or nearly complete. If the obstruction is only partial, urobilinogen excretion may be normal or even increased.

UROBILIN IN URINE

Schlessinger test

1. To 10 ml. urine in a test tube add a few drops of Lugol solution to transform the chromogen into the pigment.
2. Add 10 ml. saturated alcoholic solution of zinc acetate. Mix and filter.
3. View the filtrate in sunlight against a dark background or with light concentrated upon it with a lens; a greenish fluorescence indicates the presence of urobilin.

Bile pigment, if present, should be previously removed by adding ⅕ vol. of 10% solution of calcium chloride and filtering.

Ehrlich test

Reagent:

Paradimethylaminobenzaldehyde	10 gm.
Hydrochloric acid, concentrated	75 ml.
Water	75 ml.

Procedure:

1. Qualitative test.
   (a) Place 10 ml. urine in a test tube 15 mm. in diameter. The urine should not be too cold. If very cold, allow it to stand at room temperature or gently heat to between 65° and 80° F.
   (b) Add 1 ml. Ehrlich reagent and mix.
   (c) Allow to stand for 3-5 min.

At the end of 3-5 min. a cherry red color appears if urobilin is present in abnormal amount. A light red and shades of pink appear when it is present in normal quantity. The examination for color should be made by viewing the contents through the mouth of the tube, holding it at a slight angle over white paper.

If no color appears, the tube should be allowed to stand longer, and then if no color appears, it should be heated and again examined before reporting an absence of urobilinogen.

This test is to some extent quantitative. With a little experience one can judge by the color whether there is an increase above normal.

2. A **quantitative test** may be conducted as follows.
   (a) Place 6 test tubes (15 mm. in diameter) in a rack. In them place the following amounts of urine: No. 1: 10 ml. 1:20, No. 2: 10 ml. 1:30, No. 3: 10 ml. 1:40, No. 4: 10 ml. 1:50, No. 5: 10 ml. 1:100, and No. 6: 10 ml. 1:200. The water used for diluting should not be too cold. If tap water is used, it may be necessary to add enough warm water to bring it to about room temperature (between 65° and 85° F.).
   (b) To each tube add 1 ml. Ehrlich reagent and mix.

At the end of 5 min. examine the tubes by viewing through the mouth against a white background. Note the highest dilution which shows the slightest pink color. This is reported as positive 1:50, 1:200, etc.

When possible the readings should be made by daylight, as artificial light has a tendency to intensify the color. Highly concentrated urines may give a yellowish brown discoloration which must be differentiated from the true pink reaction of urobilinogen.

Bile pigment, if present, should be previously removed by adding 1 part of 10% solution of calcium chloride to 4 parts of urine and filtering.

UROBILINOGEN IN URINE

Wallace-Diamond method

Ehrlich aldehyde reagent:

1. Mix 20 ml. concentrated hydrochloric acid with 80 ml. distilled water.
2. Add 2 gm. *p*-dimethylaminobenzaldehyde.
3. Stir until dissolved.

Procedure:

1. Add 1 ml. Ehrlich aldehyde reagent to 10 ml. urine.
2. Warm the test tube.

A rose color appears if urobilinogen is present. The amount may be determined by diluting the specimen and observing the dilution at which the reaction is still present.

Watson quantitative test for urobilinogen in feces and urine[14]

Reagents:

1. Ferrous sulfate solution, 20%.
   (a) Dissolve 20 gm. ferrous sulfate previously ground to a powder in a mortar in 92 ml. distilled water.
2. Sodium hydroxide solution, 10%.
3. Modified Ehrlich reagent.
   (a) Dissolve 0.7 gm. of *p*-diamethylaminobenzaldehyde in 150 ml. concentrated hydrochloric acid and add to 100 ml. distilled water.
4. Saturated aqueous solution sodium acetate.
5. Petroleum benzine (petroleum ether).
6. Glacial acetic acid.

Feces:

1. Collect feces for a 4 day period, mix well, and grind a 10 gm. portion in a mortar with a few ml. distilled water.
2. Dilute to 300 ml. with distilled water or to only 100 ml. if the feces are definitely acholic.
3. Pour into an Erlenmeyer flask containing 100 ml. 20% ferrous sulfate solution.
4. Add with constant mixing, 100 ml. 10% sodium hydroxide solution.
5. Cork and allow to stand 1 hr. If the flask stands overnight, slightly lower values are obtained.*
6. Filter.
7. To 2 or 3 ml. filtrate add an equal amount of modified Ehrlich reagent.
8. Mix and add several ml. saturated aqueous solution of sodium acetate.
9. Depending upon the amount of color, use from 1-50 ml. filtrate in the quantitative procedure. If the color is intense, use 1 ml. or less; if pale red, use 5-10 ml.; if faint, use 25 ml.; if absent, 50 ml. The amount of filtrate chosen should be only enough that the final colored solution does not exceed 100 ml. and that its color is not more than 50% on the standard scale.
10. Place the amount of filtrate decided upon in a 125 ml. pear-shaped separatory funnel. Dilute filtrate to 20 ml. with water if less than this amount of filtrate has been chosen.
11. Cover with 25 ml. purified petroleum benzine (petroleum ether).
12. Strongly acidify with glacial acetic acid.
13. Shake vigorously for several seconds.
14. Separate the aqueous solution of petroleum benzine and wash twice with distilled water.
15. Shake vigorously with 1 or 2 ml. modified Ehrlich reagent.
16. Add at least twice as much of a saturated solution of sodium acetate. The maximum color now appears.
17. Shake vigorously and then separate the colored solution into a 100 ml. graduated cylinder.
18. Again extract the petroleum benzine with Ehrlich reagent. Repeat until the urobilinogen has been entirely removed as evidenced by no further development of color.
19. Follow each extraction by the addition of sodium acetate, shaking, and separation of the aqueous fraction into the cylinder.
20. Make the colored solution up to a volume convenient for calculation and mix.
21. Fill the right-hand tube of the Hellige-Dunning colorimeter† and compare with the standards. Should the intensity of color be greater than 50% of the standard, dilute the specimen further and read again. Comparisons are most accurate between 20 and 50%. The intensity of the color may also be compared with that of standards in a photoelectric colorimeter in the usual manner.

Calculation:

$$\frac{\text{ml. ferrous hydroxide mixture}}{\text{gm. feces}} \times \frac{\text{ml. final colored solution}}{\text{ml. filtrate used}} \times \%\ \text{color standard} \times \frac{\text{weight of 4-day amount feces}}{100} \times \frac{1}{\text{No. days collection of feces}} = \text{mg. urobilinogen/day.}$$

Example:

$$\frac{500}{10} \times \frac{45}{3} \times 0.35 \times 2.8 \times \frac{1}{4} = 183.75 \text{ mg./day.}$$

Standardization of the colorimeter in terms of crystalline mesobilirubinogen (urobilinogen) has been described.[14]

Urine:

1. Reagents are the same as for feces.
2. Collect a 24 hr. sample urine in a dark bottle containing approximately 5 gm. sodium carbonate and 100 ml. purified petroleum benzine.
3. Separate urine from petroleum benzine and measure.
4. Place 50 ml. mixed urine in a 500 ml. Erlenmeyer flask.
5. Add with thorough mixing 25 ml. 20% ferrous sulfate solution and 25 ml. 10% sodium hydroxide.
6. Let stand 1 hr., then make a qualitative determination, and then use this information in selecting the amount of urine to be used in the quantitative procedure.

Proceed as with the filtrate from feces. Compare in the Hellige-Dunning* colorimeter.

Calculation:

$$\frac{100}{50} \times \frac{\text{ml. final colored solution}}{\text{c.c. of filtrate used}} \times \%\ \text{standard} \times \frac{\text{vol. 24 hr. urine}}{100} = \text{mg. urobilinogen in 24 hr.}$$

Example (hepatic dysfunction):

$$2 \times \frac{20}{2} \times 0.18 \times 14 = 50.4 \text{ mg. in 24 hr.}$$

Watson's figures show that the amount of urobilinogen excreted in the urine in 24 hr. by the normal adult varies between 0 and 4 mg., usually 0.5-2 mg. He noted a great drop in the amount of urinary urobilinogen coincident with the reticulocyte response to liver therapy in cases of pernicious anemia, together with considerable decrease in the amount of urobilinogen in the feces. The normal range for the feces is between 40 and 280 mg./day, usually 100-250 mg. His conclusions based upon his exhaustive work regarding urobilinogen in feces were that inanition, inactivity, or a low-grade infection tends to lower the excretion of urobilinogen; fever of any considerable degree probably tends to increase the amount. He noted increases in the excretion of urobilinogen in feces in cases of pernicious anemia, Hodgkin's disease, and leukemia. Low values were encountered in certain cases of secondary hyperchromic anemia and in all the cases of hypochromic anemia investigated. Slight increases were observed in half the cases of polycythemia vera.

---

*Slightly lower values are obtained if the mixture is allowed to stand overnight. For this reason the values given subsequently are undoubtedly slightly too low since the mixture was allowed to stand overnight in most of these instances.

†Hynson, Westcott, & Dunning, Inc., Baltimore, Md.

*A permanent glass standard colorimeter for determination of phenolsulfonephthalein in urine made by Hynson, Westcott, & Dunning, Inc., Baltimore.

In another paper in reference to the excretion of urobilinogen in the common forms of jaundice and diseases of the liver in 135 patients examined, Watson found that jaundice due to stone is not accompanied by a considerable increase in the amount of urobilinogen in the urine unless complications are present, such as acute cholecystitis or choleangitis, biliary cirrhosis incident to persistent biliary obstruction, or severe anemia. These complications are accompanied, according to Watson, by a relatively marked increase, the actual amount of urobilinogen appearing in the urine being dependent to some extent on the degree of biliary obstruction and the consequent amount of urobilinogen formed in the bowel and reabsorbed from it.

Diffuse hepatic disease is characterized by a marked increase in urobilinogen in the urine; some of the instances of idiopathic diseases of the liver in the group of patients with cirrhosis were accompanied by evidence of an increased destruction of blood, i.e., an increase in the urobilinogen content of the feces and regenerative anemia, often macrocytic.

Increases in the amount of urinary urobilinogen in hemolytic jaundice could not be correlated with increased destruction of blood, but it occurred when other factors, which are believed to disturb the function of the liver, also were present. Urobilinogen content of the feces was usually increased to a marked degree, in the majority of cases decreasing rapidly after splenectomy.

BILIRUBIN IN URINE

Methylene blue test

In February, 1933, Fellinger and Menkes published their article on "quantitative bilirubin determination in the urine, with methylene blue method."[15] Franke had previously suggested the use of methylene blue for the quantitative determination of bilirubin in the urine by determining the number of drops of methylene blue required to change a positive green color to a definite dark blue color. Twenty drops of a 2% solution of methylene blue represented roughly 1 mg. bilirubin present in the urine. In low concentrations the change from green to blue is definite. With greater concentrations of bilirubin in the urine, the change is not so clear-cut, and the accuracy of the results is impaired by the increased volume of methylene blue in the test.

A standard containing a known amount of bilirubin was later developed. A definite bluish green hue is obtained by mixing a solution of 1 ml. 0.2% methylene blue and 5 ml. alkaline fluid containing 1 mg. bilirubin. This bluish green hue is then matched by preparing a solution of alcoholic methylene blue in a weak potassium dichromate solution which is kept in an airtight container in a dark room. The test is then carried out by adding drop by drop a 0.2% methylene blue solution to 5 ml. of urine until it matches the prepared standard.

Myers[16] in 1945 stated that it is not definitely known whether the methylene blue's changing to green in the presence of bilirubin is the result of a chemical reaction or due to a mixture of pigments. The latter seems to be more probable. The presence of the urobilin pigment normally found in urine will not give a positive test even when the urine is very dark and concentrated. The only known false positive results encountered in these tests have been found in urine containing blood and in several cases in which there was an elevated temperature above 101° F. The possibility that the hemosiderin pigment of the blood may play a vital part in this test is likely. Two drops of blood hemolyzed in 10 ml. water will give a slightly positive test when methylene blue is added, and if the number of drops of blood is increased, the green color is intensified. Istizin is the only drug that will give a false positive reaction.

A test for occult blood must be made on the urine before making the methylene blue test because if occult blood is present a false positive methylene blue test results.

To keep all factors as constant as possible, the size of the tubes, the volume of the test, and the number of drops of methylene blue for each test must never vary. Use tubes 16 × 150 mm.

Procedure: Titrate 5 ml. urine with 0.25% aqueous solution of methylene blue.

Normal urines require less than 4 drops (0.2 ml.) to give a blue color.

Interpretation: In a study by Helfferich the following conclusions were made. In hepatitis the methylene blue test reached a maximum a few days before serum bilirubin; in icterus due to obstruction this test was more sensitive than following serum bilirubins although the results of both ran parallel; in cirrhosis the methylene blue remained elevated even after serum bilirubin had returned to normal; paper chromatography of a mixture of methylene blue and bilirubin showed that the 2 substances did not form a stable complex.

Modification of Harrison test for bilirubin in urine

Bilirubin may appear in the urine in experimentally induced hepatitis before there is any elevation in the total serum bilirubin. Accordingly, there is need for a rapid test of the urine to detect the presence of bilirubin. Harrison[17] suggested a method which has been named for him. In this test barium chloride solution and urine are mixed in equal amounts, precipitate is caught on filter and then is treated with Fouchet reagent which gives a green color if bilirubin is present. Hawkinson et al.[18] described a modification better adapted for usage in large numbers of tests. They stated it is equivalent to the original method of Harrison.

Reagents:

1. Fouchet reagent.
    (a) Dissolve 0.9 gm. ferric chloride in enough 25% trichloracetic acid to make 100 ml. solution.
2. Barium-impregnated strips* or cotton swabs.
    (a) Allow pieces of extra thick and retentive filter paper (Schleich and Schull No. 470) to remain briefly in a saturated aqueous solution of barium chloride. Allow them to dry in the air or preferably in a drying oven, and then cut them into strips 4 in. long × ½ in. wide. Use a single strip for one test, as described below. If a suitable type of thick filter paper is not available, cotton swabs may be used, although the resulting test is not quite as sensitive and clear-cut as with the filter strips.
    (b) Prepare the swabs on ordinary applicator sticks, the cotton having dimensions of about 1½ × ½ in.
    (c) Dip these into the saturated aqueous solution of barium chloride; after drying, they are ready for use.

Procedure:

1. Place one end of a barium chloride-impregnated thick filter strip in the urine sample to be tested, the strip being in an approximately vertical position, at least ½ extending above the surface of the sample.
2. Allow the strip to stand in the urine for 30 sec. up to 2 min., then withdraw it, and place it on a piece of dry paper such as a paper towel or any other absorbent paper. Inspection of the filter strip will usually reveal somewhat more color in that area which corresponded to the surface of the urine.
3. Place 2 or 3 drops of Fouchet reagent directly on this area.

A positive test is denoted by the appearance of a green color, varying in intensity with the amount of bilirubin present. With smaller amounts the color is often detected as a faint green line running across the strip.

When the cotton swab is used, the method is varied slightly.

1. Immerse the swab in the urine to be tested.
2. Express the excess urine from the swab by rolling it against the side of the container.
3. Place 2 or 3 drops of Fouchet reagent in the middle of the swab.

A positive test is denoted as just described. The weaker reactions are less easy to interpret, in that the reaction is over a large area and hence more diffuse and not as clear-cut as the line reaction observed with the filter strip method. Nevertheless the swab method has considerable usefulness when the proper type of filter paper is not available.

In a number of instances a series of dilutions of bilirubin-containing urines has been made to a point where the ordinary Harrison test was either questionable or absent. In each instance the results obtained with the present method were entirely comparable. Thus it is believed that the present filter strip method is at least equivalent to the original Harrison procedure.

It may be noted that barium has a peculiar virtue, possibly of catalytic nature, in this reaction. The test is not as sensitive when calcium chloride is used although calcium salts appear to adsorb bilirubin from the urine just as efficiently as barium.

In connection with this test, Stokes and Osterberg[19] reported a study with three objectives: (1) to determine whether any correlation existed between the degree of hyperbilirubinemia and the positivity of the methylene blue test; (2) to attempt to find, if possible, at what concentration of bilirubin in the urine the result of the test became positive, and (3) to demonstrate the nature of the test, i.e., whether the color which is produced represents a chemical reaction or merely a blend of colors.

Twenty-eight patients who had diseases involving the liver and the common bile duct were studied. In all patients there was hyperbilirubinemia, and in 22 patients jaundice was present. There was not perfect correlation between the degree of hyperbilirubinemia and the positivity of the test.

Spectrotransmittance curves of urines giving positive tests and other solutions used in these experiments were determined by means of a Coleman Junior spectrophotometer, Model 6. Urines giving a positive test had a spectrotransmittance characteristic of bilirubin with maximal absorption between 425 and 450 $m\mu$. Stokes and Osterberg found two absorption bands, one at 425 to 450 and one at 660 $m\mu$, showing that the resulting green color is merely a blend of the original yellow and blue. That there is no new substance formed is evidenced by the lack of any new absorption band.

---

*Aloe Scientific, St. Louis, Mo.

Their conclusions were as follows.

1. They did not observe perfect correlation between the concentration of bilirubin in the blood serum and the degree of positivity of the methylene blue test.

2. The methylene blue test performed on urine with artificially produced bilirubinuria first became positive at a concentration of 2 mg. bilirubin/100 ml. urine.

3. Under the conditions of their experiments it would appear that the color which results when methylene blue is added to urine which contains bilirubin is due to a blend of blue and yellow colors rather than to some specific chemical reaction between methylene blue and bilirubin.

UROROSEIN IN URINE

Urorosein does not occur in normal urine but may occur in various diseases, such as pulmonary tuberculosis, typhoid fever, nephritis, and stomach disorders. It is excreted as a chromogen (indoleacetic acid) which is transformed into the pigment upon treatment with a mineral acid.

Test

1. To 10 ml. urine in a test tube add 5 ml. concentrated hydrochloric acid and a few drops of 1% solution of potassium nitrite.
2. Mix thoroughly.

A rose-red color indicates urorosein.

URINARY PHENOLS

The determination of urinary phenols deserves study because Becher[20] reported the occurrence of an increased amount of these substances in patients suffering with pernicious anemia. Volterra[21] corroborated this finding. Because of the difficulties incident to chemical analyses covering these ingredients, attention has been directed to a determination of the urinary phenols. In the determination of isocyclic amino acids it is also necessary to determine their intermediary products, aromatic hydroxy acids. To this end Volterra[22] gives a simple technic for the determination of 3 fractions of aromatic substances in the urine.

Volterra technic

1. Use the Folin and Ciocalteu phenol reagent (p. 46 for formula for this reagent).
2. Dilute this reagent with equal volume of distilled water.
3. To 10 ml. fluid in a test tube add 0.5 ml. dilute phenol reagent and 2 ml. 20% sodium carbonate. Shake. After 20-30 sec. immerse the tube in boiling water for exactly 1 min. and then cool under running water.

This technic is divided into 3 separate determinations: (1) determination of volatile phenols, (2) determination of aromatic hydroxy acids, and (3) determination of residual phenols.

Determination of volatile phenols

1. Use 10 ml. precisely measured urine from 24 hr. specimen.
2. Pour into a 250 ml. distillation flask.
3. Add 150-170 ml. distilled water and some sodium carbonate until solution is alkaline to litmus paper; then distill. Free volatile phenols are carried over in the steam. They are present in small amounts; hence stop when 30-40 ml. have been obtained.
4. After the flask cools add 2-4 ml. dilute sulfuric acid until acid to Congo red paper; start distillation again.
5. After 100 ml. are obtained, place 5 ml. specimen in a small test tube, add 0.25 ml. phenol reagent and 1 ml. sodium carbonate, and heat in a water bath.

If the phenol reaction is still present, continue distillation after adding 100 ml. water. To 10 ml. both distillates add phenol reagent and sodium carbonate and carry out the test as described. Prepare a standard solution from a stock solution of 1 mg. phenol/ml. The best suitable standard is that of 3 mg.% diluted 10 times. This 10 fold dilution has the proper intensity for colorimetric reading.

Calculation:

$$\frac{OD_u}{OD_s} \times \text{mg. in standard} \times \frac{\text{ml. distillate}}{100} \times \frac{\text{Quantity of 24 hr. urine}}{100} = \text{mg. volatile phenols in 24 hr. specimen}$$

Determination of aromatic hydroxy acids

1. Transfer the acid solution in the distillation flask to a 250 ml. separatory funnel, dilute with water to 100 ml. and shake for 3 min. with 30-40 ml. petroleum ether.
2. Draw off petroleum ether and shake twice with ether.
3. Wash ether with water and evaporate on steam bath.
4. Add 10 ml. water before complete drying; then complete evaporation.

5. Use 1 ml. of this solution which shows a yellow color with 9 ml. water. Dilute 2 or 4 times.

Use standard phenol solution.

The result multiplied by 1.5 gives the content of aromatic hydroxy acids expressed as mg. *p*-hydroxyphenylacetic acid.

Determination of residual phenols

1. Dilute the residue from the ether extraction with 200 ml. water.
2. To 10 ml. add 1-1.5 ml. silver lactate solution (3% silver lactate in 3% lactic acid) and 1-2 drops colloidal iron. Shake, bring to 20 ml. with distilled water, and filter after 15 min.
3. To 10 ml. add 1-1.5 ml. saturated solution sodium chloride in 10% hydrochloric acid.
4. Bring to 20 ml. with distilled water and filter.
5. Treat 10 ml. filtrate with Folin-Ciocalteu reagent as just described. The result, taking into account the various dilutions, gives the so-called residual phenols.

Volterra's normals are as follows: 44.4 mg. volatile phenols in 24 hr.; according to this figure on normal subjects the daily elimination of aromatic hydroxy acids averaged 71 mg. There was an average of 336 mg. of residual phenols in the normal subject.

HEMOGLOBIN AND DERIVATIVES IN URINE

Hemoglobinuria or hemoglobin in urine is caused by dissolution of red blood corpuscles. It is found in severe diseases, such as yellow fever, smallpox, and scarlet fever, following poisoning with carbolic acid, sulfuric acid, and naphthol, and after extensive burns. There are also records of cases known as paroxysmal hemoglobinurias. See the Teichmann test, p. 1916.

Heller test

1. Precipitate the phosphates from the urine by adding potassium or sodium hydroxide and heating. As they precipitate, they carry with them the hemoglobin and therefore are blood-red, not white. The coloring matter may be detected microscopically.

Almén guaiac test

1. Make tincture of guaiac by adding 1 part guaiac to 100 parts absolute alcohol.
2. Mix equal parts of tincture of guaiac and old oil of turpentine. This mixture must not have any blue color.
3. Stratify on this mixture a small amount of urine.

If hemoglobin is present, first a bluish green ring and then a light or dark blue ring appear at the point of contact. On shaking, the mixture becomes blue.

Pus gives a blue ring but disappears on boiling.

HEMATOPORPHYRIN

1. To 100 ml. urine add 20 ml. 10% sodium hydroxide.
2. Collect the precipitate by centrifuging or filtering.
3. Wash the precipitate with water and then with alcohol.
4. Add 5 ml. alcohol and 5-10 drops hydrochloric acid, c.p., concentrated, mix thoroughly to dissolve and filter. Filtrate must be absolutely clear.
5. Examine spectroscopically for absorption bands of acid hematoporphyrin.

PORPHYRINURIA

The urine excreted is Burgundy red with a brown tinge, but sometimes it varies from pale pink to almost black. It may be normal yellow when passed but darkens on exposure to light. When the feces contain large amounts of porphyrin, they turn almost black on oxidation.

Acute porphyria is apparently congenital. Patients with this condition show no light sensitivity, and porphobilinogen is excreted in the urine in large amounts. The disease is inherited as a mendelian dominant and is more common in women than in men. They show the following symptoms: abdominal symptoms, with severe, cramplike pains, vomiting, and pronounced constipation. The abdomen is distended, and there may be slight fever and tachycardia. The skin may show a diffuse or spotted pigmentation. The nervous system shows involvement by reason of constant pain in the extremities, accompanied by muscular weakness. There is paralysis of the lower motor neuron type, with flaccidity and loss of tendon reflexes. The symptoms suggest Landry's paralysis. Mental symptoms may suggest hysteria. Some patients show toxic delirium with hallucinations of vision and hearing. The urine is dark but may contain only the colorless porphyrinogen.

Hematoporphyrin is found in urine following the administration of such drugs as quinine, tetranol, and others.

Refer to pp. 98 and 1083 for a further discussion of porphyrins.

TEST FOR PORPHYRINS

Porphyrins may be detected by their fluorescence in ultraviolet light or by means of their absorption spectra.

Reagents:

1. Acetic acid, glacial, c.p.
2. Ethyl alcohol, 95%.
3. Ethyl ether, anhydrous, c.p.
4. Hydrochloric acid, c.p., concentrated.

5. Hydrochloric acid, 5% aqueous solution.
    (a) Add 5 ml. concentrated hydrochloric acid to enough distilled water to make 100 ml. solution.
6. Sodium hydroxide solution, 10%.
    (a) Use 10 gm. sodium hydroxide/100 ml. Keep closed.

Procedure:

1. Place 25 ml. urine in a separatory funnel.
2. Add 10 ml. glacial acetic acid.
3. Extract twice with 50 ml. ether.
4. Combine the extractions and wash with 10 ml. 5% hydrochloric acid.
5. Examine the washings under ultraviolet light.

A red fluorescence indicates coproporphyrin. The urinary residue under ultraviolet ray shows a red fluorescence if urinary porphyrins are present.

Confirmatory test:

1. Add 20 ml. 10% sodium hydroxide to 100 ml. urine.
2. Filter and wash the precipitate with distilled water.
3. To the precipitate on the filter paper add 5 drops concentrated hydrochloric acid.
4. Wash into a test tube with the addition of 5 ml. 95% alcohol.
5. Examine the filtrate spectroscopically for absorption bands of hematoporphyrin.

COPROPORPHYRINS AND UROPORPHYRINS

Method of Ham[23]

Examine the urine in a dark room. Expose to ultraviolet light for fluorescence, which indicates the presence of porphyrin.

Separation of coproporphyrin

1. Acidify 100 ml. urine with 10 ml. glacial acetic acid and allow to stand exposed to the air overnight.
2. Place in a separatory funnel and extract 3 times with ethyl ether. Use 1-2 times the volume of the original mixture for each extraction.
3. Combine the ether extracts and wash once with 50 ml. distilled water.
4. Return the distilled water washing to the original urine sample.
5. Extract the **ether extract** 3 times with 2 ml. aqueous hydrochloric acid, 25% by volume.
6. Cool the hydrochloric acid extracts and examine under ultraviolet light.

Porphyrins

1. Adjust the reaction of the previously extracted urine-acetic acid mixture to pH 3.0 to 3.2 by adding either aqueous hydrochloric acid (1% by volume) or solid sodium acetate.
2. Extract the urine with solid ethyl acetate, using 1 or 2 times the volume of the urine for each extraction.
3. Combine the ethyl acetate extracts and wash once with 50 ml. distilled water and save.
4. Extract the ethyl acetate extract further 3 times with 2 ml. amounts 25% hydrochloric acid.
5. Pool the acid extracts and examine for fluorescence and for the absorption spectra.

SCREENING TEST FOR PORPHOBILINOGEN IN PRESENCE OF UROBILINOGEN AND INDOLE DERIVATIVES

Watson-Schwartz method[24]

Reagents:

1. Ehrlich aldehyde—Watson modification.
    (a) Dissolve 0.7 gm. *p*-dimethylaminobenzaldehyde in a mixture of 150 ml. concentrated hydrochloric acid and 100 ml. distilled water. Store in a dark brown glass bottle.
2. Saturated solution sodium acetate.
    (a) Place approximately 1000 gm. sodium acetate ($3H_2O$) in 1 L. volumetric flask. Add distilled water to the liter mark and heat to about 60° C.
    (b) Allow to cool.
    (c) Mix thoroughly.

Procedure: The urine specimen must be **fresh.**

1. Mix 2.5 ml. fresh urine with 2.5 ml. Ehrlich reagent in a test tube.
2. Add 5 ml. saturated sodium acetate solution.
3. Observe for development of a pink color.
4. Add 3-5 ml. chloroform.
5. Shake thoroughly and observe the color of the chloroform layer.

Interpretation: If a pink to red color develops after the addition of Ehrlich reagent and sodium acetate, it may indicate the presence of both urobilinogen and porphobilinogen.

If after extraction with chloroform, the red color remains in the aqueous portion of the test tube, this indicates the presence of porphobilinogen, which is insoluble in chloroform.

If the red color is taken out of the aqueous layer and transfers itself to the chloroform layer, it indicates the presence of urobilinogen and no porphobilinogen since urobilinogen is soluble in chloroform.

If the color remains in both layers, it indicates the presence of both porphobilinogen and urobilinogen.

DRUGS IN URINE

See the section on Toxicology for a discussion of the examination of urine for drugs.

Certain drugs alter the color of urine.

Dark green: phenol, phenyl salicylate, creosote, and resorcinol

Red: antipyrine and trional

Brown or black: pyrogallol

Yellow: phenacetin and picric acid; santonin changes from bright yellow to scarlet with sodium hydroxide

Iodine: Acidify the urine with hydrochloric acid. Add a few drops starch solution and a few drops calcium chloride. In the presence of iodine a blue color develops.

Phenol: If carbolic acid is present, the urine becomes dark on standing, green-brown to black. In carbolic acid-containing urine, sulfuric acid is found.

Salicylic acids—Salol (phenyl salicylate) and salophen (phenetsal): Addition of iron chloride produces a violet coloration. If there is only a trace of these drugs present, acidifying, shaking with equal parts of ether, and then adding diluted ferric chloride will give the same reaction.

Antipyrine with ferric chloride: This gives a red color.

Phenacetin: To a few ml. urine in a test tube add 2 drops concentrated hydrochloric acid, 2 drops 1% sodium nitrite solution, and a few drops alkaline α-naphthol solution. Now alkalinize. A light red color is produced. This becomes yellow on the addition of hydrochloric acid.

Rhubarb and senna: The presence of rhubarb and senna is detected by alkalinizing the urine, which gives a deep red color.

Phenolphthalein: Phenolphthalein, which is a constituent of some purgatives, appears in the urine and can be discovered by the addition of sodium hydroxide solution, producing a red color.

Pyramidon (aminopyrine): Pyramidon in the urine is detected by the addition of tincture of iodine, producing a yellow ring.

Quinine: Quinine may be detected with the following reagent:

1. Solution 1.

Potassium iodide	10 gm.
Hot distilled water	50 ml.

2. Solution 2.

Mercuric silver iodide . . .	2.7 gm.
Distilled water	150 ml.

Mix solutions 1 and 2 together and add 2.5 gm. acetic acid. The addition of this reagent to an alkaline-free urine in the presence of quinine gives a cloudiness. As albumin will also cloud, it should be eliminated. The cloudiness produced by quinine disappears on heating, whereas the cloudiness produced by albumin remains.

Quinine—a simple field test[25]

Reagent:

Mercuric iodide	3 gm.
Potassium iodide	2 gm.
Glacial acetic acid	20 ml.
Distilled water, sufficient to make	60 ml. of reagent.

The reagent must be kept in an amber bottle.

Procedure: One or 2 ml. urine are used for a test. To a small amount of urine (1 or 2 ml.) add 5-10 drops reagent.

An immediate turbidity which appears on slight agitation is an indication of quinine. This intensifies upon standing. This method will detect as little as 0.001 mg. quinine.

Substances such as atropine, cocaine, strychnine, Atabrine, and albumin interfere with the reaction. The presence of the alkaloids would be rare; if the patient has taken these drugs, this fact would likely be known. Albumin may be more frequently encountered; its presence may give a false positive test. In a suspected false positive test a simple differentiation may be made by heating the tube. The quinine precipitate will dissolve with heat and reappear when cooled. The albumin precipitate intensifies when heated and persists.

This test may be of some value in determining whether the patient has been taking and absorbing quinine. It will detect ingestion of a 5 gr. tablet of quinine up to the thirty-sixth hour.

Sulfonamides

Refer to Chapter 12 for methods of testing for sulfonamide drugs.

Antibiotics

Refer to pp. 610 and 713 for a discussion of antibiotic assays.

Arsphenamine
Dicken modification of Autenrieth test for arsenic

Reagents:

1. Concentrated hydrochloric acid.
2. Sodium nitrite, 0.5%.
    (a) Dissolve 0.5 gm. sodium nitrite in 100 ml. distilled water.
3. Resorcinol, 10%.
    (a) Dissolve 10 gm. resorcinol in 100 ml. distilled water; should be colorless.
4. Sodium carbonate solution, 20%.
    (a) Dissolve 20 gm. anhydrous sodium carbonate in 100 ml. distilled water with heat and filter through filter paper.

Procedure:

1. To 10 ml. urine in a test tube add 3 drops hydrochloric acid. Allow to stand 5 min.
2. Add 10 drops 0.5% sodium nitrite solution. Allow to stand 3 min.
3. In another test tube place 5 ml. 10% resorcinol and 3 ml. 20% sodium carbonate solution.
4. Overlay the resorcinol solution with the diazotized urine.

In the presence of arsphenamine a rose-red ring develops slowly at the point of contact of the 2 liquids. In the presence of atoxyl a yellow ring develops. The lower portions of the test tube are used as controls. Mix the contents thoroughly. The color should remain.

OCCULT BLOOD
Phenolphthalin test[26]
Gettler-Kaye method

Phenolphthalin reagent:

1. Place 200 ml. distilled water, 20 gm. sodium hydroxide, and 1 gm. phenolphthalein in a 500 ml. Erlenmeyer flask.
2. When completely dissolved, add 20 gm. granulated zinc (20-30 mesh).
3. Using a reflux condenser to prevent evaporation, slowly boil the mixture until the red color of the alkaline phenolphthalein disappears, leaving a colorless or faintly yellow solution. This may take 2-3 hr. The phenolphthalein is thereby reduced to phenolphthalin which is colorless in alkaline solution.
4. When cool, place in a brown bottle and stopper with a rubber stopper. Some of the zinc may be added; this will aid in keeping it in the reduced form. The reagent will keep for many months if kept in a cool dark place.

Procedure:

1. Place 1 or 2 ml. portions urine, spinal fluid, thin fecal suspension, or gastric contents in a test tube and boil for about 30 sec. in order to destroy any oxydases that may be present.
2. Cool and add about 5 drops phenolphthalin reagent, followed by about 3 drops 3% hydrogen peroxide.

A pink to red color indicates the presence of blood. The intensity of the color is a rough indication of the quantity of blood present. The color may fade after 3 min.

Tests for blood in feces and in gastric contents should be applied only if the patient has been on a meat-free and fish-free diet for 3-4 days. Bleeding, as seen in hemorrhoids, as well as the admixture of menstrual blood, is to be considered in the interpretation of the results.

The phenolphthalin test is slightly more specific for occult blood than are the guaiac, benzidine, and orthotolidine tests and is especially recommended for medicolegal work.

Comparison of the sensitivity of the 4 tests was found to be as follows:

Guaiac test—1 part in 10,000
Benzidine test—1 part in 1,000,000
Orthotolidine test—1 part in 10,000,000
Phenolphthalin test—1 part in 10,000,000 (if sample is fresh); 1 part in 1,000,000 (if sample is old and decomposed)

Benzidine test

Follow the method given on p. 1916, substituting urine for gastric contents.

Benzidine dihydrochloride test

This test has the advantage over the benzidine test mentioned above in that it is used in aqueous solution, and the solution is stable for at least 3 mo.

Reagents:

1. Benzidine dihydrochloride, 1% aqueous solution.*
    (a) Shake 1 gm. benzidine dihydrochloride and 100 ml. distilled water at intervals for about 2 hr. or until dissolved; filter and keep in a dark amber bottle; do not use heat in preparing the solution.
2. Hydrogen peroxide, 3% solution.
    (a) Dilute 30% hydrogen peroxide, c.p., with distilled water in the proportion of 1 vol. 30% peroxide to 9 vol. water.
3. Sodium acetate, 1% aqueous solution.
    (a) Dissolve 1 gm. sodium acetate crystals (reagent) in enough distilled water to make 100 ml. total solution.

Detection of blood in urine:

1. Place 1 or more ml. urine in a clean test tube and dilute to about 5 ml. with distilled water.
2. Add in the order named: 1 ml. benzidine dihydrochloride solution, 1 ml. hydrogen peroxide solution, and 1 ml. sodium acetate solution.

A blue color develops in the presence of blood. The rapidity with which the color develops depends chiefly on the amount of blood present, 1-10 sec. usually being required.

When the amount of blood is very small, centrifuge the urine, pour off the supernatant fluid, and place the sediment on a glass slide. Add in the order named 1 drop benzidine dihydrochloride solution, 1 drop hydrogen peroxide solution, and 1 drop sodium acetate solution and mix by tilting the slide.

Detection of blood in feces: See Chapter 108.

1. Mix about 1 gm. feces in a test tube with 5 ml. distilled water, bring to a boil over a flame, and filter.
2. Collect the filtrate in a clean test tube and cool.
3. Add in the order named 1 ml. benzidine dihydrochloride solution, 1 ml. hydrogen peroxide solution, and 1 ml. sodium acetate solution.

Color reactions are the same as when urine is used in the test.

Orthotolidine test—Stone-Burke[27]

Orthotolidine was first proposed by Phelps in 1909 as a qualitative test for minute amounts of free chlorine or hypochlorites in water. It is a crystalline basic body of the aromatic series obtained by reduction from orthonitrotoluene, having a melting point of 129° C. and is quite insoluble in distilled water but soluble in acid solutions and in alcohol and ether. Ruttan and Hardisty[28] in 1912 reported the use of orthotolidine as a test for the detection of blood, using a 4% solution in glacial acetic acid with a small amount of Perhydrol* as an oxidizing agent to obtain a blue color in the presence of blood.

Stone and Burke reported that they had found orthotolidine useful in the detection of minute quantities of blood in urinary sediments. They pointed out that red cells in urinary sediments are often crenated or disintegrated in specimens a few hours old and may be confused with leukocytes. Red cells are frequently disintegrated in alkaline urine. The continued presence of red blood cells in urinary sediments has important clinical significance by attracting attention to glomerular inflammatory changes, which are frequently overlooked in the absence of albuminuria or other gross evidences of disturbance. Stone and Burke found that red cells were excreted more or less constantly in patients with evident foci of infection, indicating evidences of glomerular inflammation. It is well known, of course, that a few red cells, leukocytes, or casts, in the absence of other symptoms, may have little significance following unusual exercise or exertion.

Reagents:

1. Orthotolidine, 1%, in chemically pure methyl alcohol.

---

*Merck Sharp & Dohme, Division Merck & Co., Inc., West Point, Pa.

*Merck Sharp & Dohme, Division Merck & Co., Inc., West Point, Pa.

  - (a) This dissolves with slight difficulty and keeps at least 10 mo.
2. Acetic acid–hydrogen peroxide mixture.
  - (a) Glacial acetic acid, 1 part, and commercial hydrogen peroxide, 2 parts (keeps 3 or 4 mo., probably longer).

Procedure:

1. Centrifuge 15 ml. urine at 1500 r.p.m. for 5 min.
2. Pour off the supernatant fluid.
3. Prepare a portion of the sediment for microscopic examination in the usual way.
4. To the remaining sediment, add 2 drops orthotolidine solution and 2 or 3 drops acid-peroxide solution.

Undiluted blood serum, 10% sodium hydroxide, strong trisodium phosphate solutions, and probably other strong alkalies will give positive reactions. Pus cells or any of the common organic or inorganic constituents found in the urine do not give positive reactions.

Chapter 100

Rapid tests

SAM FRANKEL

A series of special tablets, sticks, and tapes is available for extremely sensitive and rapid analyses of many constituents in urine and other fluids (Table 362).

Table 362.* *Rapid tests and their uses*

Name	*Test*
Combistix	Protein, glucose, and pH
Uristix	Protein and glucose
Clinitest	Sugar
Clinistix	Glucose
Albustix	Protein
Albutest	Protein
Bumintest	Protein
Ketostix	Acetoacetic acid
Acetest	Acetoacetic acid and acetone
Hematest	Occult blood
Occultest	Occult blood
Hemastix	Hematuria
Ictotest	Bilirubin
Phenistix	Phenylpyruvic acid
Dextrotest	Blood sugar

*Available from Ames Co., Inc., Elkhart, Ind.

Also available is the well-known Tes-Tape* for urinary glucose, the lesser known Sheftel urine sugar test case,* and the Urograph,† a quantitative assay of blood urea nitrogen, described on p. 81.

Space limitations will allow only a brief discussion of these materials,‡ being confined for the most part to principles and procedures. In certain cases pertinent comments concerning special precautions will be included. Certain of the materials will be omitted when there is an overlap.

Combistix

This is a multiple test strip, offering a most convenient method of obtaining rapid results for protein, glucose, and pH.

Protein: "The Combistix colorimetric test for protein is based on the well-known phenomenon of 'protein error of indicators,' the fact that at a fixed pH certain indicators will have one color in the presence of protein and another color in the absence of protein. The citrate buffer contained in the protein test area of Combistix provides a hydrogen ion concentration of approximately pH 3. At this pH the indicator tetrabromphenol blue has a yellow color, whereas at the same pH in the presence of increasing amounts of protein the indicator will change yellowish green to green to blue.

Glucose: "Glucose oxidase, reacting with glucose in the urine, removes 2 hydrogen atoms to form gluconolactone, which is promptly hydrated to gluconic acid. The displaced hydrogen atoms are then combined with atmospheric oxygen to form hydrogen peroxide.

$$\text{Glucose} + O_2 \xrightarrow{\text{Glucose oxidase}} \text{Gluconic acid} + H_2O_2$$

"The hydrogen peroxide in the presence of peroxidase oxidizes a colorless dye, orthotolidine, which in its oxidized state assumes a blue color.

$$H_2O_2 + \text{Orthotolidine} \xrightarrow{\text{Peroxidase}} \text{Oxidized orthotolidine (blue)} + H_2O$$

pH: "It is well established that certain dyes may impart a constant color at a specific pH but may change in shade or color with variations in pH. These dyes usually exhibit this phenomenon within clearly defined limited ranges of pH. The combination of the dyes methyl red and bromthymol blue provide a series of bright orange, yellow, green, and blue colors within the range of pH 5.0 to pH 9.0, the essential range of urinary pH.

---

*Eli Lilly & Co., Indianapolis, Ind.

†Warner-Chilcott Laboratories, Morris Plains, N. J.

‡Quoted from Products profiles, Ames Co., Inc., Elkhart, Ind.

"Directions:

"*Note:* The reliability of any test depends upon the care with which it is performed.

"Follow directions meticulously.

"1. Moisten the test end of the strip in urine by dipping and removing immediately. (Prolonged immersion may cause leaching of test chemicals.)

"2. Touch tip of strip against edge of container to remove excess urine. (The avoidance of excess urine on the stick helps to prevent urine containing test material spreading from one area to another.)

"3. Read the glucose (mid) test area at **10** sec. after wetting if the glucose color chart is to be used. (The time of reading the pH and protein portions is not critical.)

"4. Hold test portions close to the appropriate color chart and match or interpolate color reactions with the appropriate color charts.

"Important: Good lighting is essential for accurate color interpretations.

"Interpretation of color reactions:

"*Protein test portion (distal test area):*

"*Negative result*—Color closely matches the 0 or negative color block.

"*Positive reaction*—If protein is present, the yellow tip changes immediately to a yellow-green to green to blue-green to blue color depending on the quantity of protein present. With experience and adherence to directions, one can interpolate Combistix color reactions lying between the color blocks on the chart. Color reactions identical with the trace color block indicate approximately 20 mg. protein/100 ml. urine. It is possible to detect lesser amounts of protein.

"*Glucose test portion (midtest area):*

"*Negative result*—No color change occurs.

"*Positive reaction*—If glucose is present, the red area changes from light to medium to dark shades of purple. A light color usually corresponds to a small amount of sugar (less than 0.5% or between 100 and 500 mg./100 ml.) and a dark color to a larger amount (more than 0.5% or 500 mg./100 ml.). A medium color may be produced by either a large or a small amount of sugar. As little as 0.1% (or 100 mg./100 ml.) of glucose in urine can be detected with Combistix. Enzyme tests for glucose are influenced by pH, temperature, and the presence of antagonistic substances such as ascorbic acid. Therefore, they should be regarded essentially as qualitative tests although in many instances they can indicate the presence of small, moderate, or large amounts of glucose.

"*pH test portion:*

"Color blocks on the color chart connote the pH of urine as follows:

Orange: pH 5
Orange-yellow: pH 6
Yellow-green: pH 7
Dark green: pH 8
Dark blue: pH 9

"Colors lying between these pH values can be interpolated.

"Precautions in using Combistix:

"1. Collect urine specimens in clean containers and protect from contamination.

"2. Test fresh urine specimens. Upon long standing, bacterial action may result in highly alkaline urines nullifying pH determinations and sometimes causing false positive protein reactions. (A sufficiently [highly] buffered urine with a pH of 8.0 or above may produce a protein color reaction in the absence of protein.)

"3. Do not touch the Combistix test areas with the fingers, which may have had prior contact with reactive substances.

"4. Do not use Combistix in presence of fumes of volatile acids or bases.

"5. Do not allow the Combistix strip to remain in the urine specimen. Quick dipping prevents possible loss of test materials.

"6. Remove excess urine from strip after dipping by touching tip to edge of container. This prevents urine [from] flowing chemicals from one test area to another.

"7. Be precise in reading the glucose test portion 10 sec. after dipping if the glucose color chart is to be used. A delay in reading will result in excessive color developing in the test area of the strip.

"8. It is essential that all readings be made by holding the test area close to the corresponding color chart. Never read by laying the strip over the collection bottle and looking down the long axis of the strip to the color chart placed in the background.

"9. Never read color reactions in poor light. Lighting must be bright whether daylight or artificial. Dim light may result in false positives or overly high protein readings. If blue fluorescent lights (nondaylight type) are present in the laboratory or if the walls are blue or green, it should be determined if these factors require compensatory readings, particularly with the protein test portion.

"10. Avoid 'overreading' the reactions of Combistix. The successful use of any colorimetric test is dependent upon the experience and color acuity of the technician. Although controlled studies have shown that both trained and untrained operators obtain reliable results with Combistix, there is a tendency for those first using the colorimetric protein test of Combistix to overread slight changes from the negative which should be disregarded."

Clinitest

"Sodium carbonate and a small amount of the citric acid act as an effervescent couple to facilitate rapid solution of the tablet. Reducing sugars present in the test urine react with the copper sulfate to reduce the cupric ions to cuprous oxide, giving a color change of blue through green to orange, depending upon the amount of reducing substances present. The sodium hydroxide provides the alkaline medium necessary for the reaction. The heat required is provided both by the solution of the sodium hydroxide and by the reaction between sodium hydroxide and citric acid.

$$2\ Cu^{++} + \underset{\text{sugar}}{\text{Reducing}} \xrightarrow[\text{alkali}]{\text{Heat and}} Cu_2O + \underset{\text{sugar}}{\text{Oxidized}}$$

"Directions:

"1. Place 5 drops urine and 10 drops water in test tube.

"2. Add Clinitest reagent tablet. Watch reaction carefully. (If solution passes through orange to some shade of brown, it indicates more than 2% urine-sugar present, which should be recorded without reference to color chart.)

"3. Wait 15 sec. after boiling stops; shake gently and compare with color chart.

"**Interpretation:** The Clinitest color chart has 6 color blocks varying from blue through green to orange representing urine sugar levels of 0.25, 0.5, 0.75, 1, 2%, and over."

Albutest

"This protein test is based on the well-known phenomenon of a 'protein error of indicators' which involves the fact that at a fixed pH certain indicators will have one color in the presence of protein and another color in the absence of protein. The salicylate buffer provides a hydrogen ion concentration of approximately pH 3.0. At this pH bromphenol blue has a yellow color, whereas at this same pH in the presence of increasing amounts of protein the indicator will have a green to blue color.

"When a drop of urine containing protein is placed on the tablet, the protein is adsorbed on the tablet surface. Following addition of 2 drops water, a considerable quantity of the urine is washed away, but protein, indicator, and buffer remain at the surface of the tablet, and the indicator produces a green to blue-green color. With a urine containing no protein, the tablet may show some color change when the drop of urine is added because of the local effect of the pH of the urine, but upon the addition of 2 drops water the yellow color of the indicator is restored.

"Directions:

"1. Place tablet on clean surface (preferably a piece of paper) and put 1 drop urine on tablet.

"2. After urine drop has been absorbed, add 2 drops water and allow penetration before reading.

"3. Compare color on top of tablet with color photograph (color photographs on insert accompanying each package).

"Interpretation:

"Negative—If no protein is present the original color of the tablet will not be materially changed at the completion of the test.

"Positive—If protein is present in the urine sample, a blue-green spot will remain on the tablet surface after the addition of water. The intensity of the blue-green spot is proportional to the amount of protein present in the urine."

Bumintest

"When the Bumintest tablet is placed in water, the sodium bicarbonate and a small part of the sulfosalicylic acid present interact with an effervescence that facilitates rapid solution of the entire tablet. The resulting solution of free sulfosalicylic acid precipitates urine proteins which are estimated quantitatively by the degree of turbidity of the solution.

"**Directions:** The reagent solution is prepared by dissolving 4 Bumintest reagent tablets in 1 oz. (30 ml.) water. This produces a 5% solution sulfosalicylic acid that is ready for use as soon as the effervescence has subsided, and it remains indefinitely stable under ordinary conditions.

"1. Place equal parts of reagent solution and urine—not less than 10 drops each—in small test tube.

"2. Shake test tube gently.

"**Interpretation:** The amount of protein present is estimated by the degree of turbidity (Fig. 618).

"Precautions:

"Stability: Bumintest reagent tablets are effervescent tablets and are somewhat hydroscopic. Exposure to moisture should therefore be avoided. The tablets are stable if kept dry

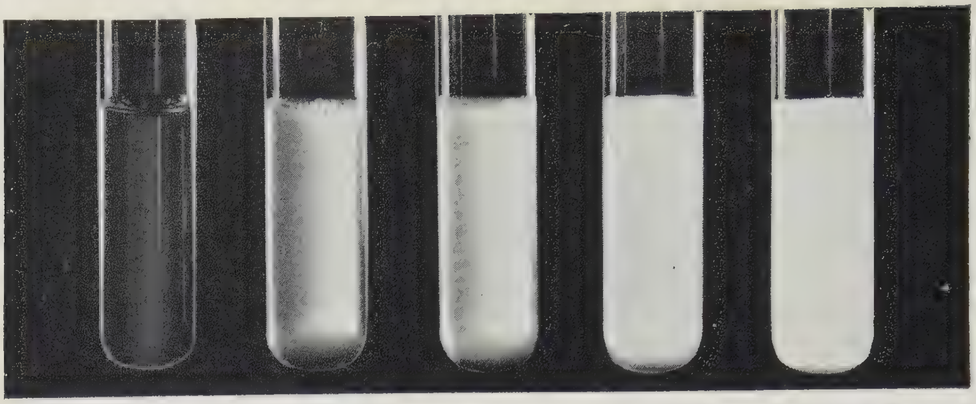

Fig. 618. Turbidity testing of urine for albumin showing negative reaction, trace, small amount, medium amount, and large amount. (Courtesy Ames Co., Inc., Elkhart, Ind.)

and in the original container. It is important that the container be kept securely closed when not in use.

"The solution made from the tablets is stable for at least a month if kept in an amber bottle at room temperature.

"*Urine turbidity:* Urine turbidity may be due to cellular debris, casts, crystals of phosphates, urates, etc. If the urine sample is turbid prior to testing with Bumintest, the sample should be filtered or centrifuged. However, if the turbidity is not great, the test with Bumintest may be done in the usual way, and the reaction is compared with the original solution to determine whether there is an increase in turbidity.

"*Interfering substances:* Metabolites of the following drugs have been found to cause false positive reactions with sulfosalicylic acid turbidity tests: (1) penicillin (massive doses), (2) tolbutamide, and (3) x-ray media (cholecystographic and urographic media).

"When these metabolites are suspected, the specimen should be checked with one of the Ames colorimetric protein tests (Albutest, Albustix, Uristix) which do not give false reactions to these metabolites.

"Occasionally tap water contains sufficient iron to produce a pink color when Bumintest reagent tablets are dissolved in it. In such cases it is best to use distilled or deionized water in making up the reagent solution."

Ketostix

"Acetoacetic acid, if present in urine or serum, will form a colored complex with nitroprusside in the presence of aminoacetic acid. Sodium phosphate provides an optimum pH environment for this reaction.

"**Directions for detection of ketone bodies in urine:**

"1. Dip test end of strip in urine or briefly pass through urine stream.

"2. At 1 min. compare color of dipped end with color chart. (Color chart on bottle label.)

"**Interpretation:**

"*Negative*—Color of test strip remains unchanged or appears cream colored from wetting.

"*Positive*—At 1 min. test end of strip develops color varying from pink to purple, depending upon amount of ketone bodies present.

"**Directions for detection of ketone bodies in serum:**

"1. Dip test end of strip in plasma or serum.

"2. At 1 min. compare the color of dipped end with color chart. This procedure is adequate to detect most ketonemias and will reliably demonstrate 25 mg. acetoacetic acid/100 ml. serum or plasma. If a more sensitive test is desired, a 3 min. reading of Ketostix can be made, in which case amounts of acetoacetic acid as small as 10 mg./100 ml. can easily be detected.

"**Interpretation:**

"*Negative*—Color of test strip remains unchanged or appears cream colored from wetting.

"*Positive*—At 1-3 min. test end of strip develops color varying from pink to purple, depending upon amount of ketone bodies present."

Acetest

"Acetoacetic acid or acetone, if present in urine or blood, will form a colored complex with nitroprusside in the presence of aminoacetic acid. Sodium phosphate provides an optimum pH environment for this reaction and lactose enhances the color quality.

"**Directions for detection of ketone bodies in urine:**

"1. Place tablet on a clean surface, preferably a a piece of white paper.
"2. Put **1** drop urine on tablet.
"3. Take reading at **30 sec.** Compare color of tablet to color chart.

"**Interpretation:**

"*Negative*—Tablet color is unchanged or turns cream color.

"*Positive*—At 30 sec. color of tablet varies from lavender to deep purple. Results may be recorded as trace, moderate, or strongly positive.

"**Directions for detection of ketone bodies in whole blood:**

"1. Place **1** drop blood on Acetest tablet. (One of the great advantages of this test is that a drop of whole blood from a fingertip puncture may be used.)
"2. Allow the blood to clot on the tablet for approximately **10 min.**
"3. Lift off clot or wash off with water. Compare color of tablet to color chart.

"**Interpretation:**

"*Negative*—Tablet color is unchanged or turns cream color.

"*Positive*—At 10 min. color of tablet varies from lavender to deep purple. Results may be recorded as trace, moderate, or strongly positive.

"**Directions for detection of ketone bodies in serum or plasma:**

"1. Place **1** drop of serum on Acetest tablet.
"2. Readings made at **2 min.** will detect as little as 10 mg./100 ml. serum, and quantities greater than this will give a color within a shorter interval of time.

"**Interpretation:**

"*Negative*—Tablet color is unchanged or turns cream color.

"*Positive*—At 2 min. color of tablet varies from lavender to deep purple. Results may be recorded as trace, moderate, or strongly positive."

Hematest

"A positive reaction with Hematest is based upon the catalytic properties of hemoglobin. When the Hematest tablet is moistened with water, the reagents are washed down onto the filter paper. Tartaric acid and calcium acetate react with strontium peroxide to form hydrogen peroxide. Hemoglobin of the blood catalytically decomposes hydrogen peroxide with the liberation of oxygen, which oxidizes orthotolidine to a blue-colored derivative.

"**Directions for detection of occult blood in feces:** Hands, glass dropper, and working area must be clean and free of traces of blood.

"1. Smear a solid specimen of feces on filter paper. Do not use an emulsion. (See color photographs for example [included in package].)
"2. Place Hematest tablet in center of specimen.
"3. Place 1 drop water on tablet, wait 5-10 sec., and flow a second drop on tablet so that it runs down the sides onto the filter paper.

"**Interpretation:**

"*Negative*—If within 2 min. color does not appear on the filter paper around the tablet, test is considered negative.

"*Positive*—Diffuse blue color appears on the filter paper around the tablet within 2 min. The amount of blood is proportional to the time of appearance and to intensity of color. (Color on the tablet is of no significance.)

"**Directions for detection of occult blood in body fluids (urine, sputum, mammary secretions, and vaginal and uterine secretions):**

"1. For fluid specimens place 1 drop liquid on the filter paper. Place tablet in the center of moistened portion of the filter paper and proceed with directions and interpretations described above.

"**Positive reactions:** A positive reaction with Hematest is based on the catalytic properties of hemoglobin. Although no drug, including iron and bismuth, has been found to react with Hematest, certain plant residues and bacteria in feces contain reactive substances which may be present in a stool specimen in sufficient concentration to produce a color reaction with Hematest that is faint and slow in appearing. If a false positive reaction is [suspected], confirmation by examination of a second stool specimen is desirable.

"**Negative reactions:** False negative reactions are prevented by fixed sensitivity and stability of the Hematest reagent tablets. However, rarely a small amount of blood may be contained in only one portion of a stool specimen. Testing of several smears from a stool specimen may result in the detection of occult blood which might be undetected by a single test."

Occultest

"A positive reaction with Occultest is based upon the peroxidase properties of hemoglobin. When the Occultest tablet is moistened with water, the reagents are washed down onto the filter paper. Tartaric acid and calcium acetate react with strontium peroxide to form hydrogen peroxide. Hemoglobin of the blood catalytically decomposes hydrogen peroxide with the liberation of oxygen which oxidizes orthotolidine to a blue-colored derivative. The sodium bicarbonate and a small amount of the tartaric acid serve as an effervescent couple to facilitate solution of the reactive ingredients and thus increase the sensitivity of the test. A red dye is added to mask discoloration of the tablet.

"**Directions:** Hands, glass dropper, and working area must be clean and free of traces of blood.

"1. Place 1 drop well-mixed uncentrifuged urine in center of filter paper square.
"2. Put Occultest tablet in center of moist area.
"3. Place 2 drops water on tablet.
"4. A positive reaction is read on filter paper within 2 min.

"**Interpretation:**

"*Negative*—If within 2 min. color does not appear on the filter paper around the tablet, test is considered negative.

"*Positive*—Diffuse blue color appears on the filter paper around the tablet within 2 min. Amount of blood present is proportionate to intensity of blue color, its area on the filter paper, and rapidity of color development.

"**Positive reactions:** A positive reaction with Occultest is based upon the peroxidase properties of hemoglobin. Although no drug, including iron and bismuth, has been found to react with Occultest, certain bacteria contain reactive substances and may be present in an old urine specimen in sufficient concentration to produce a color reaction with Occultest that is faint and slow in appearing. If a false positive reaction is [suspected] confirmation by examination of a fresh urine specimen is desirable.

"*Note:* Occultest is designed to detect occult red blood cells or free hemoglobin in urine. Another Ames product, Hematest reagent tablets, which is somewhat less sensitive than Occultest, has been specifically designed to detect occult blood in feces."

Hemastix

"Hemoglobin of blood (or myoglobin) catalyzes the interaction of orthotolidine and peroxide, oxidizing orthotolidine to a bright blue color. In the absence of hemoglobin or myoglobin no color develops.

"**Directions:**

"1. Dip test end of strip into well-mixed urine or briefly pass through urine stream.
"2. At 1 min. compare test end of strip with color chart on the bottle label.

"**Interpretation:**

"*Positive*—Test end of strip turns blue and may be read as small, moderate, or large, depending upon the intensity of the color produced.

"*Negative*—No blue color is present at the end of 1 min."

Ictotest

"When 5 drops urine sample containing bilirubin are placed on the asbestos-cellulose mat, the absorbent qualities of the mat cause the bilirubin to remain on the outer surface of the mat. The tablet containing the reactive ingredients is then placed on the mat and 2 drops water are allowed to flow over the surface of the tablet. This allows a certain amount of the reactive ingredients of the slightly effervescent tablet to dissolve and to wash onto the surface of the mat. A chemical coupling of bilirubin with *p*-nitrobenzene diazonium *p*-toluene sulfonate occurs with the formation of a blue or purple color. The sulfosalicylic acid provides a suitably acid environment for this reaction to occur. The small amount of sodium bicarbonate along with a small portion of the sulfosalicylic acid provides an effervescent mixture which ensures solution of some of the tablet ingredients in the 2 drops water.

"**Directions:**

"1. Place 5 drops urine on one square of special test mat (supplied).
"2. Place Ictotest reagent tablet in center of moistened area.
"3. Flow 2 drops water on tablet.

"**Interpretation:**

"*Negative*—Mat shows no blue or purple color within 30 sec. (A slight pink or red color that may sometimes appear should be interpreted as negative.)

"*Positive*—Mat (around tablet) turns blue or purple. Amount of bilirubin present is proportionate to speed and intensity of color reaction."

Note: In a report by Ivy and Hurley,[29] this test was performed routinely on 25,000 patients over a period of 6 yr. Clinical icterus was observed in only 20% of the examinations which were positive by Ictotest.

Phenistix

"Ferric ions will react with phenylpyruvic acid in a properly acidified medium to form a characteristic green or gray to blue color. With

Phenistix, the necessary ingredients are impregnated into a stiff cellulose strip which is merely dipped into a test urine or pressed against a wet diaper to obtain a reaction. Ferric ions are supplied as ferric ammonium sulfate. Optimum acidity for the reaction is provided in the form of cyclohexylsulfamic acid. Magnesium ions in the form of magnesium sulfate are incorporated into the formulation to prevent the interference of urine phosphates in the color reaction. The composition is such that a minimal interference is obtained from other possible urine constituents which give colored reactions with ferric ions.

"**Directions:**

"1. Dip test end of strip in urine and remove immediately or moisten by pressing against wet diaper.

"2. Compare color of dipped end with color chart at ½ min. (Color chart on bottle label.)

"**Interpretation:**

"Negative—If within ½ min. color does not appear on the test end of the strip, test is negative.

"Positive—A color change ranging from gray to blue-gray appears on the test end of the strip within ½ min. If the color of the test strip closely matches a color on the color scale, the concentration of phenylketonuria is so recorded. If the color of the test strip lies between two colors of the color scale, the concentration of phenylketonuria may be indicated accordingly (e.g., between 40 and 100 mg./100 ml.) or interpolated (e.g., approximately 60 mg./100 ml.).

"**Positive reactions:** Theoretically large amounts of ketone bodies present in the urine, as in very severe ketosis, might produce an atypical color reaction with Phenistix. However, as the color is atypical, it is unlikely that it will cause confusion. Furthermore, this atypical color reaction has been observed only under laboratory conditions (ketone bodies added to urine), and it is unlikely that such high concentrations of ketone bodies would occur under conditions of clinical practice.

"Salicylates and metabolites of phenothiazine derivatives impart a pink color to Phenistix which is differentiated readily from the gray to blue-gray colors produced by phenylpyruvic acid. (With ferric chloride solutions these differentiations may be difficult. Furthermore, ferric chloride is much more sensitive to phenothiazine metabolites than is Phenistix.)

"Phenistix will react to *p*-hydroxyphenylpyruvate, but the color is fleeting and should not be a problem if the test is read at ½ min. as recommended.

"High concentrations of bilirubin in the urine may alter the normal Phenistix color reaction.

"**Negative reactions:** The normal range of the pH of urine does not significantly affect Phenistix. However, with old decomposed ammoniacal urine specimens interference with the color reaction may occur. Therefore, old urine specimens should not be used with Phenistix.

"It must be kept in mind that with all test procedures, including highly sensitive tests such as Phenistix, factors such as dietary intake, severity of the existing condition, and dilution of the urine may result in undetectable concentrations of the substance tested. For these reasons, in a case of a negative Phenistix reaction, it may be desirable to test several specimens at the time testing is scheduled."

Dextrotest

"**P tablets:** The sodium bicarbonate and a small amount of sulfosalicylic acid act as an effervescent couple to effect rapid solution of the tablet in water. One P tablet dissolved in 2 ml. water provides a strong sulfosalicylic acid solution which will completely precipitate the protein present in 1 ml. blood. Filtration of the sulfosalicylic acid-blood mixture yields a protein-free filtrate necessary for estimation of the reducing sugars.

"**S tablets:** One S tablet added to 1 ml. protein-free filtrate obtained with P tablet as just described provides a means of estimation of the amount of reducing sugars present. The sodium carbonate and a small amount of citric acid act as an effervescent couple to ensure rapid solution of the tablet. Reducing substances present in the filtrate react with the copper sulfate to reduce the cupric ions to cuprous oxide. The solution turns from blue through green to reddish brown, depending upon the amount of reducing sugars present. Sodium hydroxide provides the alkaline medium for this reaction, and the heat required is provided both by the solution of the sodium hydroxide and by the reaction between sodium hydroxide and citric acid.

$$2\ \mathrm{Cu}^{++} + \underset{\text{sugar}}{\text{Reducing}} \xrightarrow[\text{alkali}]{\text{Heat and}} \mathrm{Cu_2O} + \underset{\text{sugar}}{\text{Oxidized}}$$

"**Directions:**

"1. Place water in narrow graduated test tube P to mark 1 (2 ml.) and add one reagent tablet P. While tablet P is dissolving, fold filter paper and place dry on test tube S.

"2. After reagent tablet P dissolves, add blood (1 ml.) to mark 2 on test tube. Invert and shake to mix contents thoroughly.

"3. Immediately pour brown mixture from tube P through dry filter into tube S. (Filter cone will hold entire contents of tube P.) Collect filtrate to mark.

"4. Add 1 reagent tablet S to filtered solution. Do not shake while boiling. After boiling ceases, shake test tube briskly 3 or 4 times, making certain that the foam is carried down into the solution. Wait 30 sec. and compare [with] color chart.

"**Interpretation:** The color scale provided with the Dextrotest kit has 3 color blocks varying from blue-green to green to orange-brown, representing, respectively, blood sugar levels of 100 mg./100 ml., 150 mg./100 ml., and 200 mg./100 ml.

"*Note:* If test indicates blood sugar levels above 200 mg./100 ml., the test may be repeated using 2.5 ml. water, 1 tablet P and 0.5 ml. blood. The same amount of filtrate is collected, and 1 tablet S is used, as described. Blood sugar concentrations read from the chart are multiplied by 2.

"**Precautions:** Dextrotest tablets (P and S) are hygroscopic but are stable indefinitely provided the foil packaging is not punctured or torn.

"*P tablets:* These effervescent tablets are somewhat hygroscopic. As long as the tablets dissolve to give a clear solution, they are satisfactory.

"*S tablets:* These tablets are very hygroscopic and should be protected from exposure to moisture, even the humidity of the air. There is one special precaution that should be observed in handling. Tablet S contains sodium hydroxide and therefore should not be handled by anyone having wet or damp hands. The tablets are also sensitive to heat. At 120° F. or above the tablets will deteriorate in a short time. The appearance of the tablets reflects their condition. Tablets which are bluish white and slightly spotted will still react satisfactorily. However, if the tablets show blue or black discoloration in spots or in overall appearance, they will not react satisfactorily."

Chapter 101

Microscopic examination

SAM FRANKEL

URINARY SEDIMENTS

There are 2 general types of urinary sediments: organized and unorganized.

Organized sediments include (1) casts—(hyaline, epithelial, granular, blood, waxy, mixed, cylindroids, and false or pseudocasts.) (2) epithelial cells, (3) leukocytes or pus cells, (4) erythrocytes, (5) spermatozoa, (6) urethral filaments, (7) tissue debris, (8) animal parasites, (9) fibrin, (10) microorganisms, and (11) foreign substances in urine.

Unorganized sediments include (1) crystals (ammonium magnesium phosphate [triple phosphate], calcium oxalate, calcium phosphate, calcium sulfate, calcium carbonate, uric acid, cystine, cholesterol, hippuric acid, leucine, tyrosine, and sulfonamides) and (2) urates.

Preparation of sediment

1. Pour the urine to be examined into a 15 ml. conical centrifuge tube. Centrifuge at moderate speed for 3-5 min.
2. Pour off the supernatant fluid. The sediment remains in the tube. Shake the tube to mix the sediment. Use a dropper with rubber bulb. Draw up a drop of sediment in the dropper and place in the center of a glass slide. Place a clean cover glass over the drop. Take care to eliminate bubble formation.
3. Make a survey examination under low magnification to detect the presence of casts, and to determine quantities of cells and crystals present. Then examine under high dry magnification to make a close study of the contents of the specimen.

If a bacteriologic examination is ordered, the procedure is different (see Chapter 31).

Organized sediments

Casts

Tubular casts were originally found in the urine by Henle in 1842. In 1867 Rovida gave a thorough account of their nature and formation. Casts are probably the products of an albuminous exudate from the blood vessels with addition of swollen and destroyed epithelia. In almost all cases in which casts are present albumin is found in moderate or large amount, but there are undoubtedly cases in which the amount of albumin is small or may be entirely absent.

The appearance of casts in the urine is always of the highest diagnostic importance. Hyperemia of the kidneys may suffice to produce casts in the urine, and they can at times be found in small numbers when the kidneys are perfectly normal. They have been described in cases of gastrointestinal inflammation, in jaundice, and in acute and chronic anemia, as well as in nervous affections of different kinds, without any inflammation of the kidneys. In general it may be said that in the majority of cases the presence of tube casts

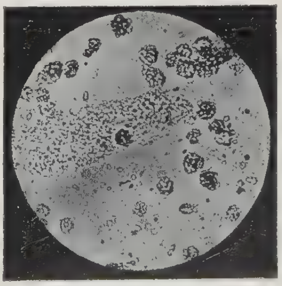

Fig. 619. Pus cells and finely granular cast. (×400.)

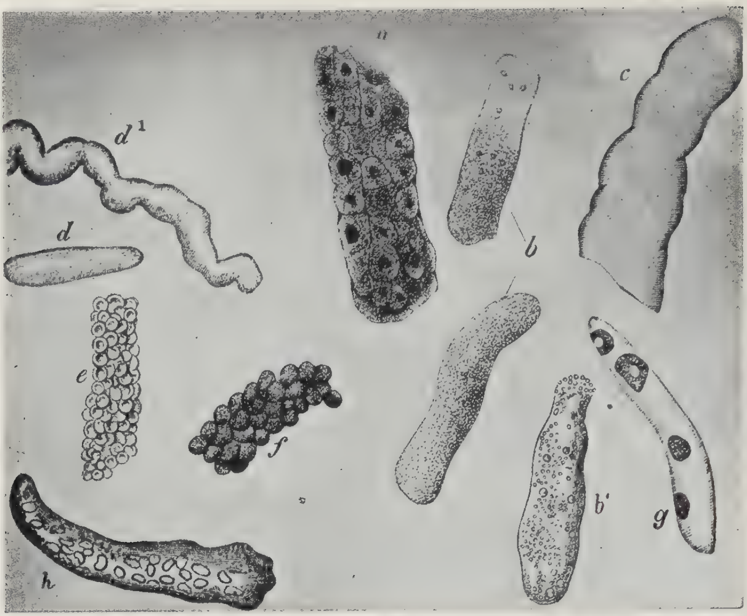

Fig. 620. Urinary casts (Bizzozero). **a,** Epithelial cast; **b** and **b**¹, nuclei; **c,** waxy cast; **d,** hyaline cast; **d**¹, convoluted hyaline cast; **e,** blood cast; **f,** pus cast; **g,** hyaline casts with epithelial and white cells; **h,** waxy cast with cells. (From Sahli, H.: Lehrbuch der klinischen Untersuchungsmethoden für Studierende und praktische Aerzte, Leipzig, 1931, Franz Deuticke.)

signifies the presence of nephritis, but small numbers of hyaline casts may be found in renal congestion unaccompanied by an inflammation.

Casts have been divided in many different ways, but perhaps the simplest is to divide them into **true** casts and **false** casts. The former denote the presence of nephritis, but the latter are accidental formations.

Generally speaking, hyaline, epithelial, and blood casts are found in acute nephritis, whereas granular, fatty, and waxy casts are found in the chronic conditions.

All true casts may appear in 3 distinct sizes, according to the portion of the uriniferous tubules from which they originate. The narrowest casts are those formed in the narrow tubules and the next in size are from the distal convoluted tubules, whereas the largest are always formed in the straight collecting tubules. Casts from the proximal convoluted tubules, those directly arising from the capsule of the tuft, never appear in the urine since they cannot pass the narrow tubules. A certain prognostic value is attached to the size of the casts. The mildest degrees of the disease are indicated by casts from the narrow tubules and a small number of casts from the convoluted tubules. Occasionally, pedunculated casts are found; that is, formations from the place of transition of the narrow tubules into the distal convoluted tubules. Casts of all 3 sizes, the largest arising from the straight collecting tubules, permit a conclusion of chronic nephritis in the whole organ, and upon this condition a very unfavorable prognosis can be established.

Repeated examinations of urine, especially from a mixed 24 hr. voiding, should always be made before an opinion as to the prognosis of a case can be of any value. All the features, chemical, microscopic, and physical findings, must be taken into consideration.

Hyaline casts: Hyaline casts are pale transparent formations of variable length and sometimes of considerable size and are the most difficult forms of renal casts to detect under the microscope. Those from the convoluted and straight collecting tubules are usually more or less regular though the latter may be very broad; those from the narrow tubules are occasionally tortuous or spiral and at times exceedingly narrow and delicate. Different formations, such as pus cells and fat globules, may be seen upon them in small numbers but are accidental and do not change the diagnosis. When casts are very delicate and pale, it is advisable to color the casts by the addition of a drop of iodine-potassium iodide solution (iodine, 1 part; potassium iodide, 2 parts; water, 300 parts) upon the slide, which will stain them yellow and render them more distinct. (See p. 1848 for a stain for urinary casts.)

Epithelial casts: Epithelial casts, when present, always denote an acute process; the more pronounced it is, the larger is the number of these casts. They vary in size according to their origin but are never as long as some hyaline casts and are usually quite regular. The number of epithelia seen upon these casts varies considerably. Sometimes no more than 2, 3, or 4 will be found upon a cast, whereas at other times the cast is completely filled with them, though still showing its structure plainly. Those from the convoluted and narrow tubules contain spherical or slightly irregular epithelia, whereas those from the straight collecting tubules usually contain a number of columnar epithelia. Occasionally these casts are of a yellowish color with a slightly increased refracting power because of their imbibition of the coloring matter of the blood. As long as the nephritis is acute, the epithelial casts will have this appearance. As soon as the inflammation enters the subacute or chronic stage, their character changes, and fat globules appear. We can then no longer consider them pure epithelial casts.

Granular casts: Granular casts rarely appear in strictly acute inflammations. They are perfectly regular and have sharply defined contours, or they are more or less curved or appear curved at one side while they are straight at the other. Their ends are either rounded or partly broken, and they may be broader at one place and narrower in another —a peculiarity especially pronounced in those from the narrow tubules. The granular material of which they are composed consists of albumin, epithelial cells, fat, or disintegrated leukocytes or erythrocytes. Their granulations vary from fine to coarse. They may be coarsely granular at both ends and finely granular in the center or finely granular above and below and coarsely granular in the center. They are due to a disintegration of the kidney epithelia. In cases of long duration the granules are changed into glistening fat granules and globules.

Blood casts: The appearance of blood casts in the urine reveals acute diffuse nephritis, acute congestion of the kidney, or renal hemorrhage. Their appearance varies greatly —they are usually more irregular than the epithelial casts, and their ends are more or less rounded. They may be studded with a varying number of red blood cells without change in color. If they are retained in the tubules for some time, the blood cells lose their shape, and the casts take on the appearance of dark, rust-brown granular clusters. Besides these, conglomerations of fibrin, the so-called **fibrin casts,** are occasionally found, but properly speaking they are not true casts. In the rare cases of hemoglobinuria, irregular dark casts, which appear granular and are composed of disintegrated blood corpuscles—the so-called **hemoglobin casts**—may be quite abundant.

Waxy casts: The chemical nature of waxy casts is different from that of hyaline casts. Waxy casts are characterized by wavy, fluted contours, a high refracting power, a more or less yellowish color, and a high degree of brittleness. They vary in size and are always more or less irregular, sometimes resembling regular corkscrew windings. These casts appear only in chronic processes and never in acute inflammations. Pure waxy casts may be found at times studded with different formations, which, of course, do not change the character of the cast. At times they are extremely large and may then be almost entirely broken in different portions.

Mixed casts: Casts in some cases do not appear in their true form but may be more or less mixed. Any 2, 3, or 4 varieties may be so intermingled as to be difficult of differentiation. There may be an epithelial-granular fatty variety, with the epithelia perfectly intact; combinations of waxy casts, fatty and waxy, granular-fatty and waxy, or blood and waxy casts.

Other casts (cylindroids): Besides these varieties, mucus casts or cylindroids are occasionally found among the true casts. They may contain a varying number of fat globules, but their striated, irregular appearance is sufficient to clarify the diagnosis.

False casts or pseudocasts: These casts have no connection whatever with diseases of the kidney. They are conglomerations of different substances upon mucus threads or casts or accidental formations in the shape of casts. Among these we designate the urate casts which are conglomerations of urates. Ammonium urate casts are described as occurring in infants and forming small, reddish brown masses; they may also be seen in adults, although very rarely. Sodium urate masses, resembling casts, may be mistaken for granular casts, but they have the characteristic yellowish brown color of sodium urate and show no outlines. We sometimes see a formation composed of granules of sodium urate changing to globules and dumbbells.

Among the other **pseudocasts** the more common are bacterial, pus, fat, and fibrin casts.

Bacterial casts: These casts occur frequently, especially when the urine has been allowed to stand in a warm room for 12 hr. or more so that a large number of bacteria have developed. They vary considerably in size, but their outlines are pale and more or less irregular. They are composed of masses of micrococci, not of granules. In order to clarify their diagnosis, it may in rare cases be necessary to add 1 or 2 drops of some strong mineral acid or alkali, to which they will be seen to have a great resistance.

Pus casts: Pus casts are sometimes found. The pus cells may be massed together, with no outlines visible, or they may be more loosely arranged and may contain a number of small fat globules. They indicate renal suppuration.

Fat casts: Fat pseudocasts are rare but they have been found in a few cases of so-called lipuria. They consist of large fat globules, of a very high refraction, and occasionally contain margaric acid needles.

Fibrin casts: These casts are found in cases of hemorrhage. They are large, have irregular, more or less sharply defined contours, and are of a yellowish or yellowish brown color.

Stain for urinary casts

The technic of Behre and Muhlberg[30] is very useful in the study of the structure and composition of urinary casts.

Reagents:

1. Aqueous solution eosin Y, 0.5%.
    (a) Dissolve 500 mg. eosin Y in 100 ml. distilled water.
2. Methyl blue-picric acid solution.
    (a) Add 1 ml. 1% aqueous solution of methyl blue to 10 ml. saturated picric acid solution. Use Merck reagent picric acid.
    (b) Add 10 drops glycerol to each 10 ml.*

Procedure:

1. Centrifuge the urine and decant the supernatant liquid.
2. Add to the sediment 1 drop eosin solution and mix by shaking from side to side.
3. After 1 or 2 min. add 2 drops methyl blue-picric acid solution and mix. The color of the sediment should be distinctly blue-green. If it is reddish brown, add more of the blue solution until the blue-green color is obtained but do not add too much.
4. Transfer some of the stained sediment to a glass slide, cover with a cover glass, and examine under the microscope.

The quantities of the stains added to the urine may be varied according to the amount of sediment. If the cells are not red enough, add more eosin to the sediment. Enough methyl blue should be in the stain to impart a distinct blue color to the casts, but too much stain will make them too dark.

To make permanent mounts, add more glycerol to the sediment and seal the edges of the cover glass with balsam.

By the use of this staining method, hyaline casts are stained a clear blue of varying intensity. The more irregularly shaped bodies, sometimes classed as cylindroids, are similarly stained. An irregular distribution of material, a mealy structure, or a striated appearance sometimes appears in bodies which seemed perfectly homogeneous before staining. Mucus threads and amorphous mucous material are also stained blue, making the differentiation from castlike bodies very evident. Mixed, finely granular casts present a striking picture of fine, dark granules powdered over the light blue hyaline body. Some coarsely granular casts are stained deep blue, the granules of others are yellow, orange, or dark reddish brown. Renal epithelial cells are usually red, sometimes orange or yellowish. Red blood cells are stained a brighter red. Pus cells are usually red, occasionally blue; epithelial cells from the urinary passages are either red or blue. Fat globules are unstained. In cells undergoing fatty degeneration, the fat globules are seen strikingly against reddish cellular material.

By the use of this stain, possible differences in structures otherwise undifferentiated may be made out. In general, the method deserves adoption and further investigation.

The preparation of permanent slides of urinary sediment has been described by Dixon and Holmes.[30a] Using a preserving medium of gelatin, glycerin, phenol, and water they have been able to retain slides in good condition for several years.

Interpretation of casts in urinary sediment: It is known from life insurance statistics that casts, either hyaline or granular and either intermittent or constant, may herald the onset of cardiovascular renal disease about 10 yr. before the cardiovascular renal apparatus is seriously affected. Too much attention, therefore, cannot be paid to the microscopic examination of urinary sediment.

The finding of casts of various types in urinary sediment provokes the question of just what significance should be attached to this finding. First, in order to answer the question the types of casts must be discussed separately. Hyaline casts, for instance, are often found in urine of healthy people after exercise. Their presence does not always parallel the quantity of albumin in cases of renal albuminuria. During recovery from acute nephritis, they may be present for some time after albuminuria has disappeared. Hyaline casts are frequently found in jaundice without any accompanying albuminuria.

---

*Instead of methyl blue solution, 1.5 ml. of blue-black fountain pen ink added to 10 ml. saturated picric acid may be used. The dye used in these inks is evidently similar to methyl blue. The results with ink solutions are almost as good as those with methyl blue.

The presence of granular casts is always indicative of a severe degenerative process in the tubular epithelium. One may expect, however, to find isolated granular casts without severe renal disease as in chronic passive congestion or febrile albuminuria.

Epithelial casts have the same significance as granular casts; namely, isolated single casts are of little significance, but a large number indicates renal degeneration.

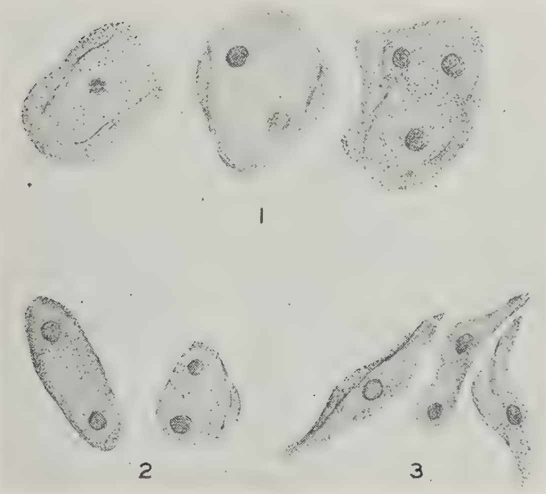

Fig. 621. Epithelia from vagina. **1**, Upper layer; **2**, middle layer; **3**, deepest layer.

Fatty casts are found in the later stages of severe acute nephritis and the subacute and chronic stages of the disease, as well as in the nephroses.

Waxy casts are found whenever there are severe degenerative changes in the kidney existing over a long period of time. At one time they were believed characteristic of the amyloid kidney, but this has been disproved.

Hemoglobin casts have been found in the presence of hemoglobinuria.

Cylindroids are found in inflammations of the urinary passages, especially in acute disturbances of the renal circulation, such as occur from embolus formation in the renal artery.

In summary, granular, epithelial, fatty, and lipoid casts indicate degenerative changes in the tubular epithelium.

Epithelial cells

There are 3 kinds of epithelia: (1) flat or squamous, (2) cuboidal, and (3) columnar or cylindrical.

Squamous epithelial cells are large, are more or less irregular in outline, and exhibit a broad front surface, whereas in edge view they are narrower and somewhat spindle-shaped. They are granular and possess one or more nuclei. Occasionally a nucleus drops out, leaving a vacuole.

Cuboidal epithelia have about the same diameter in all directions, whereas **columnar epithelia** are elongated in one direction. Columnar epithelia may be ciliated, having one or more delicate hairlike prolongations on the outer surface. All epithelia are granular and possess one or more nuclei.

MIDDLE LAYER
DEEPER LAYERS
UPPER LAYERS

Fig. 625. Epithelia from bladder.

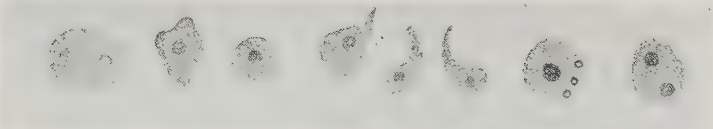

Fig. 626. Epithelia from ureters.

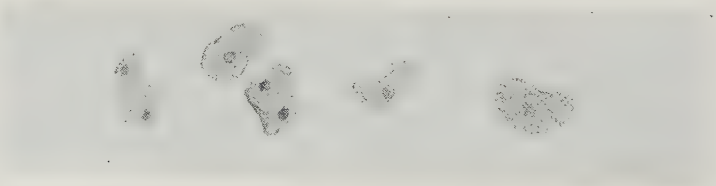

Fig. 627. Epithelia from pelvis of kidney.

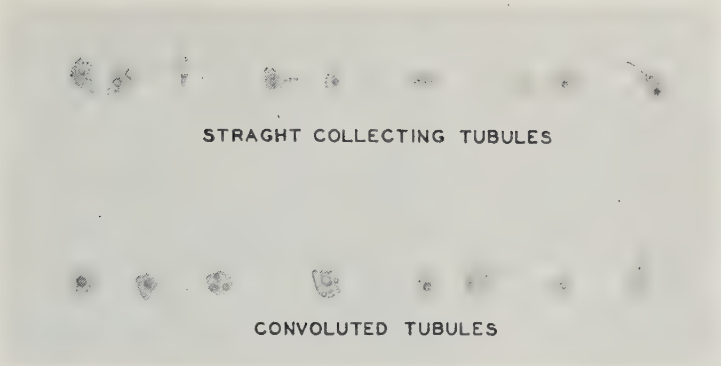

Fig. 628. Epithelia from uriniferous tubules.

Epithelia may occur in a single layer or may be stratified. They change in appearance to a certain extent in urine.

Epithelia from the **bladder** are of 3 distinct types; those from the upper layers are flat or squamous; those from the middle layers are cuboidal; those from the deepest layer are columnar. Squamous epithelia are insignificant in the urine except when they appear along with pus cells.

Epithelia from the **pelvis of the kidney** are smaller than those from the bladder but larger than those from the ureters. The majority of the pelvic epithelia are caudate, pear-shaped, or lenticular, although they are sometimes quite irregular. The regular cuboidal shapes, smaller than those from the bladder, are less numerous.

Epithelia from the **ureters** are rarely found alone but usually with those from the pelvis of the kidney. They are round, globular, or slightly irregular when seen in urine and are distinctly smaller than those from the pelvis. They closely resemble the epithelia from the prostate gland. Occasionally small columnar epithelia from the deeper layers are found.

Epithelia from the **uriniferous tubules** of the kidneys are very important. They are of 2 kinds: the cuboidal from the convoluted tubules and the columnar from the straight collecting tubules. They are distinctly smaller than either those from the pelvis of the kidney or from the ureter in the same case, though their sizes vary to a certain degree in different cases. They are round, globular, or slightly irregular. They are about ⅓ larger than pus cells.

Leukocytes or pus cells

Leukocytes or pus cells are larger than erythrocytes and smaller than renal cells. They are about the same size as or slightly larger than the nuclei of the large squamous epithelial cells. They contain one or more nuclei which are rendered distinct by the addition of acetic acid. They are dull grayish, and many are granular.

Erythrocytes

Erythrocytes appear in the urine as normal biconcave or crenated disks, usually shiny and light-refractive. They are smaller than pus cells, have no nuclei, and dissolve in acetic acid. They must not be confused with yeast cells.

The pathologic conditions in which erythrocytes are found in the urinary sediment are as follows: hemorrhage of the kidney, hemorrhage of the urinary tract, hemorrhage from congestion, traumatic hemorrhage, and hemorrhagic diathesis.

Spermatozoa

Spermatozoa appear after coitus or in the following conditions: diseases of the genital organs, nocturnal emissions, and epileptic and other convulsive attacks. They may or may not be motile. They have an oval body and a long delicate tail.

Urethral filaments

These peculiar threadlike bodies may be found in normal urines and also in the following pathologic conditions: acute gonorrhea, chronic gonorrhea, and urethrorrhea. These filaments are generally macroscopic. The first morning urine is the best specimen for filaments.

Tissue debris

The finding of fragments of tissue may sometimes be of assistance in defining a pathologic condition. These tissues may be found in the following pathologic conditions: tubercular

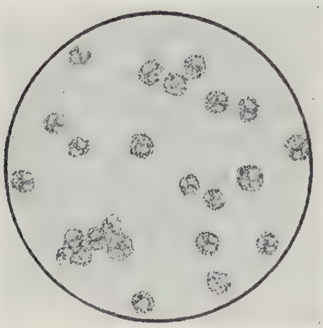

Fig. 629

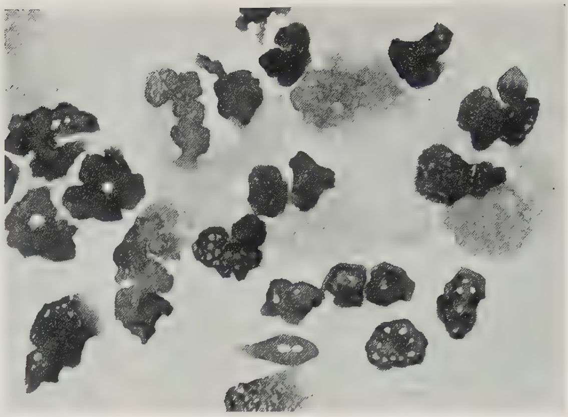

Fig. 630

Fig. 629. Pus cells in urine (unstained). (×400.)

Fig. 630. Pus cells in urine (stained). (×950.)

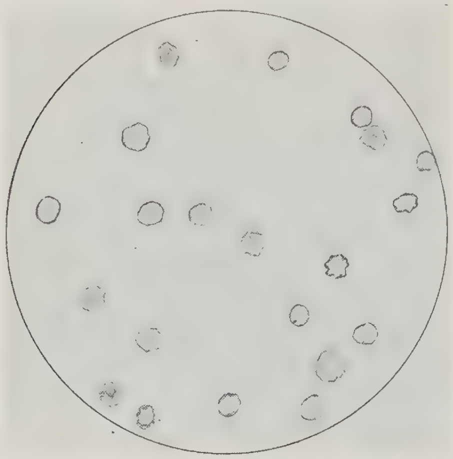

Fig. 631

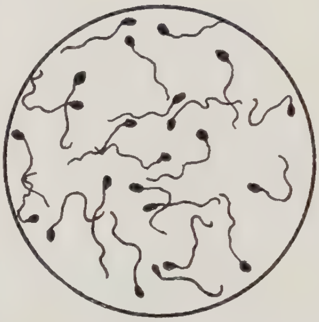

Fig. 632

Fig. 632. Schematic drawing of human spermatozoa (unstained). (×400.)

affections of the kidney, tubercular affections of the urinary tract, tumor of the kidney, and tumor of the urinary tract. It is necessary, however, to make a histologic examination of these tissue fragments before coming to a final conclusion as to their origin.

Fibrin

Fibrin clots are occasionally found in the sediment of urines following hematuria.

Microorganisms

Fresh urine does not contain any organisms and is usually considered sterile when obtained directly from the bladder, but it may be contaminated when voided by bacteria present in the urethra or vagina. Bacteria develop in a short time in urine when it is allowed to stand and are present in large numbers in pathologic conditions. Such urine is turbid, and the condition is called bacteriuria.

Microorganisms in urine may be nonpathogenic or pathogenic. The nonpathogenic microorganisms found in urine are the mold fungi, such as *Candida, Penicillium glaucum,* or one of the aspergilli.

Yeast fungi are found in acid urine, especially in urine containing sugar. They consist of variously sized globules or cells. In the larger globules the process of budding can be seen. The most common organism found in urine is the *Micrococcus ureae.* This coccus causes ammoniacal decomposition of urine, urea being transformed by it into ammonium carbonate.

See Chapter 31 for complete bacteriologic examination of urine.

Animal parasites

The most common animal parasite found in the urine is the *Trichomonas vaginalis.* It frequently causes symptoms (vaginitis, cystitis). It is an oval organism with a tail-like extremity, with rapid motility.

Echinococci are occasionally found in urine and may have developed directly in the urinary organs or may have ruptured into them from some neighboring organ. The characteristic parts of the echinococci found in the urine are the hooklets as well as portions of the membrane. Scolices may also be found. These scolices are small and round and are supplied with a wreath of hooklets. When echinococci are found in urine, there is also evidence of hemorrhage or ulceration or both. Red cells are numerous, together with epithelia and connective tissue shreds as well as pus cells. The eggs of the parasite *Schistosoma haematobium* are found in the urine but not the parasite itself. The eggs are oval or flasklike in shape and taper considerably at one extremity, the other being rounded.

Filaria appears in the urine at times, causing severe hematuria or chyluria. When a milky urine, indicating chyluria, is found, an examination for filaria must be made. In examining urine for filaria, it is advisable to take the first urine voided in the morning since it is a well-known fact that the parasite is active in the night *(Filaria nocturna* or *Wuchereria bancrofti)* or during the resting hours of the patient, whereas it is quiescent during the working hours and cannot be found.

Ascaris lumbricoides, a common worm in children, may be found in the urine, having passed into the bladder through the urethra. Other parasites which may possibly be found in the urine are *Strongylus gigas, Enterobius vermicularis,* and *Cercomonas urinarius.*

Refer to p. 1011 for a discussion of parasites.

Foreign substances in urine

Care must be taken not to overlook foreign substances in the urine which may be mistaken by beginners for pathologic changes in the body. These substances are starch granules, hair, feathers, muscle fibers, particles of fat, fibers of silk, cotton, wool, etc. The presence of these materials may be due to many causes, such as exposure to air, pouring the urine into bottles which are not perfectly clean, the use of salves or dusting powders for the genital organs, or admixtures of particles from the feces. Human hairs are not infrequently found in the urine and may be known by the flat epidermal scales, firmly attached to each other, which form the main mass of the hair and by the varying amount of pigment. Feathers may appear in branching

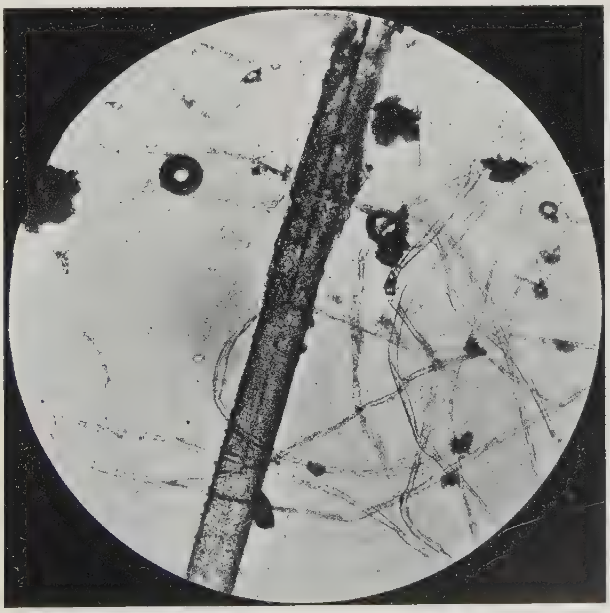

Fig. 633. Artifacts—hair, air bubble, cotton threads, soot. (×200.)

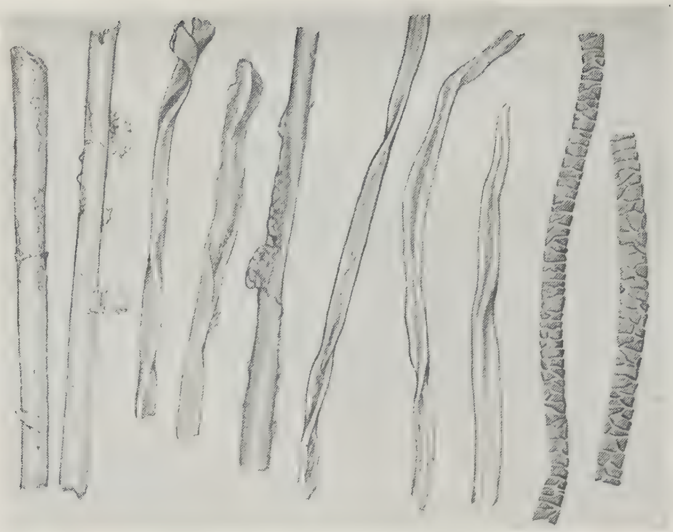

Fig. 634. Fibers—silk, linen, cotton, and wool.

formations. Scales from the wings of insects such as moths may also be found. They are more or less delicate serrated plates with a stemlike projection and vary considerably in length and breadth.

Starch globules are frequently seen in the urine. They are round or oval, are highly refractive, and vary greatly in size. The three most frequently found in the urine are rice starch, cornstarch, and wheat starch. Rice starch shows oblong even globules of medium size. Cornstarch is smaller, irregular, and at times almost hexagonal and contains an irregular hilum. Wheat starch consists of large globules as well as of small irregular formations in which the hilum may be entirely absent or is present only in the form of a dot.

Lycopodium, similar to starch and used as a dusting powder, consists of globular formations of different sizes, with a distinct shell; these globules are sometimes found in urine. Cellulose occurs in the urine in a variety of forms, sometimes in small and sometimes in large masses. A common variety of cellulose found in urine is cork occurring as single cells and having a yellowish brown color. Oil globules and air bubbles are commonly found in urine. They may be very large or extremely small, are either perfectly round or irregular, are of high refraction, and can frequently be differentiated by their yellowish color.

Flaws in glass as well as scratches in the cover glass may lead to mistakes in diagnosis. Flaws are irregular in size and shape and frequently resemble the wings of a butterfly. They show a faint blue refraction and are usually pale. Rust particles in both the cover glass and slides also occur and are larger or smaller dark or rust-brown irregular masses which must not be mistaken for coloring matter in the urine. Vegetable matter of different forms may be found in the urine as an admixture from the feces. Normal feces may occasionally be found mixed with urine, and their constituents must be known. If they are present and their accidental admixture can be excluded, the diagnosis of a fistula can be made. Among the particles seen from these sources are partly digested muscle fibers with many striations plainly visible, small numbers of connective tissue shreds from the meat diet, and mucus threads and mucus corpuscles.

Unorganized sediments

Crystals

Ammonium magnesium phosphate (triple phosphate) crystals: These crystals are found when the urine has undergone alkaline fermentation, either before or after being voided, and are crystallized in 2 forms: prisms and star-shaped, feathery crystals. These crystals may rarely appear in amphoteric or faintly acid urines, provided that the ammonium salts are present in large enough quantity. The pathologic conditions in which these crystals are frequently abundant are as follows: retention of urine in the bladder, paraplegia, chronic cystitis, enlarged prostate, and chronic pyelitis.

Calcium oxalate crystals: These crystals appear in the urinary sediment in at least 2 forms, i.e., octahedral and dumbbell. They

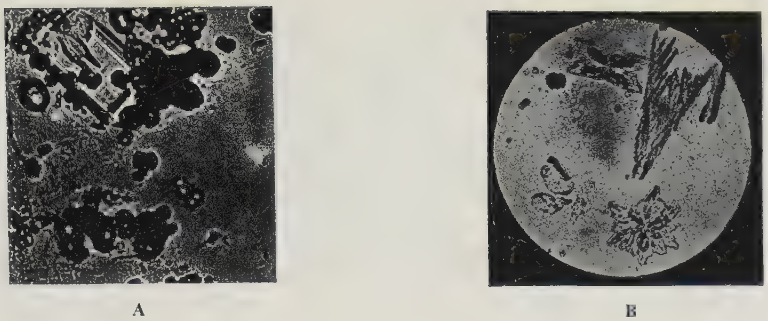

Fig. 635. **A,** Triple phosphate and ammonium urate crystals (×400). **B,** Incomplete triple phosphate (×400).

may be found in acid, neutral, or alkaline urines but are most frequently found in acid urines. Calcium oxalate crystals are found in normal urines but are increased in the following pathologic conditions: diabetes mellitus, organic diseases of the liver, diseases of the heart, and diseases of the lungs.

These crystals are found in the urine after ingestion of tomatoes, garlic, rhubarb, oranges, asparagus, etc.

Calcium phosphate (stellar phosphate) crystals: These crystals may occur in the urine in the amorphous, granular, or crystalline forms. They are wedge-shaped and often appear in rosette arrangements. They are sometimes mistaken for sodium urate but may be distinguished from the latter by adding acetic acid. Acetic acid will readily dissolve the phosphate, whereas the urate is much less soluble. The pathologic conditions in which calcium phosphate crystals are abundant are as follows: retention of urine in the bladder, paraplegia, chronic cystitis, enlarged prostate, and chronic pyelitis.

Calcium sulfate crystals: These crystals are very rarely seen and are found only in acid urines. They appear as long, thin, colorless needles or prisms and may be mistaken for calcium phosphate. They are readily distinguished, however, by the fact that calcium sulfate crystals are readily soluble in acetic acid. Calcium sulfate crystals are of practically no clinical importance.

Calcium carbonate crystals: These crystals are almost always in alkaline urine but may occur in amphoteric or faintly acid urine. They very frequently appear in the dumbbell shape and can be differentiated from calcium oxalate inasmuch as they dissolve in acetic acid with the evolution of carbon dioxide gas, whereas calcium oxalate remains unchanged in acetic acid.

Fig. 639. Calcium sulfate crystals. (×400.)

Fig. 640. Calcium carbonate crystals. (×400.)

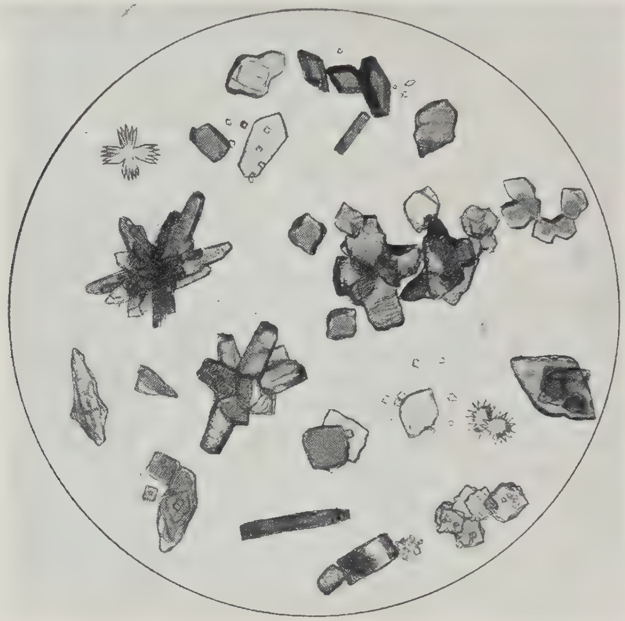

Fig. 641. Uric acid crystals.

Uric acid crystals: These crsytals appear in acid urines in the following forms: wedge-shaped, dumbbells, rhombic prisms, whetstones, prismatic rosettes, and irregular or hexagonal plates.

They generally appear in the urine colored brownish red although occasionally they are colorless. The presence of uric acid in the urinary sediment does not necessarily indicate any pathologic condition; neither does it mean that the uric acid content of the urine is increased. The pathologic conditions in which uric acid is found in the sediment are as follows: gout, acute febrile conditions, and chronic nephritis.

Cystine crystals: These crystals are rarely found in urinary sediments but may produce concretions in the bladder. Cystine is insoluble in water, alcohol, and acetic acid and is soluble in hydrochloric acid, alkalies, and especially in ammonia. This solubility in ammonia distinguishes it from uric acid. Cystine contains considerable sulfur. Cystine occurs in all members of certain families instead of uric acid, and in such families it appears to replace uric acid; in them cystine calculi are not uncommon. Cystine consists of hexagonal colorless plates of moderate sizes and of high refraction which, in side view present 1 perfect facet and 2 imperfect neighboring facets. A number of plates may lie together, one upon an-

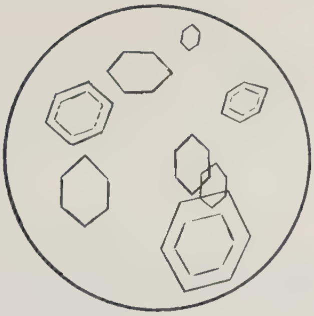

Fig. 642

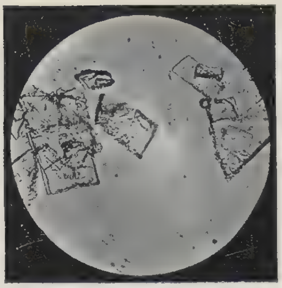

Fig. 643

Fig. 642. Cystine crystals.

Fig. 643. Cholesterol crystals. (×200.)

other, or they may form more or less regular masses.

Cholesterol crystals: These crystals are rarely found in urinary sediments. They ordinarily crystallize in regular and irregular colorless plates which are transparent. They may occasionally be found as a film on the surface of the urine instead of in the sediment. The pathologic conditions in which cholesterol crystals have been found in the urine are as follows: cystitis, pyelitis, chyluria, and nephritis.

Hippuric acid crystals: These crystals are rarely found in urinary sediments; they appear as needles or prisms which are generally pigmented like uric acid crystals. They are more soluble in water and ether than are uric acid crystals and have practically no clinical significance.

Leucine and tyrosine crystals: These crystals almost always appear in the urine together, in solution or as a sediment. Leucine crystallizes in characteristic spherical masses and is highly refractive. Tyrosine crystals appear as sheaves of very highly refractive needles.

The pathologic conditions in which leucine and tyrosine have been found are acute yellow atrophy of the liver, acute phosphorus poisoning, cirrhosis of the liver, severe cases of typhoid fever, severe cases of smallpox, and leukemia.

Urates

Urates may appear as ammonium, calcium, magnesium, potassium, and sodium urate. The calcium, magnesium, potassium, and sodium urates appear in acid urines, whereas the sediment of ammonium urate appears in neutral, alkaline, or acid urines.

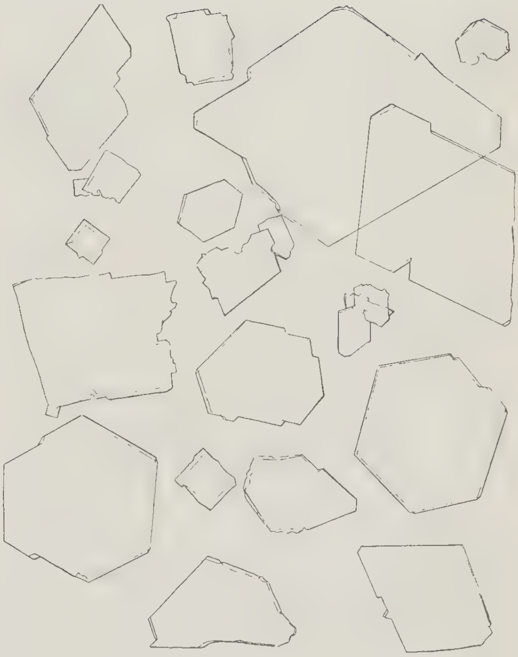

Fig. 644. Cholesterol crystals.

Sodium urate: Sodium urate may be amorphous or crystalline. When crystalline it appears in sheaves or clusters of colorless needles.

Ammonium urate: Ammonium urate generally appears in the burrlike form of the thornapple which appears to be balls with spicules attached. The pathologic conditions in which urates may appear in the urine are somewhat similar to those of uric acid.

Morphology of urinary crystals appearing during administration of sulfonamide drugs

The literature on the specific appearance of crystals produced during administration of sulfonamide drugs is somewhat scant. Lehr and

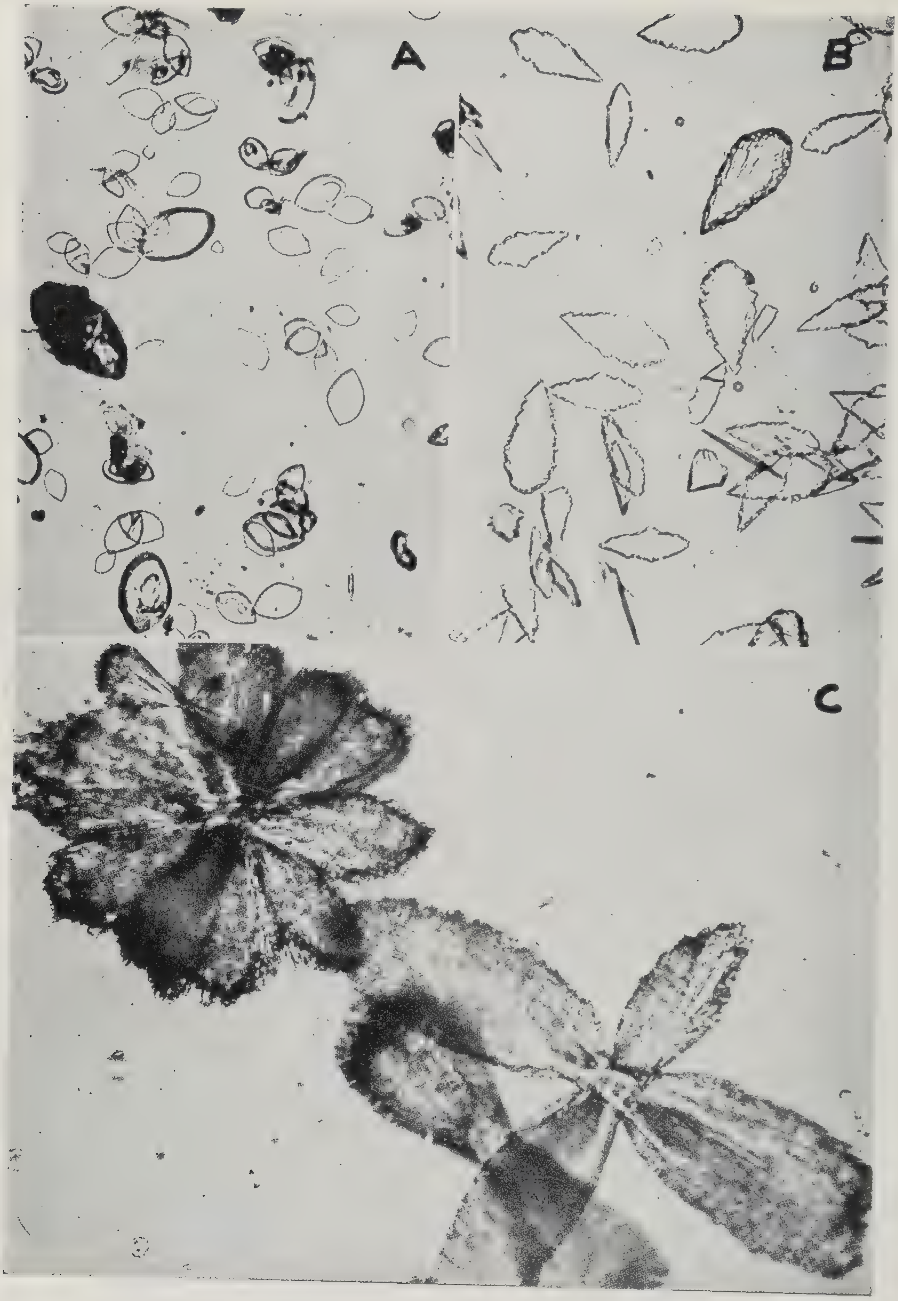

Fig. 651. Urinary crystals of acetylsulfapyridine. **A,** "Whetstones." Most common form; varying considerably in size (0.008 × 0.01 to 0.05 × 0.08 mm.), they are transparent, colorless, and usually show notching of serration of one or both edges. **B,** "Arrowheads" (0.016 × 0.56 to 0.04 × 0.92 mm.), similar to **A,** but wedge-shaped, presenting one sharp point and pronounced sawlike identification of one or both sides. The base is rounded and shows irregular notchings. **C,** Centrally waisted sheaves composed of needlelike crystals, usually rather large, as also pictured by Sadusk et al.; (largest crystal in the photograph 1 × 4 mm.). These sheaves may conglomerate and form crosslike and starlike structures. (×176.) (From Lehr, D., and Antopol, W.: Am. J. Clin. Path. **12:**4, 1942.)

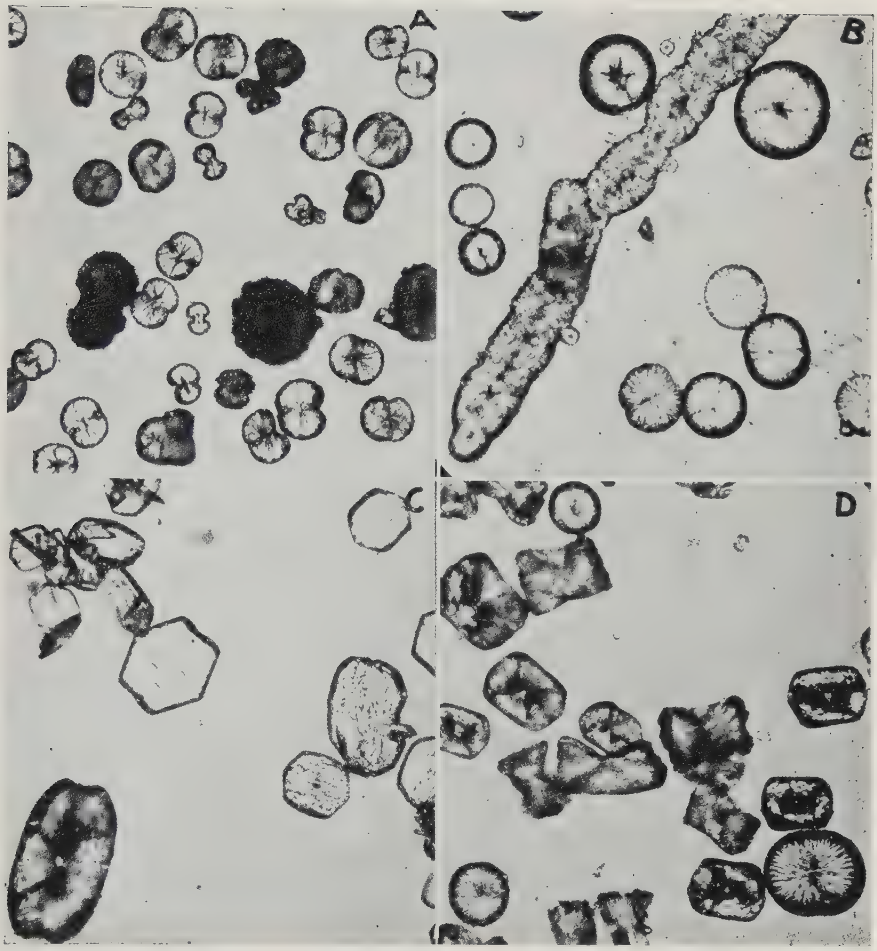

Fig. 652. Urinary crystals of acetylsulfathiazole. **A,** Dumbbells or "shocks of wheat with central binding"; the crystals start as small slender sheaves and grow in such a way that the 2 half-circle parts finally close up to form a rosette (0.004 × 0.06 to 0.06 × 0.08 mm.). **B,** Rosettes (0.04-0.1 mm.), the large rodlike structure consisting of acetylsulfathiazole, may represent a "crystalline cast." On microscopic examination both crystal forms (**A** and **B**) appear amber green and show pronounced radial striation. **C,** Hexagonal platelets (0.04 × 0.06 to 0.15 × 0.2 mm.). Sometimes very thin glass-clear, more often thick amber green with a distinct envelope-like pattern. Some of the crystals may reach considerable size and 2 opposite edges may appear indented resulting in shapes as shown in the right lower corner of the photograph. **D,** Simultaneous presence in the same urinary specimen of the 3 forms outlined in **A, B,** and **C,** a rather frequent observation. (×125.) (From Lehr, D., and Antopol, W.: Am. J. Clin. Path. **12**:4, 1942.)

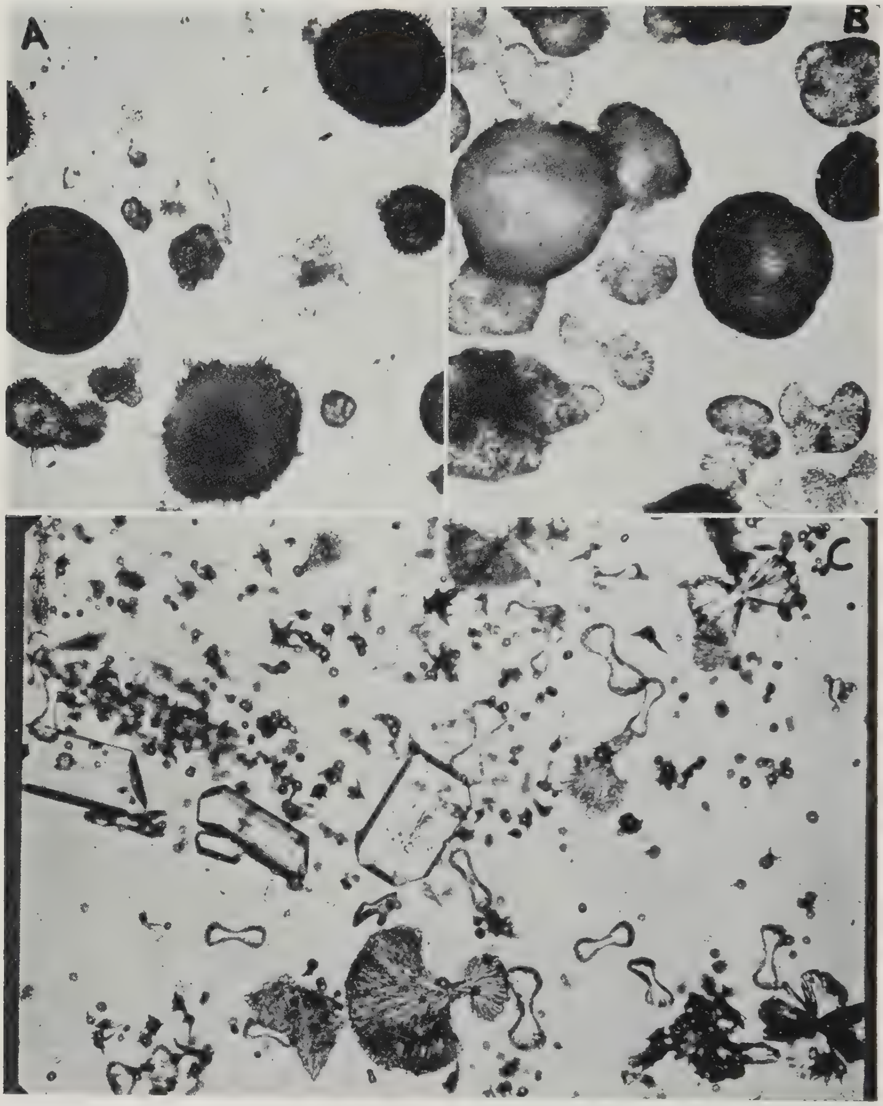

Fig. 653. Urinary crystals of sulfadiazine and acetylsulfadiazine. **A,** Dark, muddy green globules, sometimes covered with needlelike processes (chestnut burr forms), consisting almost entirely of free sulfadiazine (0.03-0.16 mm.). **B,** Among "globules" containing free sulfadiazine, "shocks of wheat with excentric binding" and "shell" forms, consisting mainly of acetylsulfadiazine. Like the corresponding sulfathiazole crystals they are amber green and have a conspicuous radial striation (0.02-0.14 mm.). **C,** Urinary sediment of a patient who had been switched from sulfathiazole to sulfadiazine treatment 24 hr. before voiding the urine specimen containing these crystals. A perfect "shock of wheat with excentric binding" (acetylsulfadiazine) can be seen among symmetrical dumbbells (acetylsulfathiazole). Also present are typical phosphate and monourate crystals. (×150.) (From Lehr, D., and Antopol, W.: Am. J. Clin. Path. **12:**4, 1942.)

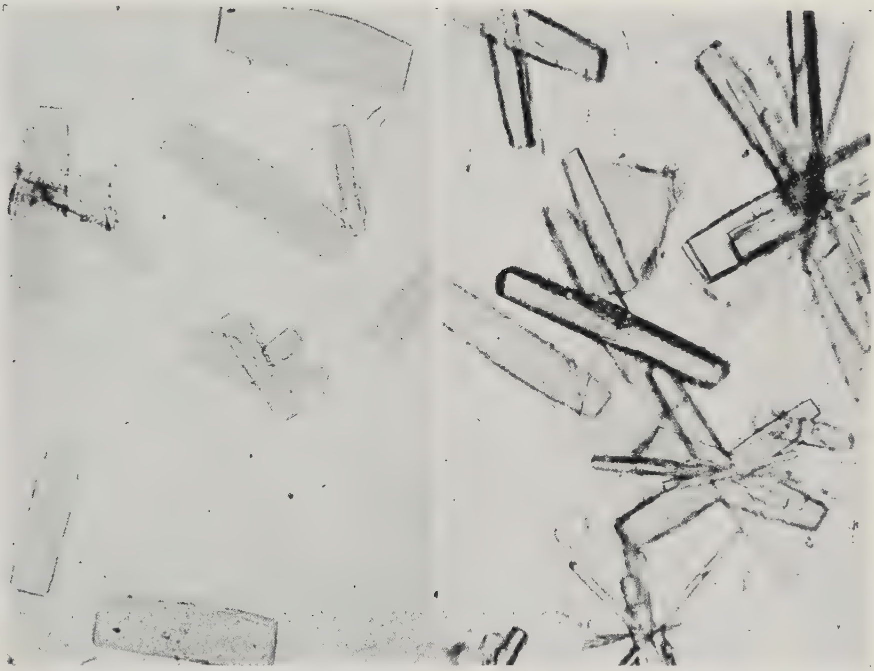

Fig. 654. Urinary crsytals of acetylsulfaguanidine. Simple rectangular oblong plates with slight bulging in the long axis. Markedly varying in size (0.02 × 0.09 to 0.05 × 0.24 mm.), these plates are either glass-clear or have a fine meshlike pattern, which makes them appear like isolated plant cells or slender tapeworm proglottides. They tend to conglomerate, forming crosslike or starlike structures. Repeatedly slender sheaves of needle crystals were seen interspersed among the plates (center in the upper part of the right photograph). (×138.) (From Lehr, D., and Antopol, W.: Am. J. Clin. Path. **12**:4, 1942.)

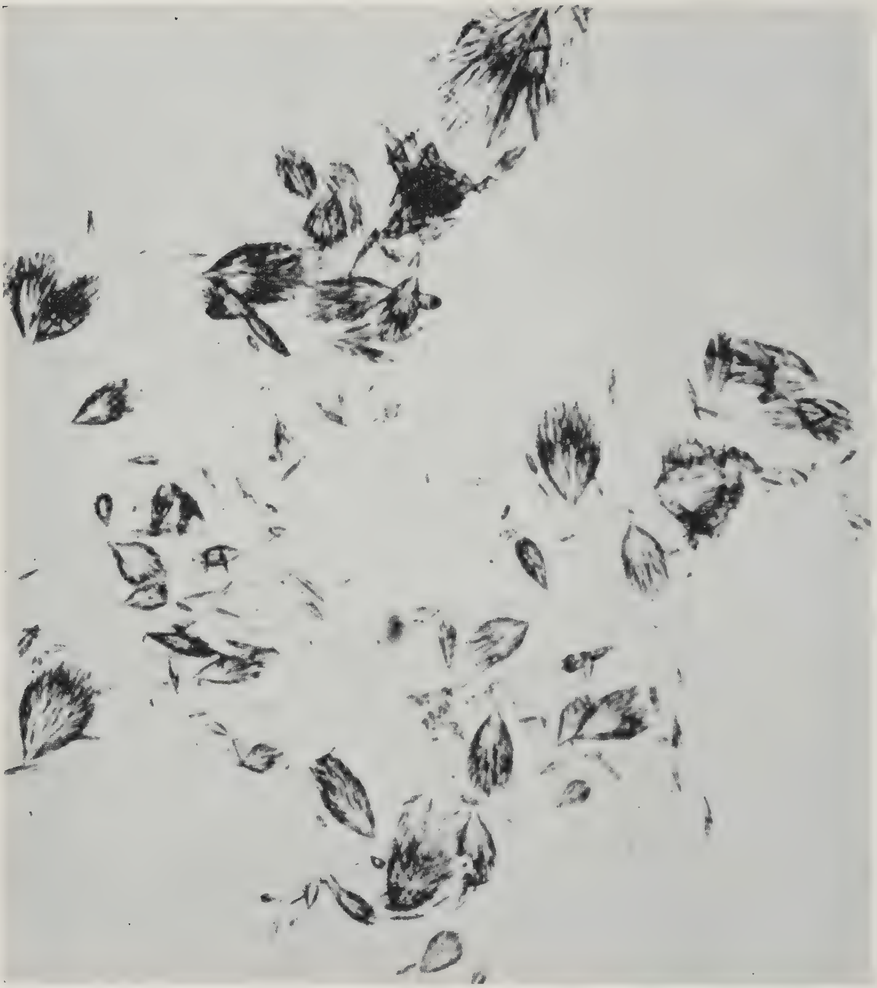

Fig. 655. Featherlike tufts of needle crystals, amber green, observed in urine of patient receiving sulfamethylthiazole. Unfortunately these crystals were not saved for analysis. The general discontinuance of sulfamethylthiazole therapy makes further investigations difficult. (×250.) (From Lehr, D., and Antopol, W.: Am. J. Clin. Path. **12**:4, 1942.)

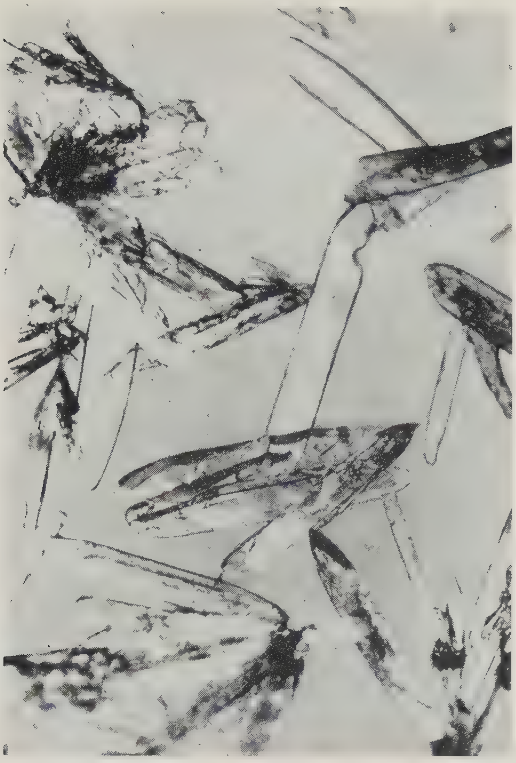

Fig. 656. Crystalline form of the sodium salt of penicillin G. (Courtesy Merck & Co., Inc., Rahway, N. J.)

Antopol[31] have made a study of this question on 260 individual urinary specimens from 175 patients to whom these various drugs have been administered. The drugs studied were sulfapyridine, sulfathiazole, sulfadiazine, and sulfaguanidine. They state that the frequency and quantity of these crystals in the urine are apparently related to the solubility of the sulfanilamide compounds and their acetylated compounds. The comparatively insoluble acetyl derivatives formed in the body from sulfapyridine, sulfathiazole, and sulfadiazine, if analyzed as urinary crystals, show a depressed melting point and a solubility which is about twice as high as that of the chemically acetylated drugs. This is true, too, of artificially produced urinary crystals. When one recrystallizes these substances from water, the shapes of these crystals and their melting points and solubility values approach those of the synthetic compounds.

The shape of urinary crystals derived from these drugs points to the influence of colloids upon crystal formation. These colloids appearing in the urine of patients taking these drugs may be due to damage to the renal filter apparatus. Lehr and Antopol state that the colloids may assume a protective action by inhibiting the precipitation of poorly soluble substances. The increase in solubility by a colloid-chemical mechanism would render additional explanation to the fact that the concentration of sulfapyridine, sulfathiazole, sulfadiazine, and their acetyl derivatives in the urine of patients treated with these compounds can significantly exceed the solubility of the same drugs in water and normal urine. This fact may be important in preventing precipitation or concrement formation in the urinary tract.

Lehr and Antopol showed photomicrographs (Figs. 651-655) which indicate the specific nature of the crystals of each of these compounds. They did not claim, however, that these pictures show **all** forms possible, nor did they deem it necessary to employ more photographs to show slight variations in the shapes described. They did state, however, that with the aid of these illustrations recognition of the particular drug has been possible on the first microscopic examination of urinary sediment in almost every case.

Chapter 102

Urinary calculi

SAM FRANKEL

Despite a vast amount of clinical observation and experimental research the problem of urinary lithiasis remains unsolved. Causation is believed to be linked with nutrition, although many exceptions exist. The problem of prevention of recurrence in the susceptible individual has been studied at length, and results have not been too successful.

Methods of analysis of urinary calculi have been devised to ascertain their exact composition with the end in view of utilizing this knowledge to prevent recurrence.

OPTICAL AND X-RAY CRYSTALLOGRAPHY

Because of the inadequacies of chemical methods of analysis as applied to identification of urinary calculi, mineralogic methods[32] have been applied, and these methods are presented here.

Urinary calculi can be divided into 2 general classes, crystalline, and amorphous. The term amorphous has been loosely applied to phosphatic concretions that are grossly opaque, dull, chalky, and apparently noncrystalline. With the exception of those exceedingly rare calculi that are composed of fibrin and bacteria it may be stated that all urinary calculi are crystalline. When the so-called amorphous calculi are broken up into a coarse powder and examined under a petrographic microscope, the fragments exhibit optical properties of crystalline substances and also give distinct and characteristic x-ray diffraction patterns.

Optical methods

Chemical compounds tend to form crystals when they pass from a liquid or gaseous state to the solid state. The external geometric form and internal molecular structure of such crystals are distinct, constant, and characteristic for any particular substance. Even when conditions in the environment are unfavorable for the development of visible geometric crystal faces, the formless crystalline mass has the same internal atomic structure.

Light passing through transparent crystalline material is influenced by the crystal structure according to the laws of optics, and these changes in transmitted light can be measured accurately. This results in data called **optical constants.** The polarizing or petrographic microscope is a useful instrument for measuring external and internal physical properties of crystalline material. A series of compounds of known chemical composition is analyzed for optical constants, and unknown substances are recognized by measuring their optical constants and comparing with prepared tables.

Another method is the so-called immersion method in which a minute quantity of coarsely ground calculus is placed upon a glass slide and immersed in a succession of liquids of known indices of refraction. A match is found for the indices of refraction. Other optical constants, including optical sign, axial angle, dispersion, extinction angle, sign of elongation, etc., may be measured at the same time. A milligram of substance is usually required, but measurements can be made on a few microscopic grains by transferring them from slide to slide.

Constituents of urinary calculi are relatively few and markedly different in optical behavior, which makes the problem of identification simple. Only a few diagnostic optical tests need usually be applied to identify a

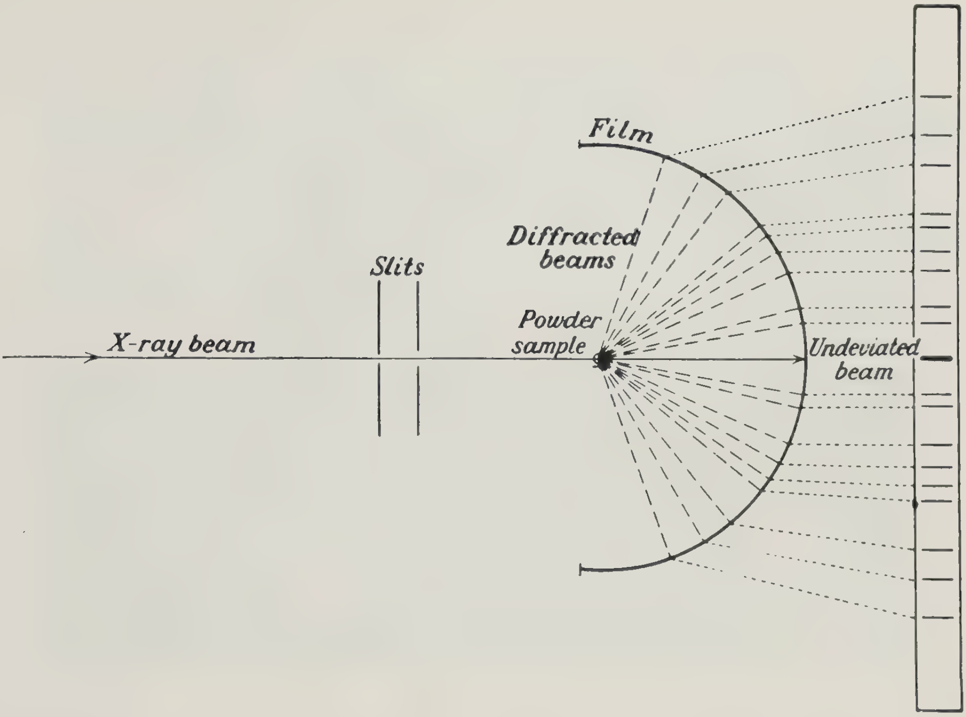

Fig. 657. Diagram showing method of obtaining x-ray powder photographs. (From Prien, E., and Frondel, C:. J. Urol. 57:949, 1947.)

substance. Confirmatory tests can be made at times.

Analysis by x-ray methods—Hull or Debye-Scherrer ("powder" method)

The method consists in irradiating a finely powdered sample of a substance with a beam of monochromatic x-rays and recording the diffracted (reflected) rays in a suitably arranged camera. The rays are reflected from planes of atoms in the substance, to be recorded as a series of lines upon a circular photographic film, forming a characteristic pattern for the substances irradiated. A diagram of the method is seen in Fig. 657. Two methods of identification may be used:

1. Spacings of the lines on the films are measured and the interplanar spacings are calculated for the substance in question. Comparison is made with a tabulated list of interplanar spacings of known chemical substances.*

2. Comparison is made of the unknown patterns with standard x-ray patterns of known substances.

For this method of testing, the size of the sample may be quite small, 1 mg., but 0.1 mg. or even less will suffice. The sample may be first examined optically, then ground to a fine powder and examined by x-ray. It is possible with this method to examine mixtures and to identify the several constituents and to estimate the approximate proportions of each.

Spacing data on x-ray powder diffraction may be obtained in the original article.[32]

TECHNIC OF OPTICAL ANALYSIS

Examination with ordinary light

Equipment:

1. Stereoscopic binocular dissecting microscope.
2. Lamp.
3. Biologic dissection needles (a small machinist's vise fitted with a heavy needle is excellent.
4. Small mortar and pestle for powdering calculi.
5. Watch glasses to hold powdered samples.
6. Corked small glass vials or bottles.
7. Pair of cutting pliers or dental extraction forceps for breaking large or firm stones.

Procedure:

1. Transfer samples of powder to the blade of a small knife. Use watch-maker's forceps or tweezers to transfer individual grains or crystals that have been spotted in a sample under magnification.
2. Fracture of the calculus permits inspection of such structural characteristics as texture, lamination, porosity, and the study of in-

---

*This list is procurable from Dow Chemical Co. or from the American Society for Testing Materials.

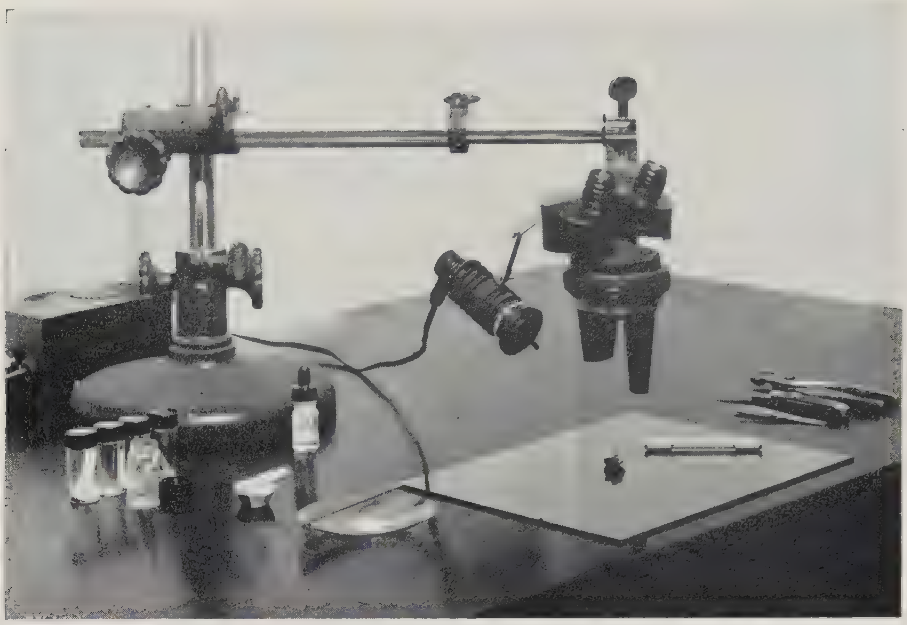

Fig. 658. Equipment for examination of calculus with ordinary light. Includes binocular stereoscopic microscope, lamp (mounted on microscope here), pliers to fracture hard calculi, mortar and pestle to grind calculi, knife blade or spatula to transfer powder, watch glasses to hold powder, pointed tool for picking at laminations, nucleus, etc., stoppered bottles for filing small calculi and powder. (From Prien, E., and Frondel, C.: J. Urol. **57**:949, 1947.)

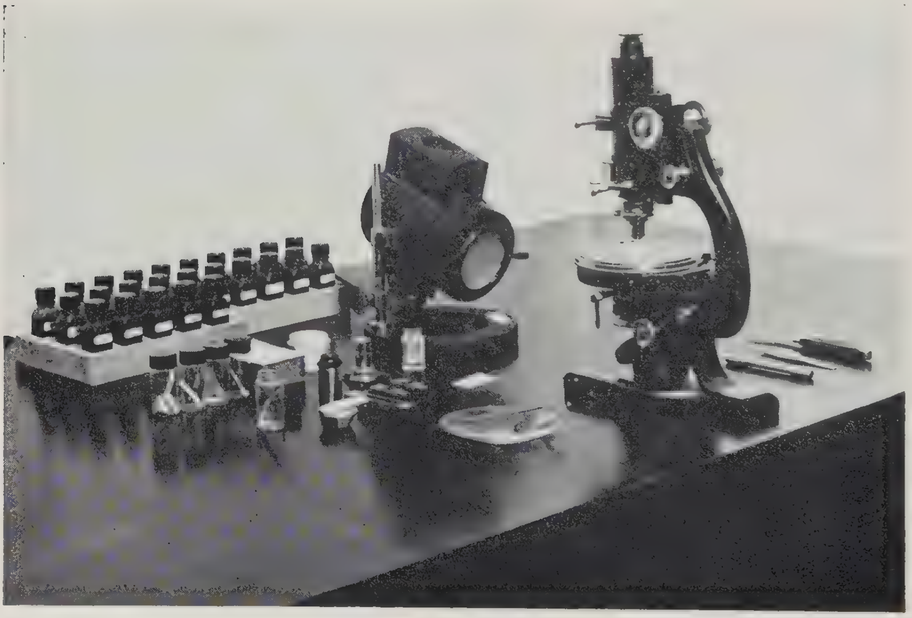

Fig. 659. Equipment for examination of calculus with polarized light. Includes petrographic microscope, lamp, set of immersion liquids with graduated indices of refraction from 1.41 to 1.75 (in bottles in rack), glass slides and cover slips, also implements for examination with ordinary light. (From Prien, E., and Frondel, C.: J. Urol. **57**:949, 1947.)

dividual crystals and is necessary if the nucleus is to be observed. The calculus should be thoroughly dried before analysis is attempted.
(a) Fracture the calculus.
(b) Inspect external and fractured surfaces with the low magnification (10× or 20×) of a hand lens or binocular stereoscopic microscopic (dissecting microscope) (Fig. 658).

Examination with polarized light

1. Remove minute samples with pointed tool and grind to a coarse powder in a mortar with pestle.
2. Place powder upon a glass slide, cover with liquid of known index of refraction, and place a glass cover slip over the specimen. Examine upon the stage of a polarizing microscope (Fig. 659).

Immersion liquids have indices 1.41-1.75, graduated in steps of at least 0.01. Liquids of intermediate index, approximately accurate to 0.005, may be prepared by mixing equal droplets of liquids of 2 adjacent steps in the series. This may be done on the glass slide but is not necessary in routine analysis. Accuracy to 0.01 is sufficient for the differentiation of all the substances in Table 364.

To analyze calculi composed of several components it is possible to approximate the percentage of each component by powdering the entire calculus, stirring the fragments thoroughly to obtain a uniform mixture, and then making grain counts on random samples through the binocular and petrographic microscopes. It is possible to estimate the percentage composition to within 5 or 10%, which is sufficient for most purposes.

CRYSTALLINE COMPONENTS OF URINARY CALCULI

In his studies of urinary calculi, Prien et al. found that pure calcium oxalate calculi constituted 36.1% of the total; mixed calcium oxalate-apatite calculi comprised 31%; or 67.1% of the total were included in this group. These calculi usually but not always occur in acid sterile urine.

Pure magnesium ammonium phosphate hexahydrate, pure apatite, and mixed magnesium ammonium phosphate hexahydrate-apatite calculi comprised 19.5% of the total. These calculi usually but not always occur in alkaline infected urine.

Calcium hydrogen phosphate dihydrate occurred in 1.6% of the calculi.

Uric acid and cystine exist more frequently in pure than in mixed form and occurred in 6.1% and 3.8%, respectively, of the series.

Sodium acid urate occurred but once in the series and in microscopic amount. It was the only urate found.

In a study of approximately 700 urinary calculi only 9 distinct crystalline substances were found. These are divided into the following groups: oxalates, phosphates, uric acid, urates, and cystine.

Calcium oxalate

Calcium oxalate is the most frequent constituent found in urinary calculi.

Calcium oxalate monohydrate (whewellite—$CaC_2O_4 \cdot H_2O$): This is more common than the dihydrate. The simplest form is the small smooth ovoid "hempseed" stone, usually multiple, and consists of concentric laminations, Fig. 660, *1* and *2*.

The second type is the "mulberry" stone of variable size and shape with irregular rounded mammillary processes (Fig. 660, *3* and *4*). On cross section these rounded protuberances are seen to be composed of radially striated aggregates. These radiating fibers are much finer than those of another fibrous constituent of calculi, $CaHPO_4 \cdot 2H_2O$, and may be almost microscopic (Fig. 661, *1*). Some predominately fibrous (radially bladed) calculi may have a finely or coarsely granular nucleus of the same material (Fig. 661, *1*).

The third type of calculus is the uncommon "jackstone" which is usually found in the

Table 363. *Formula and minerologic name of urinary calculi*

Found	*Formula*	*Mineralogic name*
Calcium oxalate monohydrate	$CaC_2O_4 \cdot H_2O$	Whewellite
Calcium oxalate dihydrate	$CaC_2O_4 \cdot 2H_2O$	Weddellite
Magnesium ammonium phosphate hexahydrate	$MgNH_4PO_4 \cdot 6H_2O$	Struvite
Carbonate-apatite	$Ca_{10}(PO_4 \cdot CO_3OH)_6(OH)_2$	Carbonate-apatite
Hydroxyl-apatite	$Ca_{10}(PO_4)_6(OH)_2$	Hydroxyl-apatite
Calcium hydrogen phosphate dihydrate	$CaHPO_4 \cdot 2H_2O$	Brushite
Uric acid	$C_5H_4N_4O_3$	
Cystine	$SCH_2CH(NH_2)—COOH$	
Sodium acid urate (not found but identity established)	$NaH \cdot C_5H_2O_3N_4 \cdot H_2O$	
Tricalcium phosphate (not found but identity acceptable)	$Ca_3(PO_4)_2$	Whitlockite
Indigo	$C_{16}H_{10}N_2O_2$	
Xanthine	$C_5H_4N_4O_2$	

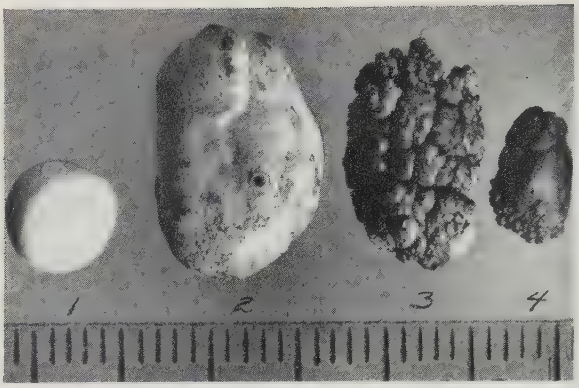

Fig. 660. Calcium oxalate monohydrate ($CaC_2O_4 \cdot H_2O$) calculi. **1** and **2**, Calculi of "hemp-seed" variety, small, smooth. **3** and **4**, Calculi of "mulberry" variety, externally showing rounded mammillary surfaces. Scale in millimeters. (From Prien, E., and Frondel, C.: J. Urol. **57**:949, 1947.)

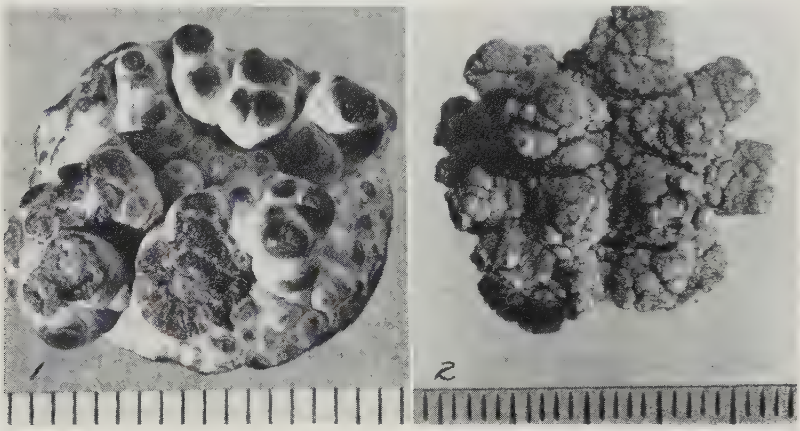

Fig. 661. 1, Calcium oxalate monohydrate calculus. Typical appearance of "mulberry" stone. Fracture of mammillary process shows concentric lamination and radial striation with central granular nucleus. **2,** Calcium oxalate "jackstone," a central mass of calcium oxalate monohydrate with radiating blunt spinous processes. A fine deposit of calcium oxalate dihydrate crystals is precipitated over the exterior. Scale in millimeters. (From Prien, E., and Frondel, C.: J. Urol. **57**:949, 1947.)

bladder and consists of a dense central mass with radiating spicules (Fig. 661, *2*).

Calculi composed of calcium oxalate monohydrate are occasionally porous or cavernous, especially toward the interior; or a particular layer in a laminated stone may be porous. The granular type of structure occurs most commonly in those calculi of mixed composition. Both the fibrous and granular calculi may show growth banding (lamination) marked by color differences parallel to the surface of the stone. Calcium oxalate monohydrate usually forms calculi that are extremely dense, tough, and hard, and it is usually the substance found when it is reported that a calculus resisted crushing or sawing.

External surface—usually smooth and may have a lustrous or varnished appearance.

External color—light honey brown to red brown or black brown or occasionally blue to greenish blue.

Fractured surface—usually some shade of brown.

Finely granulated calculi—relatively light colored.

Nuclei of other substances, uric acid and apatite, are sometimes observed, and calcium oxalate monohydrate may occur as nuclei in uric acid and other stones. Calcium oxalate dihydrate is the most common associate of calcium oxalate monohydrate and usually occurs as well-formed crystals attached to or embedded in the surface of the monohydrate stone. Apatite also is a common associate; magnesium ammonium phosphate hexahydrate (struvite), calcium hydrogen phosphate dihydrate (brushite), and uric acid are infrequent.

Calcium oxalate monohydrate is monoclinic in crystallization and possesses cleavages on (001), (010), and (110). Cleavages can be recognized in relatively large single crystals but are not easily seen in fibrous or fine-granular aggregates.

Hardness 2½-3
Specific gravity 2.23
Optical properties:
  $X = 1.491 = b$
  $Y = 1.555$
  $Z = 1.650$
  Biaxial positive (+)
  $2V = 84°$
  Dispersion $r < v$, weak
  Extinction angle $Z \wedge c = 31°$

It is easily distinguished optically from calcium oxalate dihydrate, $CaC_2O_4 \cdot 2H_2O$ by its high birefringence and high Z index of refraction.

Occasionally the granular type of calculus may show well-defined tiny crystals upon its surface (Fig. 662, *1, 2, 3*).

Calcium oxalate dihydrate (weddellite—$CaC_2O_4 \cdot 2H_2O$): This generally occurs as relatively well-formed crystals, shaped as in Fig. 662, *4,* which range in size up to 2 mm. on an edge. They are identical with the familiar octahedral or "envelope" crystals seen in ordinary urinary sediments. The crystals are usually attached to the body of the stone by their edges. Calculi composed of pure calcium oxalate dihydrate consist either of loosely intergrown aggregates of individual crystals (Fig. 662, *1*) or of compact, interlocking aggregates with a coarsely crystallized surface (Fig. 662, *2*). A secondary crop of smaller crystals may be superdeposited. In calculi of mixed internal composition a granular structure may exist, with no development of crystals. No nucleus is found in most of the loosely aggregated calculi. Pure dihydrate calculi are much less common than are pure monohydrate stones.

The color of the dihydrate is pale yellowish white to honey brown, and it is lighter than the monohydrate. The two hydrates are frequently associated; the dihydrate usually occurs as a surface incrustation of well-formed crystals upon or slightly embedded in the monohydrate. The contrast between the 2 forms may be quite striking (Fig. 662, *4*). The dihydrate is usually of later formation than the monohydrate but in part has overlapped the closing stages of growth of the monohydrate. Much less commonly the 2 may be intimately associated in those granular oxalate calculi which lack any regularity of structure. Apatite is less commonly associated with the dihydrate. Frequently the 2 oxalates and apatite exist together. Infrequent associates are with calcium hydrogen phosphate dihydrate (brushite), cystine, and uric acid.

Prien believes that both the monohydrate and the dihydrate are direct products of crystallization from the urine.

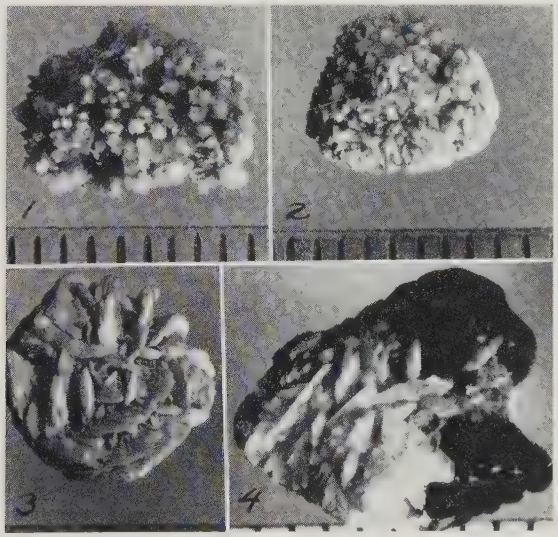

Fig. 662. Calcium oxalate dihydrate ($CaC_2O_4 \cdot 2H_2O$) calculi. **1,** Loose aggregate of crystals. **2,** Compact aggregate of crystals. **3,** Unusually large crystals seen edgewise. **4,** Dihydrate crystals (white) deposited upon calcium oxalate monohydrate calculus (black). Knifelike edges of dihydrate crystals are well shown. Scale in millimeters. (From Prien, E., and Frondel, C.: J. Urol. **57:** 949, 1947.)

Calcium oxalate dihydrate is tetragonal in crystallization. It has no cleavage.

Hardness 4
Specific gravity 1.99
Optical properties:
  O = 1.523
  E = 1.544
  Uniaxial positive (+)

It is distinguished optically from calcium oxalate monohydrate by its much lower birefringence and lower indices of refraction. Microscopically the crystals commonly show growth banding (lamination) parallel to the crystal faces.

Optical data are lacking for the trihydrate. Oxalates other than the dihydrate and the monohydrate have not been observed in urinary calculi by Prien. Prien has found stone-forming patients who produce pure monohydrate or dihydrate calculi as well as some who produce concretions composed of a mixture of the 2 hydrates. The urines of patients who produce dihydrate calculi may contain fused masses (gravel) of the familiar "envelope" crystals. It appears that calculi may at times be formed by the normal crystalline salts in urine, contrary to statements in the literature.

Phosphates

Phosphates in urinary calculi present a complex problem which has not previously been resolved by chemical methods of study. Four different phosphates have been found. Two of these, magnesium ammonium phosphate hexahydrate (struvite) and apatite, form the great bulk of the material. A third, calcium hydrogen phosphate dihydrate (brushite), is relatively uncommon, being found but 12 times in 700 calculi. The fourth, tricalcium phosphate (whitlockite), has been reported in several instances. Magnesium ammonium phosphate, triple phosphate, is usually identified in the chemical analysis of a phosphatic stone. Commonly reported with it are calcium phosphate and calcium carbonate; these separate substances have not been found in this study but are combined in one complex compound, carbonate-apatite, a carbonated calcium phosphate.

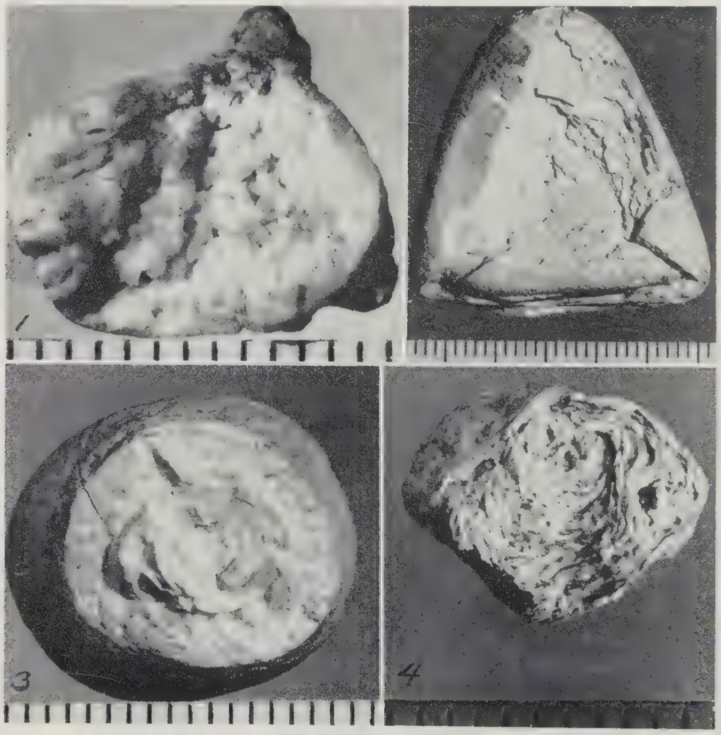

Fig. 663. Phosphatic calculi. **1,** Practically pure $MgNH_4PO_4 \cdot 6H_2O$, "triple phosphate," showing developing columnar structure. **2-4,** Pure apatite calculi. **2,** Flaking of laminations from dry calculus (triangular outline due to molding by bladder, 4 similar stones being present). **3,** Three types of apatite structure shown, central loose fluffy nucleus, intermediate zone of very dense laminations, and peripheral zone of less dense laminations. **4,** Alternating light and dark laminations are all pure apatite. Scale in millimeters. (From Prien, E., and Frondel, C.: J. Urol. 57:949, 1947.

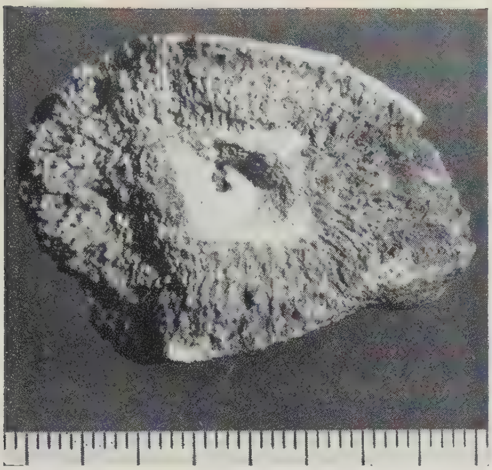

Fig. 664. Fractured surface of "staghorn" calculus. Central nucleus of apatite is surrounded by columnar structure of $MgNH_4PO_4 \cdot 6H_2O$, "triple phosphate." Intercolumnar spaces are filled with apatite. Scale in millimeters. (From Prien, E., and Frondel, C.: J. Urol. 57:949, 1947.)

Magnesium ammonium phosphate hexahydrate (Struvite—$MgNH_4PO_4 \cdot 6H_2O$ [triple phosphate]): This is usually associated with apatite in calculi. Pure calculi composed of it are quite uncommon, producing a densely granular creamy white appearance somewhat resembling lump sugar (Fig. 663, *1*). A suggestion of columnar structure is frequently present. In association with apatite, this substance forms the so-called "staghorn" calculi which occur in alkaline infected urine.

Its color is dirty to creamy white; the structure, typically cellular or columnar (Fig. 664), often resembles cancellous bone.

Triple phosphate and apatite crystals exist together in all degrees of admixture. A study showed that approximately half were composed predominantly of the one substance and half were composed of the other.

Well-formed single crystals of magnesium ammonium phosphate hexahydrate may be observed in open cracks in banded or laminated calculi of apatite and also projecting into cavities in porous stones. Crystals may also be found embedded in the central portions of some calculi where the apatite may be loose, fluffy, and grossly structureless. They also occur in urinary sediments as the well-known "knife-rest" or "coffin-lid" crystals. Crystals of typical shapes are shown in Fig. 673, *6, 7, 8*. They lack a center of symmetry in that the upper and lower halves are not mirror images.

Calcium oxalate monohydrate is an uncommon associate of magnesium ammonium phosphate hexahydrate, and the dihydrate is rare. One calculus was observed to have a nucleus of calcium oxalate monohydrate, an intermediate layer of calcium hydrogen phosphate dihydrate, and a periphery of magnesium ammonium phosphate hexahydrate. Uric acid was also observed as the nucleus of a calculus composed of magnesium ammonium phosphate hexahydrate and apatite.

It is orthorhombic-hemimorphic in crystallization. Crystals have a nearly perfect cleavage on (001) and an indistinct cleavage on (010).

Hardness 2
Specific gravity 1.71
Optical properties:
- $X = 1.495 = a$
- $Y = 1.496 = c$
- $Z = 1.504 = b$
- Biaxial positive (+)
- $2V = 37°$
- Dispersion $r < v$, strong

Microscopically it is easily distinguished by its very low birefringence and low indices of refraction.

Apatite (carbonate-apatite — $Ca_{10}(PO_4 \cdot CO_3OH)_6(OH)_2$; hydroxyl-apatite — $Ca_{10}(PO_4)_6(OH)_2$): The term apatite refers to a group of compounds that have an analogous chemical composition and identical crystal structure. They are mostly minerals. Carbonate-apatite and hydroxyl-apatite are complex phosphates occurring in calculi and belong to this group.

Calcium hydrogen phosphate dihydrate ($CaHPO_4 \cdot 2H_2O$) uncommonly exists in calculi, and tricalcium phosphate ($Ca_3(PO_4)_2$) occurs rarely. Prien has not found calcium carbonate ($CaCO_3$) in apatite calculi.

Carbonate-apatite and hydroxyl-apatite can be identified as apatite only by optical or x-ray methods. They are then differentiated from each other by releasing carbon dioxide gas from carbonate-apatite. If a large amount of gas is evolved from an apatite substance occurring in calculi, it is inferred to be wholly or preponderantly carbonate-apatite; if little or no gas is evolved, it seems to be wholly or preponderantly hydroxyl-apatite. They should be considered collectively and called urinary apatite to distinguish them from mineral apatite, which usually contains chlorine or fluorine ions.

Apatite commonly occurs with magnesium ammonium phosphate hexahydrate as one of the major components of phosphatic calculi. It is by far the most common phosphate present in calculi. Pure apatite calculi are not common; they are fine-grained, soft, and compact, usually with concentric lamination, both on macroscopic and microscopic scale (Fig. 663, *2, 3, 4*). Successive laminae may vary somewhat in color and coherency, and some laminae may be relatively hard with a translucent glassy appearance. Inner portions of some stones are loose and powdery (Fig. 664).

The color of apatite is chalky white, cream white, yellow brown, or sometimes brown. Pure apatite is an alternating lamination of white and brown (Fig. 663, *4*) in which the brown layers represent a condensation of the substance. Brown layers may be translucent or even transparent.

In mixtures with magnesium ammonium phosphate hexahydrate in "staghorn" calculi the apatite is softer and may usually be rubbed to a fine powder with the finger. In porous granular calculi composed of the oxalates it exists in interstices or cavities in variable amounts. Commonly the interspaces in the loose aggregates of calcium oxalate dihydrate crystals may be partially or completely filled with the substance; Fig. 665 shows such aggregates. It has also been observed with calcium hydrogen phosphate dihydrate, cystine, and uric acid. Calculi of apatite and magnesium ammonium phosphate hexahydrate commonly occur in alkaline infected urines.

It is hexagonal in crystallization, well-formed crystals being found only in nature. Hardness—5; specific gravity—2.95-310. Natural crystals are optically negative, with O and E indices in the range from 1.61 to 1.64, depending on the kind and amount of isomorphous substitution. In urinary calculi it appears as extremely fine-grained masses, never as visible crystals, and is isotropic. This character is due to the submicroscopic size of the crystals composing the mass with resultant aggregate polarization. Index of refraction—1.55-1.61, most samples falling between 1.55 and 1.59. This variable and low index is partly due to a large content of adsorbed and capillary water. Index may vary between different parts of the same sample. Some grains may show weak double refraction. Some grains ordinarily are colorless but may be pale yellow, brown, reddish brown, or greenish yellow due to foreign pigmenting matter.

It differs from other components of calculi in its isotropic or nearly isotropic character and the absence of crystal outlines. It may be confused with colloidal organic material when seen through the petrographic microscope because both are isotropic. The colloid frequently appears as a coating on crystals from which it may be differentiated readily. It is very confusing if on apatite, which does not form crystals. **Test for CO_2** which may be liberated from carbonate-apatite.

1. Place a few coarse grains on a glass slide and cover with a cover glass.
2. Run a drop of dilute hydrochloric acid under the edge of the cover glass.
3. If carbonate-apatite is present a brisk effervescence ensues which may be watched through low magnification.
4. To confirm that this is CO_2 add a drop of 10% barium hydroxide under the cover glass. A white cloud of barium carbonate forms about the stone, showing presence of CO_2. Failure to produce effervescence in material having the constants of carbonate-apatite indicates the presence of hydroxyl-apatite.

Colloidal apatite calculus is undoubtedly ordinary carbonate-apatite. "$Ca_3(PO_4)_2$" prostatic calculi of Huggins and Bear appear to be composed of carbonate-apatite. The powder

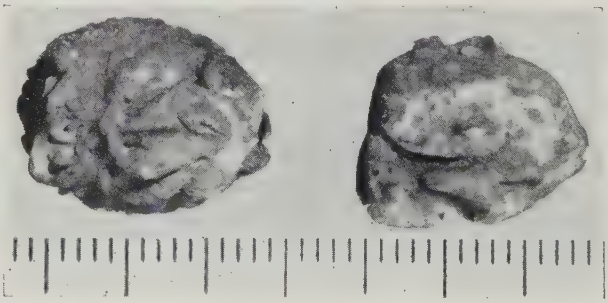

Fig. 665. Apatite upon calcium oxalate dihydrate. Linear edges of calcium oxalate crystals are seen upon the left, projecting through the apatite. On the right, calcium oxalate has been almost completely "submerged" by apatite, only the tips of the crystals being visible as irregularities in the surface. Scale in millimeters. (From Prien, E., and Frondel, C.: J. Urol. 57:949, 1947.)

pattern is actually that of hydroxyl-apatite. Although the percentage difference in composition between the 2 substances is very little, their atomic structures are quite unlike.

Carbonate-apatite is the principal constituent of calcifications variously formed in the lacrimal duct, prostate gland, tuberculous lymph nodes, appendix, testes, and walls of the bronchi as a consequence of senile degeneration and disease. It also occurs as a minor constituent in arteriosclerotic plaques.

A calcium phosphate kidney stone that afforded small amounts of CO_2 and H_2S when dissolved in acid was found to be carbonate-apatite containing a small amount of divalent sulfur in isomorphous substitution and may be termed a sulfidic apatite.

Tricalcium phosphate (whitlockite—$Ca_3(PO_4)_2$): Whitlockite is rhombohedral in crystallization. No cleavage.

Hardness 5
Specific gravity 3.2
Optical properties:
  O = 1.629
  E = 1.626
  Uniaxial negative (−)

Prien has identified whitlockite in a testicular calcification. It was creamy white, very fine-grained, and almost porcellanous in appearance, and contained a small amount of CO_2. It appeared isotropic, due to the very small particle size of the aggregate, and had a variable index of 1.59-1.60. Some of the natural material has also been found to contain CO_2 in isomorphous substitution analogous to carbonate-apatite. Urinary whitlockite probably has the same general appearance and optical properties as apatite. Probably the "$Ca_3(PO_4)_2$" reported in older descriptions of urinary calculi was apatite in most instances.

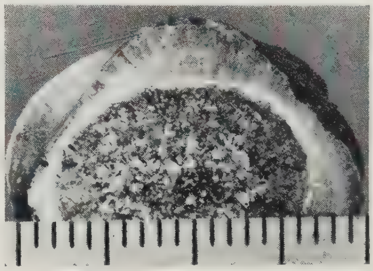

Fig. 666. Multilayered calculus. Nucleus of granular calcium oxalate monohydrate, second layer (almost invisible) of calcium oxalate dihydrate, third layer (broad) of laminated calcium hydrogen phosphate dihydrate, peripheral layer (very thin) of calcium oxalate dihydrate. Scale in millimeters. (From Prien, E., and Frondel, C.: J. Urol. 57:949, 1947.)

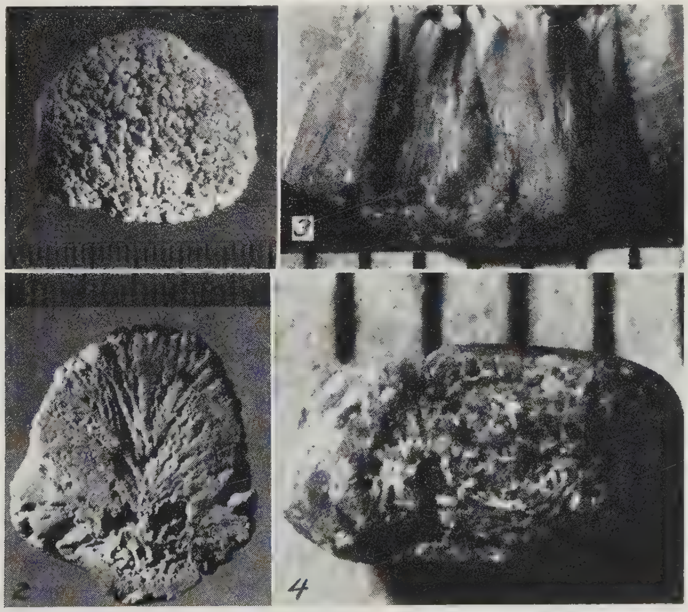

Fig. 667. Calcium hydrogen phosphate dihydrate ($CaHPO_4 \cdot 2H_2O$) in calculi. **1,** External surface of rare pure $CaHPO_4 \cdot 2H_2O$ calculus, showing ends of tufts of crystals, producing nodular structure. **2,** Cross section of same calculus showing divergent tufted structure. **3,** "Palisade" formation of $CaHPO_4 \cdot 2H_2O$, due to cleavage along fibers which are well shown. **4,** Bladed crystals of $CaHPO_4 \cdot 2H_2O$ in a granular calcium oxalate monohydrate calculus. Scale in millimeters. (From Prien, E., and Frondel, C.: J. Urol. 57:949, 1947.)

Calcium hydrogen phosphate dihydrate (brushite—$CaHPO_4 \cdot 2H_2O$): This is an uncommon phosphate occurring in urinary calculi, having been found but 12 times in 700 calculi. In at least 3 instances the calculi were present as bladder stones accompanying benign hypertrophy of the prostate and with urinary infection. Because it is an acid phosphate and is usually associated with the oxalates in calculi it is reasonable to suppose that it forms in an acid urine. It was accompanied several times by carbonate apatite, which also occurs commonly with the oxalates. In the single instance in which it occurred with magnesium ammonium phosphate hexahydrate the latter was present as a peripheral layer which could be explained as the result of a change in the reaction of the urine to the alkaline side subsequent to the precipitation of the calcium hydrogen phosphate dihydrate.

It may exist as a layer overlying a nucleus of calcium oxalate monohydrate or as bladed crystals in granular calcium oxalate monohydrate or apatite, or (one calculus) it may approach a pure state (low per cent of apatite) (Figs. 666 and 667, *1, 4*).

In pure form it has a radially fibrous or bladed structure (Fig. 667, *2, 3*). A crudely divergent tufted or fernlike structure may sometimes be seen in cross section (Fig. 667, *2*). The ends of these tufts produce a uniformly nodular appearance (Fig. 667, *1*).

Its color is creamy white or yellowish white, ocasionally light brown; structure, moderately soft. Fracture surfaces tend to have a somewhat pearly or silky luster, due to perfect cleavage. It differs from fibrous calcium oxalate monohydrate in this characteristic and in that the latter is harder, darker, and lacks a good cleavage along the length of its fibers.

They are monoclinic in crystallization, with perfect cleavages on both (010) and (301).

Hardness 2-2½
Specific gravity 2.32
Optical properties:
  $X = 1.539$
  $Y = 1.545$
  $Z = 1.551 = b$
  Biaxial positive (+)
  $2V = 87°$
  Dispersion perceptible $v < r$
  Extinction $Y \wedge a = 18°$

Microscopically, its low birefringence is approximated by magnesium ammonium phosphate hexahydrate and calcium oxalate dihydrate from which it is easily distinguished by its higher indices and bladed crystals.

Uric acid ($C_5H_4N_4O_3$)

In calculi uric acid occurs most often in a pure state. Its most common associates in calculi of mixed composition are apatite and calcium oxalate monohydrate. It occurs sometimes as the nucleus in calculi composed of calcium oxalate monohydrate or of apatite. Apatite may also be found in the interstices of coarsely porous uric acid calculi. Calcium oxalate monohydrate has also been found as the nucleus of a uric acid stone.

They have a dense fine-grained structure and are relatively heavy (Fig. 668, *1*); oblate or flattened pebblelike shape with smooth but not polished surface is typical; warty surfaces

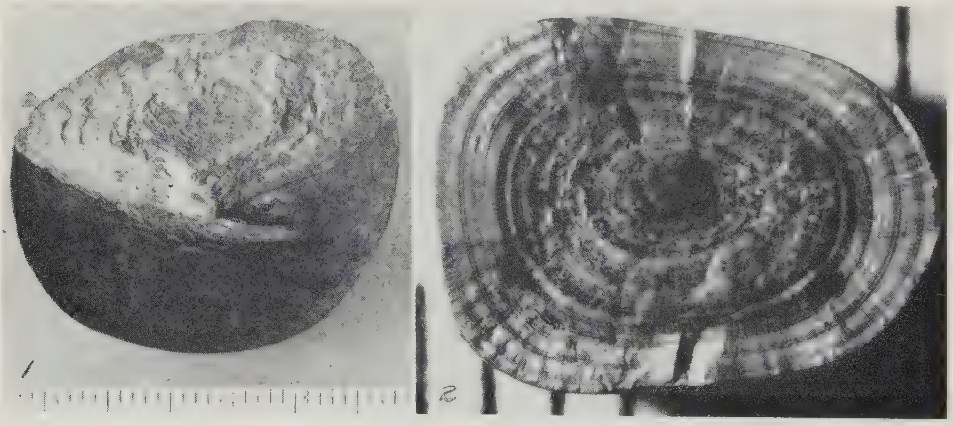

Fig. 668. Uric acid calculi. **1,** Dense fine-grained structure shown on fractured surface. **2,** Alternating light and dark laminations are all pure granular uric acid. Central nucleus of uric acid crystals. Scale in millimeters. (From Prien, E., and Frondel, C.: J. Urol. **57:**949, 1947.)

may be observed. Cross sections usually show a concentric lamination of variable coarseness with radial striation (Fig. 668, *2*). Alternating light and dark laminations are of identical composition, the dark layers probably being due to pigmentation. Some calculi have a granular appearance without evidence of lamination. Nucleus is usually composed of unoriented uric acid crystals. Its color is some shade of brown with which red or orange may be mixed.

It is orthorhombic in crystallization and has good cleavage. Hardness 2½; specific gravity 1.89. Some crystals are rectangular laths or rounded lozenge-shaped tablets flattened on (001) (Fig. 673, *9, 10*). Optically it is biaxial. Optical sign is unknown. Optic plant is parallel to (001), with $X = 1.573$, $Y = ?$, $Z = 1.830$. Polymorphous or hydrated form, stable at relatively low temperature, is said to have $X = 1.53$ and $Z = 1.73$. Pure recrystallized uric acid is white to yellowish white and pale brownish white. It has a marked tendency to adsorb foreign pigmenting substances; the pigmented material usually is pleochroic under the microscope, with absorption $Z > X$. The so-called "brick dust" precipitate from urine is pigmented uric acid.

Microscopically the high birefringence of uric acid is approached only by calcium oxalate monohydrate among the common stone-forming substances. It is distinguished from the latter by finding grains that have indices of refraction above 1.65 (the highest index of calcium oxalate monohydrate) and failure to find grains with indices below 1.573 (the lowest index of uric acid).

Urates: Many urates, including both the acid and normal salts of NH_4, Na, K, and Mg, have been described in urinary calculi. Identification is questionable or inadequate. Urates occur less commonly in calculi than would appear from the results of chemical analysis alone. Sodium acid urate has been found but once and in microscopic amount in a series of approximately 700 urinary calculi. It has been found by Prien in several tiny plaques attached to the apices of renal papillae and in the so-called uric acid infarcts of renal papillae. In the single occurrence in a calculus a large central nucleus of uric acid was surrounded by a dark gray-brown zone with a radially fibrous structure; a peripheral layer of apatite was present (Fig. 669). Dissection showed the soft fine silky needles of sodium acid urate easily visible under magnification (Fig. 670).

Sodium acid urate ($NaC_5H_3O_3N_4 \cdot H_2O$) is

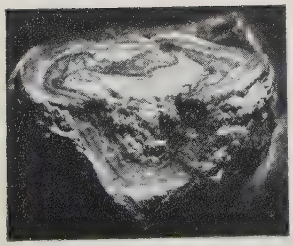

Fig. 669

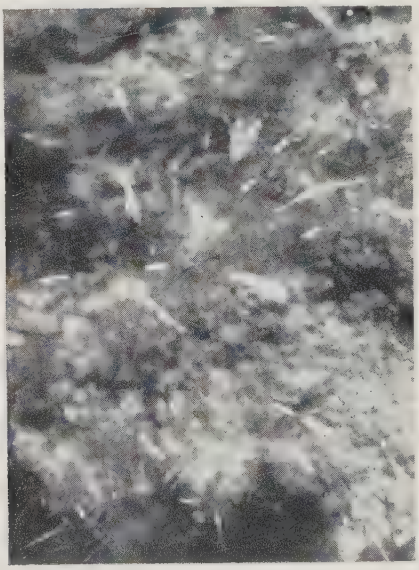

Fig. 670

Fig. 669. Sodium acid urate in fractured uric acid calculus. Narrow dark zones extending around calculus composed of needlelike crystals of sodium acid urate which extend across zone. Diameter of calculus 0.4 cm. (From Prien, E., and Frondel, C.: J. Urol. 57:949, 1947.)

Fig. 670. High-power view of sodium acid urate crystals seen upon fractured surface of calculus in Fig. 669. (×30.) (From Prien, E., and Frondel, C.: J. Urol. 57:949, 1947.)

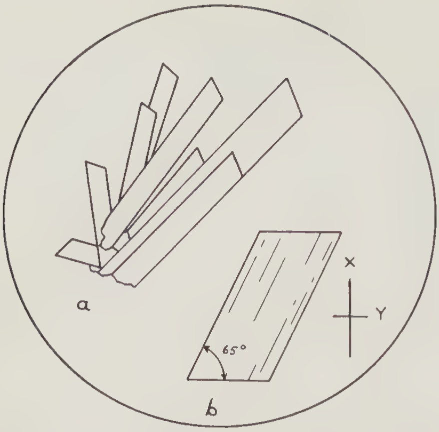

Fig. 671. Sodium acid urate crystals. (×315.) (From Prien, E., and Frondel, C.: J. Urol. **57**:949, 1947.)

monoclinic or triclinic in crystallization. Crystals are lath or needle-shaped and possess 2 perfect cleavages and probably a third imperfect cleavage. Material is very soft and plastic.

Its color is white, yellowish white, or cream yellow. Crystal aggregates have a silky luster. Microscopically crushed fragments appear as rhomboidal plates or laths bounded by cleavage faces with extinction parallel to one of the cleavages. Optically positive (+) with X = 1.448, Y $\sim$ 1.75, Z $>$ 1.84. Interior acute angle of the rhomboidal plates is approximately 65°, as shown in Fig 671.

Ammonium acid urate was found in a bladder stone from a bulldog.

Another substance was found once in microscopic amount in a depression upon the surface of a calcium monohydrate calculus. It remains unidentified but was probably a urate.

Cystine ($SCH_2CH(NH_2)$—COOH)

Cystine usually occurs in the pure state in calculi, but sometimes it is found admixed with small amounts of apatite and, rarely, calcium oxalate monohydrate. Occasionally it may exist in a pure state as the nucleus of a calculus otherwise composed of the above constituents.

Cystine stones commonly consist of porous aggregates of relatively well-formed short hexagonal prisms or hexagonal tablets (Fig. 672). Well-crystallized stones sometimes have a compact granular center. The color is honey-yellow to yellowish white. The luster is waxy. The calculi are very soft unless they are densely granular. An occasional cystine calculus may be so fine-grained and dense as to resemble uric acid externally.

Cystine is hexagonal in crystallization and possesses a perfect cleavage on (0001).

Hardness 2
Specific gravity 2.06
Optical properties:
  O = 1.700
  E = 1.640
  Uniaxial negative (−)

Cystine crystals commonly have the form of hexagonal tablets, as shown in Fig. 673, *5*. The substance is easily recognized under the microscope, affording grains with a hexagonal outline which yield a centered uniaxial negative interference figure, with O = 1.700. The crystals and cleavage fragments usually show internal growth bands parallel to the external hexagonal crystal faces.

Other substances

Prien failed to find xanthine and indigo in his study. It seems reasonable to predict that small amounts of other substances may be detected in calculi by physical methods. Cholesterol has been reported. Prien has found cholesterol crystals in urine and in gallstones but not in calculi.

Calcium carbonate ($CaCO_3$—aragonite; calcite; vaterite-B or μ-calcite)

Calcium carbonate is commonly reported to occur in phosphatic calculi. Prien et al. have not encountered it. Development of effervescence when a calcareous stone is treated with dilute acid is not necessary evidence for the occurrence of calcium carbonate.

Calcium carbonate crystallizes in 3 distinct forms and may be said to be polymorphous. The phenomenon is due to the geometrically different manner in which the constituent atoms are arranged in the crystal structure of the 3 substances. As a consequence the different forms may vary markedly in physical

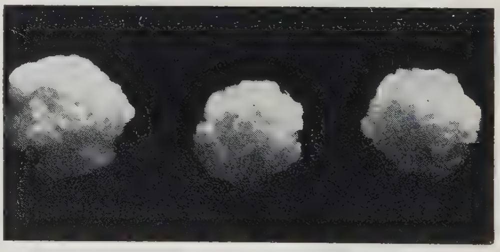

Fig. 672. Cystine calculi composed of aggregates of hexagonal crystals. Soft pearly luster difficult to photograph. Diameter of calculi 2-3 mm. (From Prien, E., and Frondel, C.: J. Urol, **57**:949, 1947.)

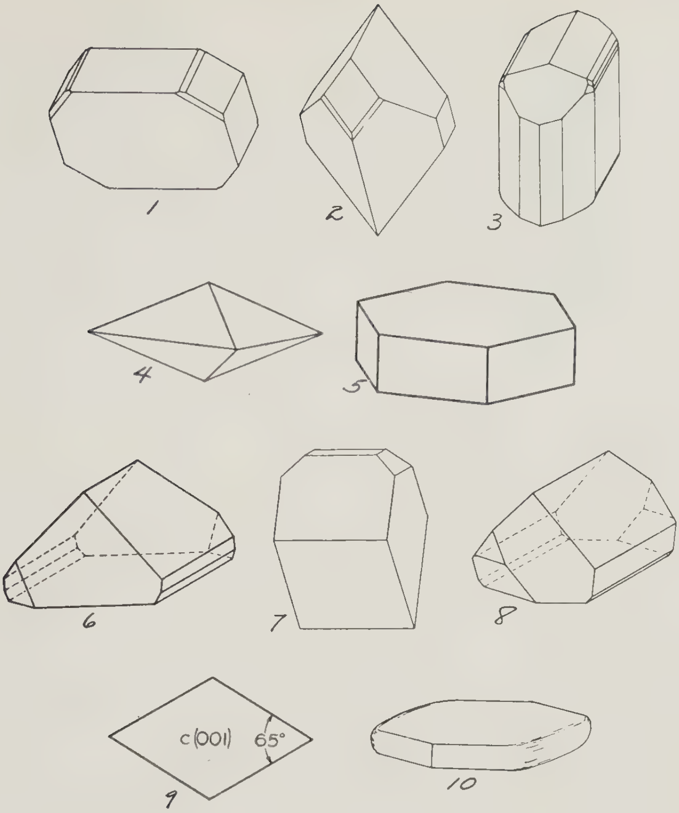

Fig. 673. Forms of crystals seen upon the surfaces of calculi. **1-3**, Calcium oxalate monohydrate, uncommon, actual size 0.03-0.1 mm. **4**, Calcium oxalate dihydrate, common, actual size up to 2 mm. **5**, Cystine, common, actual size 0.1-0.2 mm. **6-8**, Magnesium ammonium phosphate hexahydrate, common, actual size 0.5-1 mm. **9**, **10**, Uric acid, uncommon, actual size 0.2 mm. (From Prien, E., and Frondel, C.: J. Urol. 57:949, 1947.)

and chemical characters. A common example is provided by diamond and graphite, both of which are pure carbon. Calcium carbonate occurs as aragonite, calcite, and vaterite-B or μ-calcite. All 3 phases have been recognized as constituents of gallstones. So far as is known no specific phase has been identified in human urinary calculi. Calcium carbonate concretions are said to occur in herbivora.

Distinction between the 3 calcium carbonate phases may be effected optically if the grain size is sufficiently large or, in any case, by x-ray powder patterns. Aragonite, and possibly calcite as well, would probably appear as fine-grained or fibrous aggregates.

Aragonite: Aragonite is orthorhombic in crystallization with a distinct cleavage on (010) and indistinct cleavages on (110) and (011).

Hardness 3½-4
Specific gravity 2.95
Optical properties:
$X = 1.530 = c$
$Y = 1.680 = a$
$Z = 1.685 = b$
Biaxial negative (−)
$2V = 18°$
Dispersion $r > v$, weak

Calcite: Calcite is rhombohedral in crystallization and has a good rhombohedral cleavage on (1011).

Hardness 3
Specific gravity 2.715
Optical properties:
$O = 1.658$
$E = 1.486$
Uniaxial negative (−)

The E′ index afforded by grains resting on cleavage surfaces is 1.566.

Vaterite-B or μ-calcite: Vaterite-B is hexagonal in crystallization and occurs in artificial preparations as tiny hexagonal or spherulitic aggregates.

Optical properties:
$O = 1.550$
$E = 1.640$
Uniaxial positive (+)

Table 364. *Determinative table of optical constants of urinary calculi*

Name	*Crystal system*	*Sign*	*X or O*	*Y*	*Z or E*	*2V*	*Dispersion*	*Extinction angle*	*Distinguishing features*
Calcium oxalate monohydrate (whewellite)	Monoclinic	+	1.491 = *b*	1.555	1.650	84°	r < v weak	Z ∧ *c* = 31°	Distinguished from uric acid by indices; no index above 1.650; has index below 1.573
Calcium oxalate dihydrate (weddellite)	Tetragonal	+	1.523		1.544				
Magnesium NH_4PO_4 hexahydrate (struvite)	Orthorhombic	+	1.495 = *a*	1.496 = *c*	1.504 = *b*	37°		r < v strong	
Carbonate-apatite	Hexagonal	Isotropic	Index variable, usually 1.55-1.59 (extreme range 1.520-1.610)						Isotropic; spherulitic; effervesces with HCl
Hydroxyl-apatite	Hexagonal	Isotropic	Index variable, as above						Isotropic; spherulitic; no effervescence with HCl
Calcium hydrogen PO_4 dihydrate (brushite)	Monoclinic	+	1.539	1.545	1.551 = *b*	87°	v < r perceptible	Y ∧ *a* = 18°	Coarse radial fibers
Uric acid	Orthorhombic	?	1.573	?	1.830			Parallel to cleavage	Yellow color; see under calcium oxalate monohydrate
Sodium acid urate	Monoclinic or triclinic		1.448	1.75	1.84			Parallel to cleavage	Rare; needlelike crystals with internal acute angle = 65°
Cystine	Hexagonal	–	1.700		1.640				Hexagonal crystals; good cleavage
Tricalcium phosphate (whitlockite)	Hexagonal	–	1.629		1.626				Rare; like apatite

Calcium sulfate dihydrate (gypsum—$CaSO_4 \cdot 2H_2O$)

Calcium sulfate has been said to occur occasionally as a urinary deposit but has not been observed in calculi by Prien et al. Gypsum, the particular phase which would be stable as a urinary deposit, is monoclinic in crystallization. Hardness 2; specific gravity 2.32. Gypsum has a perfect cleavage on (010) and imperfect cleavages on (111) and (100). Optically gypsum is biaxial positive, with $X = 1.521$, $Y = 1.523$, $Z = 1.530$, and $2Z = 58°$. The optic plane is parallel (010), the direction of perfect cleavage. Strongly inclined dispersion, with $r > v$.

Calcium acid phosphate (monetite—$CaHPO_4$)

Monetite has been reported as a urinary sediment in carnivorous animals but has not been reported from human beings. Crystals are rhomboidal plates of laths and are triclinic in crystallization. Optically monetite is biaxial positive (+), with moderately large 2V, and $X = 1.600$, $Y = 1.614$, $Z = 1.631$. In comparison to brushite, $CaHPO_4 \cdot 2H_2O$, monetite forms artificially at relatively higher temperatures from acid solutions.

Cholesterol ($C_{27}H_{46}O$)

Cholesterol has been described in urinary calculi; it occurs rarely as a heavy suspension of crystals in urine and in hydrocele fluid. It crystallizes in thin, transparent rhomboidal plates of varying size, often imbricated and united to one another. A rhomboidal notch frequently exists at one corner. The crystals should be recognizable at sight. Melting point 147.5°-148.5°. Perfect cleavage (010). Optical properties: monoclinic in crystallization. $Z = 1.566$, $Y = 1.532$, $X = 1.520$, $2V = 60° \pm$.

Tribasic magnesium phosphate hydrate (bobierrite—$Mg_3(PO_4)_2 \cdot 8H_2O$)

Magnesium phosphate has been said to occur rarely as a urinary deposit but has not been observed by Prien et al. The phase stable as a urinary deposit probably is the octahydrate, bobierrite. This substance is monoclinic in crystallization, with a hardness of 2 and a specific gravity of 2.2. Optically biaxial positive, with $X = 1.510$, $Y = 1.520$, $Z = 1.543$. $2V = 71°$, weak dispersion, with $r < v$. Extinction angle Z to c = +29°. Optic plane perpendicular to (010).

CHEMICAL ANALYSIS OF URINARY CALCULI

In examining the larger urinary calculi chemically, the most valuable data are obtained by examining each of the concentric layers separately. Saw the calculus through the nucleus and separate the various layers. Material may also be obtained by scraping enough powder from each layer to carry out the examination. If the latter is adopted, the layers should not be separated.

Murexide test

To a small amount of unknown material in a small evaporating dish, add 2 to 3 drops of concentrated nitric acid. Evaporate to dryness over a water bath. If uric acid is present, a red or yellow residue remains which turns purplish red after cooling the dish and adding a drop of very dilute ammonium hydroxide. The color is due to the formation of ammonium purpurate or murexide. If potassium hydroxide is used instead of ammonium, a purplish violet color due to the production of the potassium salt is obtained. The color disappears upon warming; with certain related bodies (purine bases) the color persists under these conditions.

Table 365 shows a scheme proposed by Heller for the chemical examination of urinary calculi and will be found very useful in determining their composition. Reduce the calculus to powder and proceed as directed.

Kamlet method

Table 365 is designed to give an outline of the pure chemical analysis of calculi. A very useful technic has been introduced by Kamlet.[33] In this method, as in the one just described, the larger calculi are cut up, and each of the concentric layers is subjected to a separate analysis. Small calculi are examined in toto. If possible, 100 mg. of powdered material are examined.

1. Describe the calculus as to shape, size, color, weight, and appearance on transection.
2. Divide the specimen into 2 equal parts for analysis. Reserve one portion for the detection of cystine, xanthine, urostealith, fibrin, cholesterol, and indigo. Macerate the other portion to a fine powder in a clean, dry porcelain mortar and add to 50 ml. 10% hydrochloric acid (sp. gr. 1.05) in a small Pyrex flask. Effervescence at this point indicates the presence of carbonate ion. Gently boil the mixture for 5 min., filter through ashless filter paper, and distribute the filtrate evenly into 5 clean test tubes 6 × 1 in.
3. Render 1 tube faintly alkaline with 10% sodium hydroxide solution and add 5 ml. Nessler reagent. A brown turbidity or sediment (the iodide of Millon base) indicates the presence of ammonium ion.
4. Render 1 tube faintly alkaline with 10% sodium hydroxide solution and then cautiously reacidify with dilute acetic acid. Add 1 ml. arsenophosphotungstic acid and 4 ml. 5% sodium cyanide solution. A blue color develop-

On heating powder on platinum foil, it									
Does not burn				Does burn					
The powder when treated with HCl				With flame			Without flame		
Does not effervesce								Powder gives murexide test	
Powder gently heated, then treated with HCl								Powder when treated with KOH gives	
Powder when moistened with a little KOH									
Abundant ammonia; powder dissolves in acetic acid or HCl; solution gives crystalline precipitate with ammonia	No ammonia or at least only traces of ammonia; powder dissolves in acetic acid or HCl; solution is precipitated by ammonia (amorphous)	Effervesces	Effervesces	Flame yellow, continuous; odor of burnt feathers; insoluble in alcohol and ether; soluble in potassium hydroxide with heat; precipitated herefrom by acetic acid and generation of hydrogen sulfide	Flame yellow, pale, continuous; odor of resin or shellac on burning; powder soluble in alcohol and ether	Flame pale blue, burns a short time; peculiar sharp odor; powder dissolves in ammonia; 6-sided plates separate on spontaneous evaporation of ammonia	Does not give murexide test; powder dissolves in nitric acid without effervescence; dried yellow residue becomes orange with alkali, beautiful red on warming	Strong ammonia reaction	No noticeable ammonia reaction
"Triple phosphate" (mixed with unknown amount of earthy phosphate)	Bone-earth (magnesium and calcium phosphate)	Calcium oxalate	Calcium carbonate	Fibrin	Urostealith	Cystine	Xanthine	Ammonium urate	Uric acid

*Scheme proposed by Heller; from Hawk and Bergeim, ed. 6, Philadelphia, P. Blakiston's Son & Co.

ing within 60 sec. indicates uric acid or urate ion.

5. Render 1 tube faintly alkaline with 10% sodium hydroxide solution and then reacidify with dilute acetic acid. A white turbidity or precipitate indicates the presence of calcium oxalate. If no turbidity results after standing for 10 min., add 5 ml. saturated ammonium oxalate solution. A white precipitate or turbidity at this point indicates the original presence of calcium ion only (probably as calcium carbonate).
6. Render 1 tube ammoniacal with strong ammonia water and add 1 ml. 0.5% solution of of *p*-nitrobenzeneazoresorcinol in 95% alcohol. A blue color developing within 30 sec. indicates the presence of magnesium ion.
7. Add to the last tube 2 ml. acid molybdate reagent (equal parts of 10N sulfuric acid and 7.5% sodium molybdate solution) and 1 ml. dilute tin chloride ($SnCl_2$) solution (1 ml. of a solution of 10 gm. $SnCl_2$ in 25 ml. concentrated hydrochloric acid diluted with 200 ml. water). A blue color developing within 60 sec. indicates the presence of phosphate ion.
8. Agitate the residual half of the specimen for analysis with 10 ml. chloroform. An indigo calculus will turn the chloroform blue. The chloroform is then decanted from the insoluble sediment.
9. Evaporate a few drops of the chloroform extract on a glass slide and stain the residuum with Sudan III. Residual fat globules on the slide indicate a urostealith calculus.
10. Add to the remainder of the chloroform solution 5 ml. acetic anhydride and 0.5 ml. concentrated sulfuric acid. A Liebermann-Burchard reaction (play of colors ending in a naphthol green shade) indicates the presence of cholesterol.
11. Divide the insoluble sediment from step 8 into 3 parts. Dissolve 1 part in nitric acid and cautiously dry over a free flame. A yellow residue which turns orange on the addition of 10% sodium hydroxide solution and deep red on warming indicates the presence of xanthine.
12. To the second part of the insoluble sediment from step 8 add 2 ml. Millon reagent (p. 1809) and heat. A positive protein reaction (red precipitate) indicates the presence of fibrin in the calculus.
13. To the last part of the insoluble sediment from step 8 add 2 ml. concentrated ammonia water and agitate for 2 or 3 min. Allow 1 drop of the resultant solution to evaporate on a slide.

If cystine is present, 6-sided platelets will separate on the spontaneous evaporation of the ammonia. For a confirmatory test, dissolve 5-10 mg. of powdered calculus in 5 ml. N/10 hydrochloric acid, add 2 ml. 5% sodium cyanide solution, mix, and let stand 10 min. Add 1 ml. 0.5% aqueous solution of 1:2-naphthoquinone-4-sodium sulfonate and 5 ml. 10% solution of sodium sulfite (Na_2SO_3) in N/2 sodium hydroxide solution. Mix and let stand for 30 min. In the presence of cystine a reddish brown color forms and will turn deep red on the addition of 1 ml. 2% solution of sodium thiosulfate ($Na_2S_2O_4$) in N/2 sodium hydroxide solution.

Chapter 103

Kidney function

SAM FRANKEL

There are a number of tests for the estimation of kidney function. Before proceeding to outline the manner of performance of these tests, some fundamental facts regarding the physiology of the kidney must be reviewed. For those who desire an exhaustive and timely knowledge of the true physiology of the kidney, it is suggested that the textbook of Homer W. Smith, *The physiology of the kidney,*[34] be carefully read. Attention is to be called to the diagram from Smith's book (Fig. 674) showing the essential features of the typical nephron in the human kidney. This anatomic study of the nephron or unit of kidney structure shows the glomerulus in which the formation of urine begins. The glomerulus is a tuft of capillaries supplied with blood through an afferent arteriole. The capillary tuft is thrust into the expanded but closed end of the tubule so far that the tuft has come to be enveloped by a double layer of tubular epithelium, the inner or visceral layer being closely applied to the capillaries, extending in between all the loops and surrounding each loop almost completely, and the outer or parietal layer forming a smooth spherical capsule, Bowman's capsule, about the tuft of capillaries. Any fluid passing through the capillaries enters the capsular space around the tubule. This is lined with a thin glomerular basement membrane, anatomically continuous with the basement membrane bounding the outer surface of the tubule cells. The tubule shows a convolution near the glomerulus, known as the proximal convoluted tubule, passes by a more or less straight course toward the pelvis of the kidney, and abruptly reverses its direction, forming what is called Henle's loop. It then returns to the region of its own glomerulus where it undergoes the second series of convolutions, the distal convoluted tubule, and later joins a collecting duct. The proximal and distal convoluted segments of one tubule are closely intertwined in one locality.

It is believed that the process that takes place in the glomerulus is pure filtration. The capsular fluid contains all the filtrable constituents of blood plasma in the same concentration per unit volume of water as these are present in the plasma, according to Smith, "except for such inequalities in the distribution of ions as might arise from the presence of nonfiltrable proteins."

We know that the substances that are present in the plasma but absent from the urine must be reabsorbed by the tubules as the glomerular filtrate passes along them on its way to the bladder. A large portion of the water present in the filtrate is also reabsorbed by the tubules. This is evidenced by the fact that products such as creatinine and urea may be present in the urine in many times the concentration that they are present in the plasma. According to Smith, in every man about 90 ml. filtrate are formed in the kidneys every minute, of which 89 ml. water are reabsorbed by the tubules, leaving 1 ml. of urine to be excreted, even under conditions of relatively high urine flow. Variations in urine flow are referable primarily to variations in the amount of water reabsorbed rather than to the variations in the amount of filtrate formed.

Some consider that the glomerulus is a filter for urea nitrogen and therefore tests for identifying urea nitrogen in blood and urine are tests of glomerular function. The proximal convoluted tubule must be considered as that part of the kidney structure that is concerned with the reabsorption and elimination of other

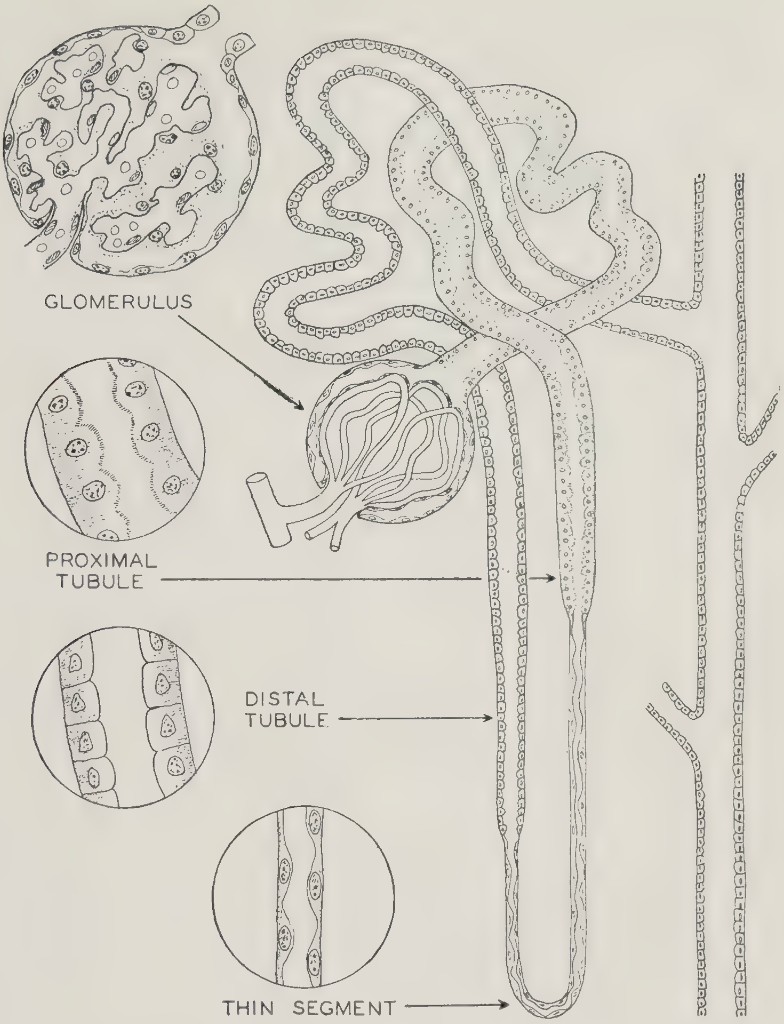

Fig. 674. Diagram showing essential features of a typical nephron in human kidney. (From Smith, H. W.: The physiology of the kidney, London, 1937, Oxford University Press.)

components of urine. Tests for concentration of urine are therefore used to demonstrate the function of the proximal convoluted tubules of the kidney.

There are a number of physiologic factors in connection with these 2 elementary principles. First, the glomerular blood pressure is of importance in relation to effective filtrate pressure. From a number of experimental observations it has been shown that increase of pressure in the renal circulation causes corresponding increase in urine formation. This supports the evidence derived from anatomy that the glomerulus is the structure in which changes in pressure operate to cause changes in urine volume. Furthermore, the contractility of the efferent vessel is of importance in regard to the regulation of glomerular filtration. Another factor involved in the maintenance and adjustment of glomerular capillary pressure and associated with the filtration of cell-free, protein-free fluid from the blood as it flows through the glomerular capillaries is viscosity. The number of cells per unit volume in the blood in the efferent arteriole is higher than that in the afferent. This is a factor that must vary with the rate of blood flow, volume of glomerular filtrate, and caliber of vessels.

The function of the proximal tubule is normally bound up with the process of reabsorption. Wearn and Richards[35] first showed by puncture of the capsule of Bowman that the urine from that portion contained sugar, whereas urine issuing from the ureter contained none: hence the principle of reabsorption was established. At the same time Bieter and Hirschfelder[36] showed that when they injected phenol red into frogs, the contents of the tubules were more intensively stained than were the contents of the capsule of Bowman. This observation was presented by them as reabsorption of water from the tubules. From experiments with phenol red it was shown that it is a substance the excretion of which cannot be accounted for by glomerular filtration. In other words, this substance which cannot be diffused through the walls of the tubule must be secreted in the proximal portion.

Expressed in other terms, the glomerular portion of the kidney is able to eliminate practically all soluble and diffusible substances which may enter the blood stream. This process is in line with the filtration theory of glomerular function. The evidence is definite that reabsorption takes place in the proximal portion of the tubule. Urinary secretion consists of glomerular filtration, tubular reabsorption, and tubular secretion, with possible evidence of some amount of glomerular secretion. It is thought that the formation of the urine is effected through the following processes:

1. Ultrafiltration of large amounts (for the human kidney, about 150 ml./min.) of protein-free fluid in the glomeruli.
2. Active reabsorption of water.
3. Active reabsorption of threshold bodies, like sugar and chlorides.
4. Passive back diffusion of all other substances in degrees varying according to the permeabilities of the tubule walls for each—with creatinine at one end as the most highly concentrated and alcohol at the other end as a substance not concentrated at all.
5. Secretion of substances not preformed in the blood.

Regarding the **excretion of sugar in the urine,** it has been known for a long time that whenever the quantity of glucose in the blood increases, sugar is likely to be found in the urine. This occurs when there is failure on the part of the blood to metabolize carbohydrates. Sugar filters out through the glomerulus, and its presence in the urine must be due to the fact that the tubules fail to reabsorb it rather than to any impairment of renal function. The threshold point for sugar is generally supposed to be around 170 mg.%, although in some cases it is as high as 210 mg.%. In other words, the threshold point in man is variable. In renal diabetes the threshold point is lowered, and sugar appears in the urine with a normal plasma glucose level.

As Smith states, "The nature of the glucose 'threshold' mechanism of the kidney can be examined by the simultaneous determination of the rate of glucose filtration and the glucose clearance. The quantity of glucose filtered per minute will be the filtration clearance (in the dog, the creatinine clearance) multiplied by the concentration of glucose in the plasma; the difference between this quantity and the quantity excreted per minute gives the quantity reabsorbed by the tubules. The glucose clearance is essentially zero until the plasma level reaches a critical value (the 'threshold'); above this level glucose begins to be excreted, the clearance increasing rapidly with rising plasma level and approaching the filtration rate as its asymptote. Ni and Rehberg,[37] assuming that reabsorption takes place in the proximal tubule before any reabsorption of water occurs, calculated the equilibrium concentrations in the blood and urine at various levels of hyperglycemia and concluded that the reabsorptive process is limited by a maximal concentration difference between these two fluids. They recognized, however, that the quantity of glucose which the tubule cells could reabsorb per minute might have some upper limit. But in point of fact, so long as the rate of filtration remains constant, the reabsorption of a constant quantity of glucose will lead to a constant concentration difference between tubular urine and blood, under their assumption, so that this latter relationship may be purely fortuitous."*

Glucose is almost completely reabsorbed by the tubules when it is present in the glomerular filtrate in the same concentration as in blood plasma. If, however, the plasma level is elevated, part of the glucose is not reabsorbed and escapes into the urine.

The **transit of urea from the blood into the urine** seems to occur in the glomerulus. There is no evidence at this time that there is any active reabsorption of urea in the sense that glucose is reabsorbed by the tubules. A test for glomerular function consequently must be the urea clearance test, which is fully explained on p. 74. **Urea clearance** means the volume of blood cleared of urea by 1 min. excretion of urine. An adult with a normal volume of urine excretes per minute the amount of urea in 75 ml. blood. According to Smith, "the deficit in the urea clearance is due to the escape of urea from the lumen of the tubules back into the blood in consequence of a high concentration gradient established by the reabsorption of water, supplemented by an as yet unknown reabsorptive process which takes up something like 40% of the filtered urea at the highest urine flow obtainable. During the time when the urine flow is increasing, the urea clearance may be raised to abnormally high values, relative to the rate of urine formation. In view of the multiplicity of the factors influencing the rate of excretion of urea, it appears best to adhere to the empirical description of this process in terms of standard and maximum clearances, using the latter wherever practicable."*

---

*From Smith, H. W.: The physiology of the kidney, London, 1937, Oxford University Press.

Another method is the **Ambard coefficient.** In this test the rate of urea excretion in the urine varies directly as the square of the urea concentration in the blood. With urea concentration of the blood remaining constant while that of the urine varies, the rate of urea excretion of the urine is inversely proportionate to the square root of its concentration in the urine. Furthermore, if both the blood urea concentration and the concentration of urea in the urine are variable, the rate of urea excretion varies directly as the square of urea concentration in the blood and inversely as the square of urea concentration in the urine. Ambard[38] has given us his formulas as follows:

$$\frac{\text{Urea in blood}}{\text{Rate of excretion}} = \text{Constant, or}$$

$$\frac{\sqrt{\text{Urea in blood}}}{\sqrt{\text{Excretion/unit of time}}} = \text{Constant}$$

Again, the

$$\frac{\text{Rate of excretion I}}{\text{Rate of excretion II}} = \frac{\sqrt{\text{Concentration II}}}{\sqrt{\text{Concentration I}}}$$

Expressed by Mosenthal and Lewis,[39] the formula is as follows:

$$K = \frac{Ur}{\sqrt{D \times \frac{70}{P} \times \frac{C}{25}}}$$

In which K = the coefficient of urea excretion.
Ur = urea gm./L. blood.
D = urea gm. excreted in urine in 24 hr.
C = urea gm./L. urine.
P = body weight in kg.
70 = standard body weight in kg.
25 = standard concentration of urea gm./L. urine.

K, or the coefficient of urea excretion, lies between 0.06 and 0.09 for a body weight of 70 kg., with an average of 0.08.

The constant is unaffected by diet. With increasing degrees of renal impairment the constant rises. A constant above 0.09 indicates impairment of urea excretion; in fact, in severe grades of nephritis, values of 0.30 to even 1.0 may be encountered. Quoting from Mosenthal and Lewis,[39] "When the values rise above 0.09, some impairment of the power of the kidney to excrete urea is indicated. Inability of the kidney to eliminate urea in proportion to the concentration of the blood urea results in an increase in Ambard's coefficient. In a normal individual it will remain within the limits mentioned, no matter what the height of blood urea; in persons with impaired renal function, however, the kidney does not answer the diuretic stimulus of the blood urea adequately, too little urea is put out, and the result is a rising coefficient, whether the urea in the blood be high or low. This test of Ambard is important in the detection of early kidney functional deficiency."*

Van Slyke and Cullen[40] conclude as follows regarding the Ambard coefficient:

> "1. The Ambard formula (original or modified by McLean) is not a precise expression of the law of renal function insofar as elimination of urea is concerned. This is particularly true as regards the effect of urinary urea concentration.
>
> "2. The upper limit of blood urea in normal individuals taken under normal circumstances is 0.35 gm. urea per liter of blood. Higher figures, under normal conditions, indicate evidence of impaired renal function.
>
> "3. With McLean's modification of Ambard's formula, in the majority of nephritic cases, a lowering of the index is accompanied by a rise of blood urea above the 0.35 gm. per liter limit. The index affords no valuable diagnostic or prognostic information which one cannot deduce from the blood urea alone.
>
> "4. In some instances, for example, arteriosclerosis and cardiac decompensation, blood urea was normal with a lowered index. Since it is important to distinguish between vascular and renal cases, the index loses its clinical value.
>
> "5. There is possibility of error from undetected incomplete collection of the urine. This cannot occur in a simple blood urea estimation.
>
> "6. Urea index estimations in the same individual yield wider variations in normal or nonnephritic individuals than in nephritics.
>
> "7. The estimation of blood urea is more useful for ordinary clinical diagnosis and prognosis than the estimation of the urea index or the Ambard quotient."†

Usefulness of blood chemical tests: It is true that there may be severe impairment of kidney function with a normal blood chemistry because the patient has so adjusted his food intake as not to exceed the functional capacity of the kidney or because the diminished concentrating capacity of the kidney has been balanced by a relative polyuria. For the estimation of the impairment of renal function, particularly so far as the glomerular function is concerned, blood chemical methods alone constitute the laboratory criterion of accumulation of the urinary constituents in the blood. The substance in which we are the most interested is the accumulation of urea. The accumulation of total nonprotein nitrogen is not nearly so important in this regard as is the accumulation of urea because there is much more nonprotein nitrogen in the tissues than in the blood. The estimation of the other nonprotein nitrogenous substances, such as uric acid, creatinine, indican, etc., although important, may be routinely dispensed with in the estimation of kidney function. The interpretation of the urea content of the blood must be guided somewhat by the previous diet of the patient. This was well illustrated by von Dolivo,[41] who found that in the normal person 2 hr. after the ingestion of 20 gm. urea the urea content of the blood rises to about 40 mg.% above the initial value. It then declines, to reach the normal in somewhat less than 24 hr. He found that patients with nitrogen retention reach a maximum more slowly, attaining it in about 4-6 hr., the increase in urea concentration being 60-70 mg.%. In addition to this, patients with renal insufficiency require 2-3 days to return to the original values. King[42] obtained similar results, according to studies he made on the effect of the ingestion of urea on the level of this substance in the blood.

It is evident, therefore, that while making chemical tests of blood, data on the previous diet of the patient must be known. As Fishberg[43] states: "This is also illustrated in patients with the oliguria of chronic nephrosis who may have considerable elevation of the nonprotein nitrogen of the blood as a result of high protein diet and the administration of urea, even though renal function is unimpaired. The prognostic significance of nitrogen retention in one who has previously been on rigorous protein restriction is more serious than in one who has been eating meat and other nitrogenous foods at will."*

We know that urea nitrogen accumulates in the blood in renal insufficiency. The normal value is about 8-20 mg./100 ml. blood. This may rise to as much as 300 mg.%. Uric acid usually parallels urea, but exceptionally it may rise before urea begins to accumulate. Fishberg found hypertensive patients with elevated blood uric acid for protracted periods which did not indicate the onset of renal insufficiency. In general it may be stated that uric acid accumulation, indicative of kidney functional impairment, goes hand in hand with blood urea accumulation.

Creatinine is the last substance to accumulate in the blood following derangement of kidney function. It is therefore to be found in large quantities in the terminal stage of kidney function impairment.

Amino acids: There is generally no elevation of amino acids under circumstances of kidney failure. Elevated amino acid content of the blood has been found in the terminal stages of uremia, although there is no increase in ammonia as a result of impaired kidney function. Supposedly, the ammonia found in the kidney has its origin in the kidney, which explains the depletion of the alkali reserve in the body under certain conditions. If the efficiency of the kidney becomes impaired, the formation of ammonia is diminished, or if it does not keep pace with the rate of an excessive acid production, other fixed bases in the body must be called upon in the regulation of the body neutrality. In other words, in nephritis we have here an explanation of the increase in the intensity of the urinary acidity. It is to the study of urinary acidity that we must turn in our estimation of renal efficiency rather than to the study of data determined from an analysis of ammonia findings in the blood under these circumstances. The ammonia of urine, in other words, may be an index of impaired renal efficiency, but it is no index as to the degree of acid production. It is generally believed that the kidney is the seat of urinary ammonia formation.

Chlorides: There is usually a diminution in the amount of chlorides in blood in cases of impaired kidney function. This is due to loss of chlorides by vomiting and to ingestion of little or no salt. De Wesselow[44] found in advanced nephritis an inability of the kidney to excrete phosphoric acid, with resulting accumulation of the acid radical in the blood. Alterations in the inorganic blood chemical picture of the nephritic in the terminal stages of the disease are (1) a great increase in the phosphoric and sulfuric acid radicals and (2) since acids circulating in the blood are of necessity neutralized, abstraction of base from the plasma bicarbonate for combination with the acid excess occurs and the resulting volatile carbonic acid is excreted by the lungs. Though the diminution in the bicarbonate of the plasma is reasonably ascribed to the accumulation of phosphoric acid in the blood, it has been pointed out that the phosphate increase and the bicarbonate decrease are not in all cases proportional. It is probable, according to de Wesselow, that some form of redistribution of base must occur in which radicals other than phosphate play a part. In an observation on one case, de Wesselow noted that whereas the phosphate and the various basic radicals remain comparatively constant, the bicarbonate and chloride varied inversely. The rise in the bicarbonate content is accompanied by a fall in the chlorides.

---

*From Fishberg, A. M.: Hypertention and nephritis, Philadelphia, 1934, Lea & Febiger.

In the vomiting of intestinal obstruction an extreme fall in the chloride content of the blood occurs and at the same time the plasma bicarbonate rises to a figure above the upper limit of the normal. These changes occur probably in the following way: Large quantities of hydrochloric acid are lost in the vomitus; this hydrochloric acid is derived in the process of gastric secretion from the plasma chloride, the residual sodium ions being balanced by bicarbonate. Under normal conditions the bicarbonate thus formed passes into the intestines with the pancreatic secretions and combines with the gastric hydrochloric acid to form sodium chloride, which can be reabsorbed. With vomiting the circle is broken, and, although the chloride content of the blood falls, the bicarbonate content rises.

It would appear then that the vomiting of uremia may be regarded as constituting a protective mechanism. By removal of hydrochloric acid, base is provided and the bicarbonate content is to some extent conserved in spite of phosphate retention. The vomiting is not the result of the reduction of the bicarbonate since vomiting is by no means a marked feature of diabetic acidosis.

For a more complete discussion of chlorides refer to pp. 174 and 175.

Phosphate: Inorganic phosphate increases as a result of renal insufficiency. As much as 10 mg./100 ml. are not uncommon in the plasma of uremic patients. The normal in adults is about 3 mg./100 ml. This accumulation is due to the changes in the lecithin content of the blood that accompany alterations in the level of the plasma proteins.

Sulfates: It is claimed by many authorities that inorganic sulfates may accumulate in the blood in renal insufficiency. Denis and Hobson,[45] in a study of 22 cases of nephritis and cardiorenal disease, found there was a marked increase over normal of the sodium and chloride in only 4 cases; the inorganic phosphate fraction was increased in 10 cases; whereas the inorganic sulfates were determined in only 17 cases, 11 of which showed increased values. Magnesium and potassium remained more or less constant while calcium was found to be decreased in 5 cases. Their studies demonstrated the specific selective activity of the kidney toward the various normal inorganic constituents of serum, somewhat similar to the selective activity which has been shown to exist for the various nonprotein constituents of blood.

It is probable that sodium and chloride, like creatinine, are excreted with great ease and, even in the case of badly damaged kidneys, retention of these elements seldom occurs. On the other hand, the sulfate ion is apparently excreted with difficulty so that in kidney insufficiency the concentration of this fraction may increase enormously, in some cases to 3000% above the normal value. In this respect the sulfate ion may be compared with the uric acid fraction, although the percentage increases observed are far above any concentrations of uric acid so far observed.

Relationship between uremia and blood chemical findings: It is generally believed that uremia is the direct result of accumulation of urea and kindred substances in the blood. Bright is responsible for this theory. In his Goulstonian lecture, delivered in 1833, he said: "What seems in some way to account for the general derangement and suffering of the constitution is the fact that urea becomes demonstrable in the circulating mass, and the blood becomes impregnated with that substance." Over 100 yr. after this statement was made this conception of the significance of urea retention has been amplified. We know now that urea is but one of the nitrogenous bodies that accumulate in the blood in nephritis and have learned that a similar retention occurs in the case of certain nonnitrogenous substances. This aspect of nephritis was given a fresh impetus at the beginning of the present century by the work of Widal and Javal and by that of Achard. Bennett[46] in his first Goulstonian lecture in 1928 in discussing "Some problems of nephritis" states that although the retention of nitrogenous substances in the blood is an invaluable aid in the diagnosis of renal failure, and although one may appreciate the fact that high nitrogen figures may become of great prognostic importance, one must also realize that nitrogen retention by itself offers no explanation of the actual phenomena of uremia. In summarizing the chief reasons against nitrogen retention as the cause of uremia, Bennett gives the following:

"1. The administration of urea and kindred substances to animals does not produce uremia.

"2. Conditions such as cystic disease of the kidney or prostatic obstruction often persist for years with marked nitrogen retention but no evidence of uremia.

"3. Cases of uremia without nitrogen retention are occasionally observed."*

The retention of nitrogenous substances in the blood is marked in renal failure, according to Bennett, largely because they are quantitatively among the more important substances which the kidney is normally called upon to excrete; but evidence accumulates to show that other chemical substances will show increased concentration in the blood, although to a lesser degree. In a very interesting case of cystic disease of the kidneys which Bennett was enabled to study up to the very last moment of life (ending in uremia) the blood analyses were in full agreement with the findings of most modern authorities; the actual figures in the terminal stage are given in Table 366.

Table 366. *Terminal phosphorus and chloride values in a case of cystic disease of the kidneys*

	Blood phosphorus (normal, 2-3)	*Whole blood chlorides (normal, about 85 mEq./L.)*
Nov. 2	6.3	86
Nov. 4	6.2	96
Nov. 5	8.3	97
Nov. 6	8.5	94

Bennett calls attention to the curious diazo reaction, first described by Andrews, given by the blood and cerebrospinal fluid in cases of uremia. It has been shown by Blotner and Fitz[47] to appear rapidly in dogs after nephrectomy, and, although its significance is still obscure, it seems very possible that this again is an example of the retention and concentration in the blood of some substance that the normal kidney would excrete.

Bennett in his lecture called attention to the outstanding features of similarity in cases of advanced renal destruction and cases of pyloric obstruction with tetany. He showed that in progressive renal disease there is found the following:

Acid accumulation in blood	Nitrogen retention
Acidosis	Calcium reduction
Phosphorus retention	Twitchings and convulsions

He found the following in nonmalignant pyloric obstruction:

Acid loss from vomiting	Nitrogen retention
Alkalosis	Calcium reduction
Chloride loss	Tetany

He called attention to the literature describing cases of pyloric or upper intestinal obstruction, in which routine histologic examination of kidneys removed at autopsy showed entirely unsuspected changes of a markedly degenerative nature in the renal tubules. These changes were of the type seen in cases of mercurial poisoning. It is evident that not only will renal damage produce profound changes in the blood chemistry but also that chemical changes in the blood may themselves exert a destructive effect upon the kidney substance.

Bennett has given full credit to the information obtained from biological chemists in elucidating facts concerning abnormal physiology of the kidney, but the fact remains that the phenomena of uremia are not altogether explained by the accumulation of blood chemical products in kidney degeneration.

TESTS FOR KIDNEY FUNCTION

There are a number of tests of kidney function, each group dependent upon certain physiologic principles. According to Belt[48] the requirements of a test of renal function may be summarized as follows:

1. It should be easy for the physician to apply and for the patient to carry out.
2. It should be easy of interpretation.
3. It should be carried out through the agency of a nondeleterious substance, preferably one with which the kidney is regularly called upon to deal.
4. The substance used should be one that is not influenced by any other organ in the body.
5. The test should reveal slight impairment and yield an answer in per cent of normal, ranging uniformly through all changes from

---

*From Bennett, T. I.: Lancet 1:535, 1928.

slight impairment of function and structure to a total loss of kidney function.

6. It should reveal the nature of anatomic change occurring within the kidney.

7. The test applied in a chronologic series should have a prognostic value, indicating further degeneration or recovery.

Belt states further that no single test encompasses all of these criteria, that although the urea clearance test is constant and exact and covers the greatest range of function, it has the disadvantage of requiring technical aid in the form of chemical estimates of urea in both blood and urine. The range of the phenolsulfonphthalein test is much more restricted, being insensitive to slight failure in function and diminishing to the zero point long before the kidneys have approached a level of function in which life is in danger. As pointed out by Frothingham and Dennis, it indicates the function for the moment and not over an extended period of time. Its greatest value, which accounts for its popularity, is the fact that the laboratory procedures involved require the minimum of effort.

Dilution and concentration tests give the earliest warning of an impending failure of renal structure. Belt further emphasizes that the qualitative tests for albumin in the urine are very delicate and reveal quantities of this substance smaller than are pathologically significant. The xanthoproteic test gives a warning highly significant for judging danger to life.

Urea clearance test

For full details of the technic see p. 74. This test depends upon the excretion of a natural metabolite as it occurs in the body without artificial administration. For full data on the significance on the urea clearance figures see p. 74. In general, a reading of 5% shows that uremia is near at hand. The patient is still able to be up and about with readings of 10%. Twenty per cent is recognized as a dangerously low level although at this level an existing edema may clear and a

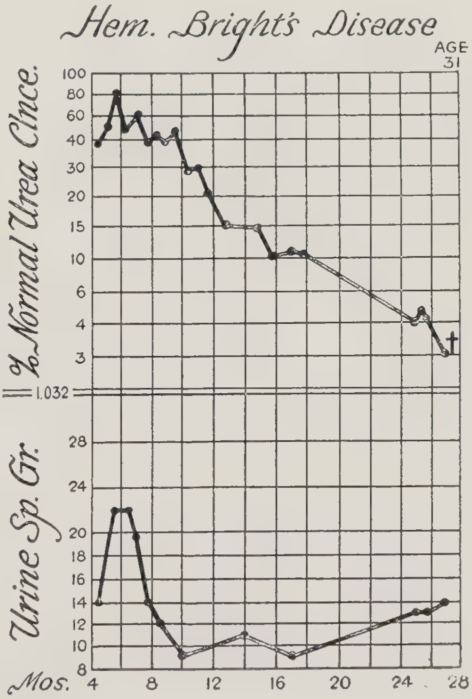

Fig. 676

Fig. 675. Recovery case of acute hemorrhagic nephritis. Changes of urea clearance and of urine specific gravity in Addis concentration test. Note that 3 mo. after onset clearance had returned to full normal value, whereas specific gravity test showed no improvement. Eleven months after onset both tests normal. (Courtesy Alving and Van Slyke.)

Fig. 676. Case of acute hemorrhagic nephritis with temporary improvement, followed by lapse into progressing chronic nephritis with eventual death in uremia. (Courtesy Alving and Van Slyke.)

sense of improvement in physical welfare is noted by the patient. At 52-56% the phenolsulfonphthalein test begins to be impaired. Readings of 70% or above indicate normal function. High readings indicate hyperfunction.

Sources of error in this test occur through inaccuracy in timing urine collections and incomplete emptying of the bladder.

The great value of this test is demonstrated in 2 charts reproduced from Van Slyke.[49] In explaining these charts Van Slyke stated that in Case 1 (Fig. 675) the clearance was first noted 1 mo. after onset, at 15% of average normal. Then during 2 mo. it rose to 100%. The specific gravity, which was very low at 1.010, showed no rise at all during these 2 mo. Improvement in this patient was genuine and was followed by complete recovery. The specific gravity figures 6 mo. after discharge were also found to be normal. For some time after the second month an abnormality remained in the kidneys which, although it did not interfere with urea excretion, was nevertheless indicated by the low specific gravity values that the concentration test continued to yield.

In Case 2 (Fig. 676) during the first 7 mo. the specific gravity test followed the urea clearance more or less closely. However, between the seventh and tenth months the specific gravity fell to 1.010, which is nearly the minimum reached in terminal nephritis. At this time the urea clearance still showed 30% of normal function. During the subsequent 20 mo., although the clearance gradually approached the uremia level at 5% of normal, the specific gravity showed no further fall.

Dye test of renal function

A number of different substances have been suggested for the so-called dye test of kidney function. The first dye used was methylene blue, which was introduced by Achard and Castaigne[50] in 1897. Later, indigo carmine was used by Heidenhain in his investigation of the physiology of the kidney. Later on, in 1903, Voelcker and Joseph suggested the use of the dye for the testing of renal function. Twenty ml. of a 0.4% solution were injected into the muscles of the gluteal region. Normally the urine became greenish blue 10-15 min. after the injection. Our experience with indigo carmine has been limited to the separate determination of the functions of the kidney when a cystoscope is introduced into the bladder and the appearance of colored urine trickling down from each side noted. This was termed chromocystoscopy. Rosaniline was introduced by Lepine[51] in 1898. One ml. of a 1% solution was injected subcutaneously. Geraghty and Rowntree[52] deserve credit for introducing the phenolsulfonphthalein test for estimating renal function.

Phenolsulfonphthalein test (PSP) of kidney function

The phenolsulfonphthalein test is frequently used in medical and surgical diagnoses. It has a definite field of usefulness but cannot be relied upon to the exclusion of other methods of testing kidney function. A low phenolsulfonphthalein output is very suggestive of renal injury. In surgical cases, in connection with operability or operative risk, the test is quite useful.

Reagents:

1. Ampules of phenolsulfonphthalein.*
    - (a) Dissolve 0.6 gm. phenolsulfonphthalein in 0.84 ml. 2N sodium hydroxide in 0.75% sodium chloride solution.
    - (b) Dilute to 100 ml. with 0.75% sodium chloride solution.
      This is the monosodium or acid salt, which is slightly irritant locally when injected.
    - (c) Add 2 drops 2N sodium hydroxide. Solution should change to a Bordeaux red. This solution is nonirritant.
    - (d) Ampule in 1.5 ml. quantities, seal hermetically, and sterilize.
    - (e) One ml. of this dye is injected intramuscularly.
2. Standard solution of phenolsulfonphthalein (100 ml. contains 0.6 mg. phenolsulfonphthalein).
    - (a) Add 1 ml. phenolsulfonphthalein solution (reagent 1d or commercial ampule of PSP) to 10 ml. 10% sodium hydroxide.
    - (b) Dilute to 1000 ml. with distilled water. This represents the 100% standard.
    - (c) Dilutions of the 100% standard should be made to represent 90%, 80%, etc., if desired.
3. Sodium hydroxide, 10%.
    - (a) Dissolve 10 gm. NaOH in enough distilled water to make 100 ml. Keep tightly stoppered.

Procedure for IM administration:

1. Instruct the patient to omit breakfast before reporting to the laboratory in the morning.
2. Give the patient 600-800 ml. water about 30 min. prior to the injection.
3. 30 min. later inject 1 ml. sterile PSP solution.
4. Allow 10 min. for the beginning of the excretion of the drug.
5. 1 hr. 10 min. after the injection collect the urine in a bottle labeled "No. 1." Collect the entire specimen.

---

*Ampules containing 6 mg. PSP/ml., sterile, may be obtained commercially.

6. 1 hr. after this instruct the patient to collect the second specimen in a bottle labeled "No. 2." In patients with obstruction to the flow of urine, the urine is drawn off at the end of each hour. Other patients may simply be allowed to urinate at hourly periods.
7. To the entire first-hour specimen in bottle No. 1 add 10 ml. 10% sodium hydroxide.
8. Rinse the mixture into a 1000 ml. graduated cylinder with a few ml. water.
9. Dilute to 500, 750, or 1000 ml., depending on the depth of color. The color must be lighter than the color of the standard soluion if visual colorimetry is used.
10. Read in the colorimeter.
11. Calculate the results of the first specimen.
12. Carry out the same procedure with the second specimen and calculate the results. Report the entire amount of dye excreted.

Procedure for IV administration:

1. Steps 1 and 2 above.
2. 30 min. later inject 1 ml. sterile PSP solution intravenously.
3. Collect urine specimens at 15, 30, 60, and 120 min.
4. Measure PSP specimens as described above.

Calculation*:

$$\frac{\text{Reading of standard}}{\text{Reading of unknown}} \times \frac{\text{Dilution of unknown}}{\text{Dilution of standard}} = \%\text{ of dye excreted}$$

Example: Reading of standard is 15; reading of unknown is 20; dilution of standard is 1000; dilution of unknown is 750.

$$\frac{15}{20} \times \frac{750}{1000} = 56\tfrac{1}{4}\%$$

Photoelectric colorimeter: Wavelength 520 mμ.

$$\frac{OD_u}{OD_s} \times \frac{\text{mg. standard}}{6} \times 100 = \%\text{ of dye excreted}$$

Suppose 56¼% of dye were eliminated the first hour and 30% the second hour. Report as follows:

First hour	56¼%
Second hour	30 %
Total dye eliminated	86¼%

Normally about 60-75% of the dye should be excreted in 2 hr.

Many prefer to collect specimens at 15 min., 30 min., 1 hr., and 2 hr. Normal ranges for these time intervals are 28-51, 13-24, 9-17, and 3-10% excretion, respectively.

This is a very important test in connection with the estimation of kidney function. Normal kidneys excrete 60-75% of this dye in the 2 hr. period allowed for the test. A fall to 40% indicates impaired function. Reduction to 20 or 30% is the rule in well-marked cases of nephritis, whereas excretions of less than 10% may be interpreted as very serious. The exact interpretation of the findings of the phenolsulfonphthalein test, however, is that it indicates a pathologic condition of the kidneys for the moment and not over an extended period of time. In order to obtain a true estimate of the condition of the kidneys over an extended period of time, one must resort to blood chemical methods.

According to the work of Frothingham and Dennis, it is known that the phenolsulfonphthalein test may be normal or may be increased in acute glomerulonephritis. In certain other cases of acute nephritis there may be an extremely low excretion, almost to zero. These figures are based largely upon experimentally induced nephritis, induced by the injection of uranium nitrate. In chronic nephritis in clinical practice we have known the phenolsulfonphthalein output to be between 70 and 85% and still there was marked damage to kidney function. It is a clinical fact that low excretion from 10 to 15% is the rule in cardiac decompensation with chronic passive congestion of the kidneys. This rises rapidly when the congestion is relieved by improved heart action. In chronic nephritis, although the estimation of this test is important, it sometimes presents inexplicable variations.

LaMotte phenolsulfonphthalein apparatus—roulette type

Phenolsulfonphthalein is injected and the specimen collected as in the test described on p. 1892. The method of reading the test, in which advantage is taken of the chemical indicator properties of phenolsulfonphthalein, may be termed the bicolor method. This completely eliminates the effects of color and turbidity of the specimen in making the color comparison.

Concentration and dilution tests

As indicated before, the concentration tests of urine are mainly for the purpose of determining the functional ability of the tubules.

Mosenthal 2 hr. specific gravity test

This is a simple method of ascertaining the concentration power of the kidneys. The specific gravity is taken on 2 hr. samples of day urine, and the amount of the night urine is then measured. For healthy individuals this amount is 400 ml. or less, while the specific gravity is 1.018 or higher. In the 2 hr. samples of the day urine the specific gravity fluctuates 10 points or more from the highest to the lowest point.

Impairment of kidney function is noted by an increase in the night urine, that is, it goes above 400 ml., while the specific gravity is low, around 1.015. Lower specific gravity is seen with very little variation in the 2 hr. specimens of day urine. The specific gravity is fixed and does not change.

---

*Comparators are available.

The patient must be directed not to take any liquids or foods after supper or in the morning until the morning urine is voided. He is permitted to take breakfast or noonday meal of an ordinary type but must take no liquids or foods between meals.

This test is extremely valuable in nephritis because it tells some general points about kidney efficiency and gives data on the water excretion.

Interference with the transudative power of the glomeruli and the secretory property of the tubules can be ascertained by observing the disproportion between fluid intake and fluid elimination. Use the **water test of Volhard.**

Patient must remain in bed during the test. Give 1500 ml. water in the morning on an empty stomach. Collect the urine every hour for 4 hr. and later every 2 hr. After 4 hr. the patient is on a dry diet. Normally most of the consumed liquid is eliminated during the 4 hr.; small amounts are eliminated during the latter part of the day. In the second and third hours after water consumption specific gravity varies between 1.001 and 1.003 rising later in the day to 1.027.

Deviations from the normal: If in the first 4 or 5 hr. more urine is eliminated than water consumed, e.g., 1600 ml., with a specific gravity of about 1.008 to 1.010, but not very low (isothenuria), it indicates severe kidney damage. Some patients may eliminate less fluid than was consumed, as in cases approaching edema, such as hypothyroidism, cardiac decompensation, and the later stages of nephrosis.

Fishberg concentration test

This is a simpler method than that of Mosenthal. It is fully described in the classic volume of A. M. Fishberg, *Hypertension and nephritis.* On the evening before the test the patient takes his supper at 6 P.M. This meal should contain a large amount of protein, but the fluid intake should not be more than 200 ml. No food or drink may be taken after this until the test is finished. The urine should be voided before retiring and should be discarded. The first specimen saved is the morning urine. The patient remains in bed and another specimen is collected 1 hr. after the first in another container. A third specimen is collected in still another container 2 hr. after the first. The specific gravity of each of the 3 specimens is taken. Under normal conditions the specific gravity should be over 1.024 in at least one specimen.

This test is based upon the fact that concentration is the most essential function of the normal kidney, especially the tubular portions, and that any decrease in this quality is a prime indication of renal impairment. Accordingly, under the conditions of this test the specific gravity, which indicates the concentration of urinary constituents, should be increased if the kidney function is normal, for the reason that no fluid is being ingested during the performance of the test. At the same time, if the kidney function is materially disturbed, the specific gravity will be lower than usual. Accordingly, the figure 1.024 is fixed as the minimum level for normal urine. In cases of uremia the specific gravity figures are surprisingly lower, sometimes as low as 1.010.

The test cannot be used when there are conditions of uremia, but it is very useful in early cases of renal impairment, especially to indicate the impairment of the tubular portions of the kidney.

Sodeman-Engelhardt concentration test[53–56]*

The renal concentration test employing posterior pituitary extract is based upon the renal action of this substance, which has been shown to inhibit water diuresis as well as increase the chloride excretion. It reduces urinary volume and increases the concentration of solids in the urine. This action takes place in spite of the ingestion of water, so that previous preparation of the patient by fluid restriction is unnecessary.

In practice the following procedure is carried out: The unprepared subject empties the bladder and the specimen is saved. Immediately 10 units (1 ml. obstetric or 0.5 ml. surgical) posterior pituitary extract is given subcutaneously. The subject receives nothing by mouth until the test is completed. Specimens are obtained at the end of the first and second hours. The specific gravities of the 3 specimens are then taken, and the usual corrections for albumin and temperature are made, if necessary.

In normal individuals at least one of the specimens will show a specific gravity of 1.022

---

*Courtesy of the originators of the test, Drs. W. A. Sodeman and H. T. Engelhardt of New Orleans, La.

or more. Urinary volumes may be small, but inexpensive and accurate urinometers requiring only 4-6 ml. urine are available.

The dosage of posterior pituitary extract used does not affect the blood pressure. Hypertension is not a contraindication to the test. The extract causes coronary constriction and should be used with caution in angina pectoris. Acute coronary occlusion, sensitization, and late pregnancy are contraindications to its use.

The test is simple, requires only minimal cooperation by the patient, particularly as far as fluid restriction is concerned, and can be carried out immediately, without preparation of the patient, at any time of day. It is particularly indicated in edematous patients when other concentration tests are inaccurate because of diuresis. Furthermore, it is of value in surgical patients when restriction of fluids is contraindicated.

Volhard-Fahr concentration and dilution tests[48]

Concentration procedure:

1. Allow no fluids from the evening before the test until the test is completed and no food between meals. All 3 meals must be without liquids and without liquid food.
2. 8 A.M. Have patient empty bladder. Thereafter collect urine in separate containers every 3 hr. until 8 P.M.; that is, at 11 A.M., 2 P.M., 5 P.M., and 8 P.M., and collect all urine from 8 P.M. until 8 A.M. the next morning in 1 container.
3. Note the quantity and specific gravity of each 3 hr. sample and of the 12 hr. sample and plot as a curve. Normally the specific gravity of at least one sample should be 1.030 or at least 1.025.

Dilution procedure:

1. Have the patient omit breakfast on the day of the test. For lunch and dinner give the patient the diet to which he has been accustomed.
2. 8 A.M. Have patient empty bladder and give him 1500 ml. water.
3. Collect urine in separate containers at 8:30, 9, 9:30, 10, 10:30, 11, 11:30 A.M., and 12 noon, 8 specimens in all.
4. Collect all the urine from 12 noon to 8 A.M. the next morning in one container.
5. Note the quantity and specific gravity of each sample and plot as a curve. Normally the total quantity voided should be 80-120% of the intake (1200-1800 ml.). The specific gravity of at least one sample should be as low as 1.003.

Isberg-Newburgh 18 hr. concentration test of kidney function

Isberg and Newburgh[57] described a simplified concentration test of kidney function based on the 38 hr. concentration test of Lashmet and Newburgh.[58] The test is performed over a period of only 18 hr. and does not require the use of a special diet. It is particularly convenient for use on ambulatory patients. A simple, rapid, and accurate method for quantitative determination of proteinuria may also be made. This test is based on the comparison of the turbidity of urine, in which protein has been precipitated by 2% sulfosalicylic acid, with the turbidity of a permanent, standard suspension of inorganic substance.

Procedure: The subject finishes his usual supper by 6 P.M. He then has nothing to eat or drink until noon the following day; he may carry on ordinary activity during this time. Collect urine specimens at 8 A.M., 10 A.M., and 12 noon, with complete emptying of the bladder each time. Determine the specific gravity of each specimen with the urine at room temperature and with an ordinary urinometer which has been checked with distilled water.

Test the most concentrated specimen for the presence of protein, and, if present, determine the amount quantitatively in order to correct the specific gravity when necessary. For every 1% of protein present in the urine, subtract 0.003 from the observed specific gravity; any proteinuria less than 0.3% does not need to be considered. Thus the specific gravity of most urines will not require correction.

Isberg and Newburgh have further simplified the easy and accurate method of Lashmet and Newburgh[58] for quantitative measurement of proteinuria.

Reagents:

1. Standard turbidity suspensions.
    - (a) Stock suspension. To 200 ml. of distilled water in a 500 ml. volumetric flask add 50 ml. N/10 sodium hydroxide solution and 8 gm. copper sulfate, hydrous. Dilute to 500 ml. with distilled water. Shake vigorously to ensure uniform turbidity.
2. Standard tube.
    - (a) Shake the stock solution thoroughly and transfer exactly 2 ml. to a test tube, using a pipet.
    - (b) Add 23 ml. distilled water.
    - (c) This standard tube can be made permanent by drawing out its open end and sealing in a flame. **Before using, invert the standard tube several times to obtain uniform turbidity.**
3. Sulfosalicylic acid, 2%.
    - (a) Dissolve 2 gm. sulfosalicylic acid in enough distilled water to make 100 ml. solution. This reagent may turn pink on standing. Such solutions should be discarded, for the pink cast interferes with accurate comparison with the standard.

Procedure:

1. Use graduated 15 ml. conical centrifuge tubes. Place mark U at 1.66 ml. for tube 1, at 0.83 ml. for tube 2, and at 0.5 ml. for tube 3. Place mark R at 12.5 ml. on each tube. Tube

1 represents 0.3% protein, tube 2, 0.6%, and tube 3, 1% protein. (See Fig. 677.)

2. To 1 ml. urine, add 9 ml. distilled water, making a dilution of 1:10. Add the diluted urine to U mark of tube 1 and then add 2% sulfosalicylic acid up to mark R. Mix thoroughly and allow to stand for 3 min. If the resulting turbidity matches that of the **standard tube**, the urine contains 0.3% protein; the specific gravity of the urine is then corrected by subtracting 0.001. If the turbidity is less than that of the standard tube, no correction of the observed specific gravity is necessary.
3. If the turbidity of tube 1 is greater than that of the standard tube, add the urine diluted 1:10 to U mark of tube 2 and then add 2% sulfosalicylic acid to R mark. Mix thoroughly and allow to stand; if the turbidity matches that of the standard tube, the urine contains 0.6% protein. The observed specific gravity then is corrected by subtracting 0.002. If the turbidity is greater than that of the standard, add the diluted urine to U mark of tube 3 and sulfosalicylic acid to the R mark. If the turbidity resulting in tube 3 matches that of the standard tube, the urine contains 1% protein. The observed specific gravity is then corrected by subtracting 0.003. Urine containing more than 1% protein should be diluted 1:20, and the foregoing procedure with the 3 tubes repeated.

A maximum specific gravity of 1.025 is considered the lower limit of **normal** for this 18 hr. renal concentration test.

Of 200 cases of essential hypertension, 124 cases, or 62%, showed impaired concentrating ability. The concentration test was found to be more sensitive than the urea clearance test in detecting early kidney damage in essential hypertension. These authors also found that in each of 8 cases of glomerulonephritis, both subacute and chronic, there was impaired concentrating ability. The maximum specific gravity in these cases ranged from 1.010 to 1.020.

Addis urea concentration test

This test is for ambulant patients—not for patients with edema or very high diastolic pressure or failing heart or in the late stages of Bright's disease.

Procedure:

1. Instruct the patient to abstain from fluids of all sorts after breakfast on one day until he arises from bed on the following day and tell him to collect a 12 hr. specimen of night urine, voided directly into a wide-mouthed bottle. It must be made plain that the urine passed at the beginning of the 12 hr. period is to be discarded and only the urine saved

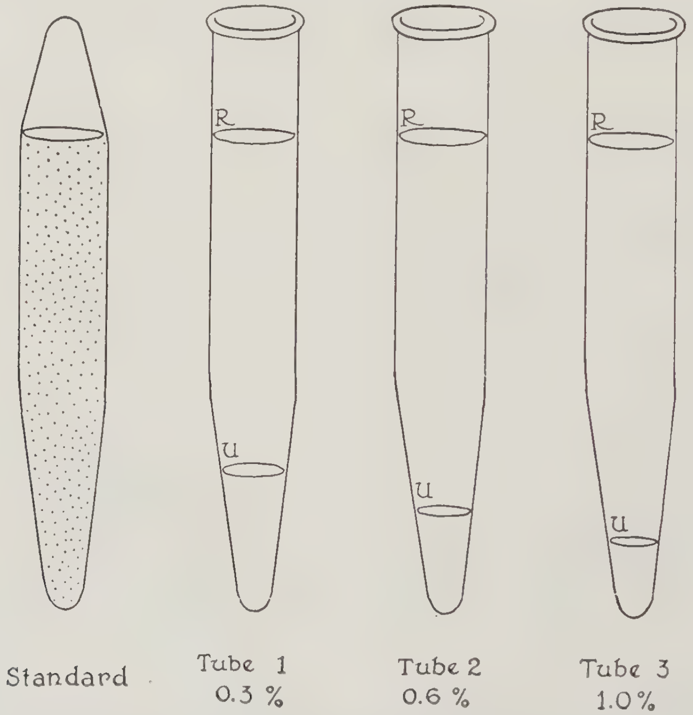

Fig. 677. Set of tubes for rapid quantitative determination of proteinuria. **Tube 1: U** mark **is** at 1.66 ml. = 0.3% protein. **Tube 2: U** mark is at 0.83 ml. = 0.6% protein. **Tube 3: U** mark is at 0.5 ml. = 1% protein. The **R** mark is at 12.5 ml. (From Isberg, E. M., and Newburgh, L. H.: Am. J. M. Sc. **211**:701, 1946.)

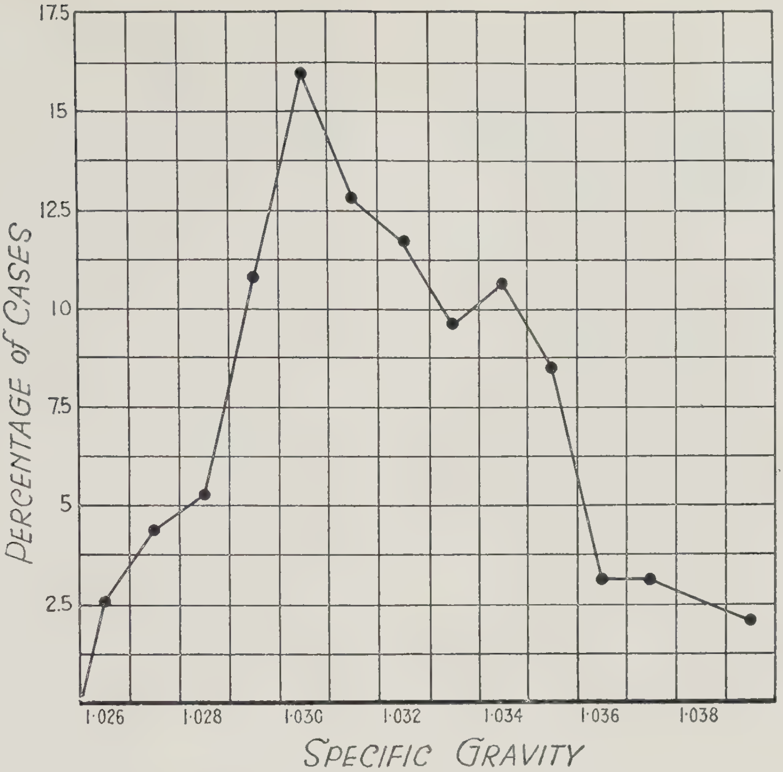

Fig. 678. Percentage frequency distribution of specific gravity of the night urine in normal individuals after restriction of fluids. (From Addis, T., and Shevky, M. C.: Arch. Int. Med. **30**:559, 1922.)

that has been formed by the kidney during the 12 hr. of the night.

2. Instruct patient that usual diet may be taken but that water, tea, coffee, milk, soup, or any other fluids must be avoided.
3. Measure the specific gravity.

In standardizing this test Addis made 94 observations on 75 normal persons. The average specific gravity was 1.032; the standard deviation ± 0.00281, and the variability 8.8%. Fig. 678 shows Addis' chart revealing the percentage frequency distribution of specific gravity.

Addis count of urinary sediment

The Addis count is a procedure to make the differentiation of the formed elements of the sediment of the urine more accurate. It was described by Thomas Addis in a communication entitled, "A clinical classification of Bright's disease."[60]

Procedure: Secure the intelligent cooperation of the patient by written instructions given to him and spending some time with him to be sure he understands what is required. Let him take his usual breakfast next morning, including coffee, tea, or milk. Thereafter, he must abstain from all fluids during the day and night until the urine has been collected on the following morning. Fluids are defined as all substances that can be poured from one vessel into another. In other respects his usual diet is left unaltered, and he is specifically instructed not to take more fruit than is customary, even though he may become thirsty. The collection of urine may extend from any convenient hour in the evening until the patient rises from bed in the morning, say from 6 P.M. to 6 A.M. Be sure that the bladder is completely empty at the beginning and at the end of the collection. Note the time exactly. Unless there is a considerable volume of urine in the bladder, it often does not completely empty itself. The patient is therefore asked not to urinate during the afternoon of the day on which the collection is begun and to void the total night urine when the collection is completed. The time at which the collection is begun and the time at which it is ended must be written by the patient on a label on the bottle into which the urine is voided.

Remember that the urine passed at the beginning must be discarded and not collected at all. The urine is passed into a wide-necked bottle which has been thoroughly cleaned, washed with distilled water, dried in the inverted position, and finally rinsed with a clean solution of formaldehyde, which is allowed to drain out for a short time before the bottle is closed with a clean rubber stopper. In women, catheterization is essential for this procedure. The nurse must take pains to be sure that the bladder is really emptied, though even the possibility of an incomplete collection must be remembered.

The patient returns the next morning, early, with the bottle of urine. It is almost always in a condition suitable for examination. If it is neutral or alkaline, there is a precipitate of phosphates. If the salt concentration is not too low, hyaline casts may still be found after the urine is cleared by the addition of concentrated acetic acid; but, since it is impossible to be certain that partial solution may not have occurred, cast counts are never made on such specimens, although the number of white blood cells and small round epithelial cells may be determined. If there is a precipitate of urates, the precipitate should be dissolved by placing the bottle in hot water.

Measure the volume of urine and return it to the bottle in which it was collected, reinsert the rubber stopper, and mix thoroughly by repeatedly inverting the bottle.

Immediately thereafter, transfer 10 ml. to a special graduated centrifuge tube with a diameter so narrow toward the tip that an accurate reading may be made.*

Centrifuge the tube for 5 min. at 1800 r.p.m.

In normal persons there is a deposit in the centrifuge tube of about 0.2 ml. of what seems to be mucus. In the initial stage of the condition described as hemorrhagic Bright's disease (glomerular disease), if the renal lesion is pronounced, there is a large amount of brown precipitate. In the active stage there are diminishing degrees of the brown color until in some cases it is imperceptible and the sediment is white. In the latent stage there is often no appreciable deviation from what is observed in normal urine. In the terminal stage there is no mucus; therefore the cells and casts form a closely packed white deposit at the extreme tip, giving a characteristic appearance.

In degenerative Bright's disease (disease of the tubules) no brown color is ever to be seen, and the amount of cloudy white deposit varies with the number of casts and epithelial cells. In arteriosclerotic Bright's disease (disease of the blood vessels) there is simply the colorless mucus as obtained from the urine of normal persons.

Decant the supernatant urine and remove part of the remainder with a pipet until it is reduced to a volume the magnitude of which will vary with the amount and nature of the deposit. In urines with appreciable concentration of protein a precipitate appears at the surface of the urine as its meniscus approaches the narrowing tip of the tube. In such cases add a few drops of 1% sodium chloride solution and again draw the fluid off until a convenient volume has been reached.

All the casts and cells from the 10 ml. sample of the urine are concentrated in the volume that has been selected. Draw up and blow out the fluid with a capillary pipet, thus securing an even distribution of these elements. Add a drop into each side of a blood-counting chamber and count the number of casts under the low-power field over all the ruled areas. The area counted depends on the concentration of casts. In the urine of normal persons there are very few casts, and 10 drops are usually examined. When casts are numerous, the deposit is diluted 1:5, and only 2 drops are counted over a known area. The cells are counted under a high dry objective and usually over unit areas of 0.1 sq.mm. The differential cast count is made while the casts are being counted.

In the latent stage of hemorrhagic Bright's disease, when the number of casts is small, it is best to obtain a more concentrated mixture by centrifuging urine pipetted from the bottom of the collecting bottle after it has stood still for an hour or more.

Calculation: Since the chamber is 1/10 mm. deep, the volume contained over the total ruled area is 0.9 c.mm., or 0.0009 ml. If 10 areas are examined, the volume of urine in which casts are counted is 0.009 ml. Suppose that in this volume 90 casts are found and that the volume of urine or salt solution in which the sediment was mixed was 0.9 ml. In that case $90 \times \frac{0.9}{0.009}$, which is 9000, the number of casts in 0.9 ml. But all the casts in 10 ml. urine were concentrated in that 0.9 ml. volume—so 9000 is the number of casts in 10 ml. urine. If the urine volume for 12 hr. was 300 ml., the number of casts in 12 hr. is $9000 \times \frac{300}{10}$, or 270,000. The same method of calculation is used in the cell counts. The general formula is as follows:

$$\text{No. counted} \times \frac{\text{Vol. in ml. in which sediment was mixed}}{\text{Vol. in ml. in which count was made}} \times \frac{\text{Vol. of urine in ml. per 12 hr.}}{10} = \text{No. in 12 hr. urine}$$

Addis count in children: Boyle et al.[61] investigated the usefulness of the Addis count in estimating recovery of children from post-infectious nephritis. The Addis count, described by Addis,[60] was based upon the idea that the type of renal pathology might be predicted from study of the sediment. In 1926[62] he published what he considered to be normal figures for the various constituents, particularly red blood cells, leukocytes, epithelial cells, and casts. Goldring[63, 64] made studies of the sediment of clinically well adults and of adults with nephritis, rheumatic heart disease, subacute bacterial endocarditis, and pneumonia. His averages for normal adults were higher than those of Addis. Naeraa[65] reported figures for normal adults higher than those of Addis and lower than those of Goldring. He claimed that the number of red blood cells increases with the age of the individual.

---

*Convenient and accurately made tubes are furnished by Arthur Thomas & Co., Philadelphia, Pa.

The results of the examination of the urinary sediments of the patients who were investigated by Addis fall into classifications in consonance with the classification of Bright's disease used by him. He calls the first division hemorrhagic Bright's disease; the second, degenerative Bright's disease; and the third, arteriosclerotic Bright's disease.

Addis count in hemorrhagic Bright's disease: This is glomerulonephritis. In this condition the urine contains so many red blood cells that it has a mahogany brown appearance. The precipitate consists of lysed and distorted red blood cells, with a considerable admixture of pus cells and epithelial cells. Casts found in this cellular debris vary from lemon yellow to dark brown. Red blood cells are found. Blood casts are found which are pathognomonic of hemorrhagic Bright's disease. The symptomatology of this disease is quite variable, but there is usually a moderate increase in diastolic pressure and often a slight, generalized edema.

The active stage follows the initial stage, or it may be the result of an exacerbation of the continuing streptococcal infection in a patient with latent hemorrhagic Bright's disease. It is accompanied by an increase in the number of casts and in the rate of protein excretion and by the appearance of fatty casts and fat droplets on all the hyaline casts. If there is no increase in blood pressure, it is only by the large number of red blood cells and the finding of an occasional blood cast that the condition can be distinguished from what Volhard and Fahr called "genuine nephrosis." With the disappearance of the inflammation the lesion may become latent and heal; with its continuance it will progress, either directly or after an interval of latency, to the terminal stage.

As the terminal stage approaches, there is a gradual change in the nature of the urinary sediment. As one after another of the inflamed glomeruli become completely disabled and fibrosed so that urine no longer flows down their tubules, fewer red blood cells and pus cells come from the shrunken kidney, and blood casts are hard to find. When the amount of secreting tissue is decreased to less than ⅓ of its original amount, the urea concentration of the blood begins to rise; and, as the kidney grows smaller and smaller, the blood urea concentration rises higher and higher. All the casts are renal failure casts.

Addis count in degenerative Bright's disease: This second classification has been called degenerative Bright's disease because the most prominent feature of the sediment is the large number of epithelial cells in various stages of granular or fatty degeneration. It is impossible to determine whether they were originally epithelial or white blood cells. Addis counts them together.

Degenerative Bright's disease is not an entity but only a convenient term under which to group all those many pathologic conditions that may give rise to degenerative changes in the kidneys. They may be summarized under 6 divisions.

1. Certain cases of unknown etiology are called cryptic degenerative Bright's disease. These cases are usually seen only when edema has developed. Nothing is known of the initial stage.
2. There are patients with degenerative Bright's disease in whom the chemical constitution of the causative agent is known, such as mercury, chromium, and uranium salts, as in jaundice and in some cases of malaria.
3. The unknown toxin derived from the fetus in the latter half of pregnancy produces a degenerative Bright's disease accompanied by hypertension.
4. Toxemia that may accompany any generalized infection is likely to produce a slight cloudy swelling of the kidney. This may take the form of desquamation of renal cells with many epithelial and granular casts and much protein.
5. Focal infections are not often associated with any but minor grades of renal degeneration, but some patients develop proteinuria and edema.
6. Mixed infections which are found in long-standing osteomyelitis with sinus formation tend to produce the waxy kidney.

Addis count in arteriosclerotic Bright's disease: This is the final classification of Addis. It occurs more commonly than any other form of Bright's disease. So far as the kidney is concerned, it is of negative character, for, when the diagnosis has been made, it is no longer necessary to consider the renal lesion as a factor in the management of the patient. These are the patients with hypertension who are often told that they are suffering from "chronic interstitial nephritis" and who consequently live in fear of death of a uremia that never comes. With examination of the urinary sediment by Addis' method, it is possible to construct a clear picture of the genesis, the rise and fall, and, if fibrosis advances, the terminal diminution in the activity of the renal lesion; the classification that grows out of such observations is an advance toward a purely etiologic classification, the classification that must always remain the one toward which we strive.

Xanthoproteic reaction

Volhard termed the xanthoproteic test a criterion for judging the danger to life of the kidney lesion. It was assumed by Beecher that the symptoms of uremia parallel the accumulation of products of intestinal putrefaction, such as phenol, phenol derivatives, paracresol, and oxy acids in the blood. These undetoxified products of intestinal decomposition accumulate in the blood and tissues because the detoxifying processes are no longer carried out completely in the wall of the intestine and the liver. The chromogen materials are retained in the skin, and these give the yellow color to the skin of uremics.

Procedure:

1. To 2-3 ml. of the solution to be tested add concentrated nitric acid.
2. Upon the addition of nitric acid a white precipitate forms which disappears; the solution turns yellow upon heating.
3. Cool and add ammonium, potassium, or sodium hydroxide. The color of the yellow solution deepens to orange.

This chemical reaction is due to the phenol group with which nitric acid forms nitro modifications. Hawk criticized the test as not satisfactory for use in urinary examinations because of the indeterminate color of the end point, thereby making it qualitative only.

CORRELATION OF RENAL FUNCTION TESTS

It is not often possible to correlate the various tests which are supposed to express kidney function in per cent of normal. As Belt[48] has summarized in his excellent review of this subject, readings taken at the same time in the same individual may be quite low in one type of test and definitely high in another. On the other hand, a very close correlation will be found to exist between different readings of the same test done on successive days. This discrepancy arises through the fact that each particular test must be an expression of a slightly different phase of kidney function. In order to give a graphic expression of these facts, Belt compiled a chart (Fig. 679) which

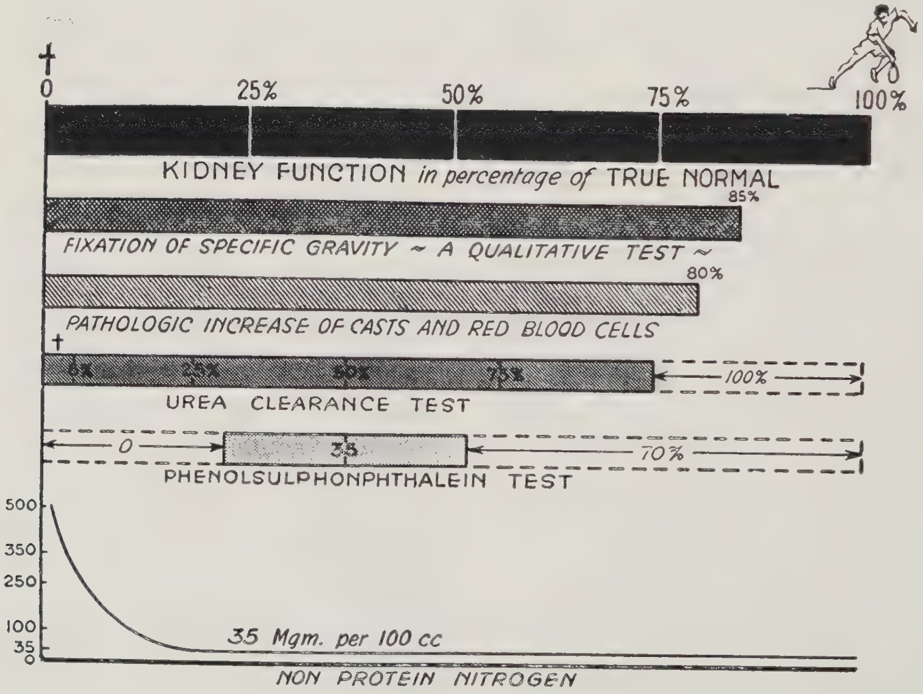

Fig. 679. Correlation of renal function tests. Solid bar at the top represents true kidney function. This is never completely measured by any test. The tests in current use are represented below by a series of shaded bars. The length of each indicates its range in comparison with the others and with the true normal. (From Belt, E.: In Cabot's modern urology, Philadelphia, 1936, Lea & Febiger.)

shows that the earliest sign of renal dysfunction is a fixation of specific gravity. This test is extremely sensitive in revealing slight renal damage, but it does not distinguish between a moderately advanced and a terminal stage of the disease. He states that an abnormal number of casts and red cells is the next most sensitive indication of disorder. This has a slightly quantitative significance when differential counts are compared from time to time. He calls attention to the fact that the urea clearance test has the widest range of all the tests attempting to express function in per cent of normal. It is not sensitive to changes less advanced than are represented by a loss of 20% of the kidneys' functional capacity but does permit readings on the low side of the scale all the way down to 5%.

Furthermore, the phenolsulfonphthalein test is less sensitive to early changes than is the urea clearance test. Zero readings are recorded by it when a wide margin of kidney function still exists.

The nonprotein nitrogen begins to be elevated as the phenolsulfonphthalein test approaches zero and is always high when the urea clearance test is 20% or below. In the absence of general metabolic factors which might influence the degree of elevation of the nonprotein nitrogen, its level above normal marks the diminution of secreting tissue toward zero.

Chapter 104

Interpretation of urinary findings

SAM FRANKEL

Chyluria

There are 2 kinds of chyluria: (1) the tropical form due to invasion of the blood and urinary tract by the *Wuchereria bancrofti* and (2) a variety that is not parasitic but is of unknown etiology. The disease is the result of lymphatic obstruction. The urine is of an opaque white color, closely resembling milk; under the microscope the turbidity seems to be caused by numerous minute granules, the fat being in molecular form. The only difference between lymph and chyle is that the latter contains a much larger percentage of fat.

The generally accepted theory of the cause of chyluria holds that there is a fistulous communication between the lymphatic and urinary tracts and presupposes a lymphatic obstruction somewhere between the small intestines and the thoracic duct. Chyluria occurs in the presence of thoracic duct obstruction only when the collateral lymphatic circulation is inadequate.

The lymphatic vessels of the kidney form 3 plexuses: one in the substance of the kidney, a second beneath its fibrous capsule, and a third in the perinephric fat. The second and third communicate freely with each other. The vessels from the plexus in the kidney substance converge to form 4-7 trunks which issue at the hilum. Here they are joined by vessels from the plexus under the capsule and, following the course of the renal vein, end in the lateral aortic glands. The perinephric plexus is drained directly into the upper lateral glands.

The route from the intestinal to the renal lymphatics has been the subject of much speculation. According to Magnus-Levy, the chyle must first go from the mesenteric lymph channels through the mesenteric lymph glands to the thoracic duct. Then, because of obstruction, there is a retrograde flow to the upper lumbar lymph glands which drain the renal lymphatics. To obtain such a retrograde flow an insufficiency of the valvular system of the lymphatic channels must be assumed. Many explanations have been offered for chyluria, but the theory of lymphatic block and direct urinary tract communication is probably the most sufficient for the present.

Symptoms: The symptoms of chyluria are mainly the milky appearance of the urine, which suddenly follows the partaking of a meal rich in fats. It may develop after a strain, or it may appear without any demonstrable cause. It has been noted during childbirth with subsequent cessation after delivery. It may be continuous or intermittent. In some cases it is present at all times; some have observed it in only the night urines, clearing as the patient became active during the day; still others noted chyle in the day urine only; again it was found only when the patient had been exercising vigorously; it may be influenced by posture.

Lipuria and marked **pyuria** may be confused with chyluria; in the former the fat is present in the droplet form although occasionally emulsified to the extent of a milky color. Microscopic examination will differentiate the pyurias. The fat in the urine of chyluria is in molecular form and therefore presents no morphology. In such cases the presence or absence of fibrinogen, cholesterol, or lecithin will be of significance.

In chyluria the urine contains coagula, due to the large amount of fibrin. These clots may form in the bladder and be abundant enough to give rise to symptoms. The specific gravity is low, reaction is acid, and there is a large amount of albumin. Microscopically the clots show fibrin with a number of red cells embedded with small plates of hematoidin. There are many red cells and many small fat globules. Pus corpuscles and epithelia from the ureters and bladder are found. In the tropical variety one may see the embryonal forms of the filaria.

Two glasses of equal parts milk and cream should cause chyle to appear in a catheterized specimen of urine removed at the end of 1 hr. A second specimen should be taken at the end of 4 hr. If the test is negative, it should be repeated with the patient in the recumbent position. Since chyluria is intermittent, all the tests may be negative, but if injected perirenal lymphatics are present and the tests are repeated at intervals, chyluria will undoubtedly be found. Hampton kept his patient on Johns Hopkins Hospital diet, adding an extra amount of butter and giving 2 glasses of milk before each test. He catheterized the kidneys every hour for 4 hr. Chyle was present in large amounts in the first-hour specimen and had practically disappeared in the last collection.

Renal tuberculosis

In early cases of renal tuberculosis the urine may be practically normal in appearance, but it is frequently cloudy from pus. The volume may not be affected but is likely to be increased, the reaction is acid, and there are traces of albumin and a few renal cells. In advanced cases the urine is usually pale, cloudy, and alkaline, has an offensive odor, and is irritating to the bladder. In such cases albumin and pus are always present though frequently not abundant. The pus is generally intimately mixed with the urine and does not settle as quickly as does the pus of cystitis. Casts are seldom abundant and are obscured by the pus. Tubercle bacilli are nearly always present even when the pus is extremely slight and their detection is essential for the diagnosis. In some cases they may be found by appropriate staining of the sediment after prolonged centrifugation. In other cases they cannot be found, and it is necessary to inoculate guinea pigs to make the diagnosis.

Hirschberg[66] has discussed the demonstration of tubercle bacilli in the urine. The guinea pig inoculation method has been criticized because many guinea pigs contract tuberculosis spontaneously or have internal lesions which resemble those caused by the tubercle bacillus. Howell and Schultz[67] report an epizootic among guinea pigs due to a paratyphoid B bacillus which caused lesions closely resembling tubercles in the spleen and liver. Magath and Feldman[68] conclude that with reasonable care spontaneous tuberculous infection of guinea pigs can be avoided. Cummings[69] reported the incidence of spontaneous tuberculous infection in laboratory animals in Saranac, a tuberculosis center. Hirschberg attempted to make comparisons between the direct smear, the guinea pig inoculation, and culture methods for the demonstration of tubercle bacilli in the routine specimens received in the laboratory of a large hospital, reaching the conclusion that for the demonstration of tubercle bacilli in the various types of specimens the culture method gives a greater percentage of positives more quickly than either of the other 2 methods. Of the various media used for the isolation of the tubercle bacilli, Corper, Hohn, and Miraglia were found to be suitable for routine diagnostic cultures. The Hohn medium is made by the addition of a small amount of methyl green to sterile liquid egg white. The Corper medium is made according to his standard method (see Bacteriology). The Petrik medium is excellent and is highly recommended. More recent media are Tarshis and Whalen.

Corper's standard method of cultivation of tubercle bacilli: Prepare Corper glycerol water crystal violet paper medium by cutting large clean potatoes into cylinders that are soaked 1-2 hr. in a 1% sodium carbonate solution, which contains crystal violet in concentration of 1:75,000. This dye must be added just before use since the mixture tends to decolorize. These potato cylinders are wiped clean and placed in sterile tubes containing 1.5 ml. 6% glycerol water and sterilized at 120° C. 15 lbs. pressure for 30 min.

Malignant tumors of kidneys

In malignant tumors of the kidneys, we often find hematuria, intermittent or constant, as a urinary sign. In about ¾ of the cases it is the first definite symptom.

Renal calculus

In stone of the kidney the urine is somewhat concentrated, with high color and strongly acid reaction. Small amounts of albumin and a few casts may be present as a result of kidney irritation. The finding of blood cells is a very important suggestive fact in this disease, especially during the day and after severe exercise. The presence of a stone usually produces pyelitis, and variable amounts of pus then appear, the urine remaining acid in reaction. Diagnosis is confirmed by catheterization, x-ray, etc.

Pyelitis

In pyelitis the urine is slightly acid and contains a small or moderate amount of pus, together with many spindle and caudate epithelial cells. These findings may be intermittent, because of occasional blocking of the ureter on the diseased side. Pus casts and also other froms may appear when the process extends up into the kidney tubules. Albumin is always present. Even when pus is scanty, albumin is rarely under 0.15%. In all these cases, of course, bacteriologic studies must be made. *Proteus vulgaris* is found in about 50% of the cases.

Cystitis

In acute and in many chronic cases of moderate severity the urine is acid and contains a variable amount of pus, with many epithelial cells from the bladder, which are large, round, and pyriform cells. Albumin is present in small amount—less than 0.15%. *Escherichia coli* is most frequently found in these cases. In old chronic cases, especially when due to prostatic obstruction, the urine is alkaline. The sediment contains amorphous phosphates and crystals of triple phosphate and ammonium biurate. Many organisms are present.

Stone in bladder, tumors, and tuberculosis

These conditions will produce chronic cystitis, with its characteristic urine. Blood is more frequently present and is more abundant than in ordinary cystitis. With neoplasms, especially, considerable hemorrhage is likely to be found, and sometimes particles of the tumor are passed with the urine. In cases of tuberculosis it is comparatively easy to find tubercle bacilli.

Diabetes insipidus

Diabetes insipidus is characterized by an excretion of increased quantity of pale watery urine. The specific gravity is very low, around 1.001. The urine shows no sugar. There is, however, a marked increase in urea in many cases of diabetes insipidus.

Diabetes mellitus

Tests for diabetes mellitus are given in the discussion on clinical chemistry, pp. 89ff. The quantity of urine is increased up to as high as 4 L. in 24 hr. The urine is pale. The specific gravity is high, around 1.030-1.040. The urine shows the presence of glucose to a greater or lesser extent. Blood sugar is above normal. The quantity of glucose in the urine varies from 2 to as much as 8%. In advanced cases acetone is present; in very severe cases diacetic acid and oxybutyric acid appear.

Renal diabetes

In this disease there is no increase in blood sugar. There is a condition of lowering of the threshold point; that is, instead of no sugar appearing in the urine until the blood sugar reaches 170 mg.% or more, sugar appears in the urine with perfectly normal blood sugar content. It seems to be a disease of the filtration process of the kidney or represents a disturbance of the permeability of the kidney for sugar.

Nephrosis and nephritis

The meaning of the term **nephritis** in the light of present knowledge of pathology of the kidney has been changed to mean only those conditions that are **inflammatory** in nature. The primarily **degenerative** forms of kidney disease are called **nephroses.** The arteriosclerotic kidney, which is a result of changes in the kidney due to arteriosclerosis of the renal arteries, is not classified as nephrosis. Amyloid disease, which starts as a degenerative change in the vessels, is a nephrosis.

Nephroses are those diseases characterized anatomically by primarily degenerative lesions of the renal parenchyma. According to Fishberg,[70] nephroses may be divided into 4 groups as follows:

1. Larval nephroses, in which the renal lesions are of comparatively slight degree and are manifested clinically by albuminuria and the presence of some formed elements in the urine in the absence of impairment of renal function.
2. Necrotizing nephroses, in which there is necrosis of the tubular epithelium. In these cases renal insufficiency is common.
3. Chronic nephroses, in which there is chronic degenerative process in the renal epithelia, with edema as the most striking clinical feature.
4. Amyloid nephrosis.

Among the larval nephroses may be catalogued febrile albuminuria, diabetic nephrosis, nephrosis due to long-standing jaundice, pernicious anemia, and Graves' disease.

Of the necrotizing nephroses we are concerned with that type seen in acute mercury poisoning.

Chronic nephrosis is characterized clinically by edema and severe albuminuria with no arterial hypertension. Anatomically in these cases are found degenerative lesions of the renal parenchyma. Chronic nephrosis is the present term for what was formerly called parenchymatous nephritis, the large white kidney of the pathologic anatomist.

The etiology of chronic nephrosis is as follows: It is a disease of childhood and young adult life, decreasing in frequency with advancing years. Infection is supposed to play an important role in this condition. Of all the infectious agents the *Treponema pallidum* is the most clearly defined. Diphtheria, as well as pneumococcal infections, has been known to have been complicated by chronic nephrosis.

In chronic nephrosis one may find edema, proteinuria, diminution in the colloid osmotic pressure, lipemia, no impairment of renal function, arterial hypertension, and no primary inflammatory lesion of the kidney.

Albuminuria is the most common feature of chronic nephrosis. Slight and temporary glycosuria is sometimes found. In the sediment doubly refractive lipoids are found, first described by Munk. In order to determine the presence of these bodies one must use a polarizing device that can be attached to any microscope. In the blood one finds a decrease in the total protein content of the plasma, an increase in the fibrinogen content of the plasma, a decrease in the colloid osmotic pressure of the plasma, an increase in the velocity of sedimentation of the red blood cells, and an increase in the concentration of fats and lipoids in the plasma.

Amyloidosis: In amyloid nephrosis the amount of protein in the urine is very great; as much as 30 gm. protein may be lost in the urine daily. The blood picture in these cases shows profound anemia. There is sometimes a hypercholesterolemia. Edema is a common clinical symptom.

Nephritis: The type of nephritis that is most common is the acute glomerulonephritis secondary to infection, such as scarlet fever, tonsillitis, subacute bacterial endocarditis and pneumonia.

The urine is diminished, blood is present, and albuminuria is present in all cases, usually 0.2-0.4%. In the sediment, in addition to red cells and urates, we find casts—hyaline and blood casts, sometimes fatty and rarely waxy casts—leukocytes in great numbers, and epithelial cells. Specific gravity of the urine is high. There is usually impairment of renal function with retention of the nonprotein nitrogenous constituents. Nonprotein nitrogen of the blood is usually not markedly elevated, but occasionally may be as high as 180 mg./100 ml. In some cases concentration of serum chloride is high, in others low. Total protein content of the plasma is within normal limits.

See p. 1899 for further discussion of this condition.

Chronic glomerulonephritis: This is a condition of an unresolved acute glomerulonephritis. There are 3 types of chronic glomerulonephritis: the nephrotic type with edema, the hypertensive type, and the recurrent type. The amount of urine is decreased, and the specific gravity is low. The nonprotein nitrogenous constituents in the blood show no changes so long as renal function is unimpaired. With the beginning of renal decompensation retention occurs. Albuminuria is constantly present. Casts of all varieties are found in the urine—hyaline, granular, epithelial, and fatty.

Focal nephritis: According to Fishberg the term focal nephritis is used to indicate a nephritis that is a manifestation of infection, occurring at the height of the infection. Fishberg emphasizes, as Volhard[71] has already pointed out, an important difference between focal nephritis and acute glomerulonephritis, "for the latter most often, though not invariably, occurs after the primary infection has started to subside, as is seen in glomerulonephritis complicating scarlet fever and often tonsillitis. The close linkage of focal nephritis to the height of the infection is well illustrated by the old observation of Kannenberg[72] that in focal nephritis complicating relapsing fever the renal process waxes and wanes with the periods of the disease."* It is probable that the lesion in focal nephritis is due to the direct action of microorganisms on the renal structures. The types of infection in which this condition occurs are as follows: streptococcal infections, pneumonia, typhoid fever, and rarely in scarlet fever, measles, cerebrospinal fever, influenza, rheumatic fever, and many others.

In these cases hematuria is the leading symptom, occurring at the height of the infectious process. Together with blood in the urine, we find albumin, moderate in quantity, and varying numbers of hyaline, granular, and blood casts. Leukocytes are abundant, and epithelial cells may be present. In cases complicating tonsillitis we are likely to find bacteria in the stained sediment. Renal function is usually not impaired to any great degree, although the volume of urine is diminished.

---

*From Fishberg, A. M.: Hypertension and nephritis, Philadelphia, 1934, Lea & Febiger.

Nephropathies due to vascular disease: In the majority of elderly persons there is some sclerosis of the renal arteries which extends into the prearterioles. This form of renal disease is called the arteriosclerotic kidney, and it may be found in persons who have had no signs of renal disease or hypertension.

Arteriolosclerotic or hypertensive kidney: In this condition there is disease of the small arteries and afferent glomerular arterioles, with persistent elevation of the blood pressure. The patient sooner or later develops signs of involvement of the heart, brain, or kidneys. In these cases death occurs from congestive heart failure, coronary disease, cerebral vascular accidents, or renal insufficiency. Autopsies on many cases of primary hypertension have shown normal-sized kidneys with finely granular surfaces. The so-called "primary contracted kidney" is a hypertensive condition with a high degree of atrophy. One must distinguish chronic glomerulonephritis from primary hypertension with uremia since the 2 diseases are different in etiology.

Section Two

GASTRIC SECRETION AND DUODENAL CONTENT

Examination of the contents of the upper gastrointestinal tract contributes information pertinent not only to the function of the stomach and the duodenum but also of the accessory organs of the alimentary canal such as the gallbladder and the pancreas. As a result of the many changes in concept regarding diseases of the gastrointestinal tract, however, the analysis of gastric and duodenal contents has not proved as valuable as originally anticipated.

The most frequent assay concerned with gastric analysis is the determination of the presence or absence of free acid, both before and after stimulation. In this regard, however, a choice must be made as to the method of obtaining a suitable specimen. When properly performed, intubation of the patient is usually an innocuous procedure, although it does involve some discomfort. The tubeless test now available appears to be quite satisfactory and has an obvious advantage over the classical method.

Examination of the duodenal contents is at the present time used most often in conjunction with various research programs. The relative difficulty in obtaining the specimen and the lack of clinical applicability of the data obtained have resulted in little use of the available tests in this area. Information concerning the structure or mechanical function of organs such as the stomach, small intestine, and gallbladder is better obtained by radiologic examination, and abnormality of pancreatic function may be detected by the measurement of the level of activity of various pancreatic enzymes found in serum or urine.

Chapter 105

Gastric secretion

STANLEY REITMAN
SAM FRANKEL

GENERAL CONSIDERATIONS

Gastric contents

The clinical laboratory is concerned frequently with the determination of the chemical analysis of so-called "gastric contents." Gastric contents in this sense means material that remains in the stomach 1 hr. after a classical test meal has been administered. The test meal that has been in use for many years is the so-called "Ewald breakfast," later to be described. The purpose of placing a sample meal in the stomach is to determine after 1 hr. just how gastric activity has affected the material during this period. Normal gastric digestion is at its height 1 hr. after the administration of the meal.

Reviewing the physiology of gastric digestion, it is known that the secretion of gastric juice begins soon after food is placed in the stomach. It is a transparent, light-colored, yellow fluid which is acid in reaction and contains about 1% of solids. The specific gravity of gastric juice is very low, varying from 1.001 to 1.010. The principal phenomenon that goes on in gastric digestion is the splitting of the protein constituents of food by pepsin in the presence of hydrochloric acid. The action of rennin on milk is also of importance. Pepsinogen and renninogen are secreted by the gastric glands and are converted into pepsin and rennin by the action of hydrochloric acid. Hydrochloric acid combines loosely with the proteins and is called "combined" hydrochloric acid. That part of hydrochloric acid that is formed after the proteins have been converted into acidmetaprotein is designated "free" hydrochloric acid.

At the time the gastric contents are removed, namely, 1 hr. after the meal has been taken, **normally** the contents consist of water, hydrochloric acid, combined hydrochloric acid, pepsin, rennin, mineral salts, acid phosphates, and the remnants of undigested food. It also contains various products of digestion in solution. In pathologic conditions these materials are present in greater or lesser amounts and sometimes some of them are absent. Under certain conditions lactic acid is present. Microscopically, structures such as blood cells, bacteria, and abnormal cells may be seen.

Facts about gastric secretion

The stomach normally secretes hydrochloric acid, pepsin, rennin, and mucin. It is important for the laboratory to assist in estimating the degree and activity of the secretory function. Gastric acidity is an index to the concentration of the protein-splitting enzyme pepsin and the milk-clotting enzyme rennin. There are 2 kinds of mucin present in gastric secretion, a soluble mucin which plays an important part in buffering the acid and, in addition, the glairy mucus that is not concerned with this function.

According to Meakins[1] the amount of increased gastric secretion is best determined in a fasting state, and at this time the normal stomach should contain less than 100 ml. of more or less opaque liquid which, although acid to phenolphthalein, should not contain more than a low (under 10%) concentration of free hydrochloric acid. Greater quantities than 100 ml., and particularly if the amount of free hydrochloric acid is high, are significant of hypersecretion. Decreased secretion of acid is of considerable diagnostic importance in organic gastric lesions and systemic diseases, and such a decrease even to absence of hydrochloric acid is a common accompaniment of carcinoma of the stomach. However, since it occurs in 10-15% of normal people, it cannot be taken too seriously unless substantiated by other evidence of local disturbance. Meakins called attention, further, to lowered hydrochloric acid, or its absence as a prominent sign in the diagnosis of certain diseases of the blood, particularly pernicious anemia. The presence of free hydrochloric acid practically eliminates the diagnosis of pernicious anemia.

Meakins stated that gastric digestion depends almost entirely upon the presence of pepsin which is active in acid medium, but the determination of peptic activity is laborious and is seldom indicated. He believes that in rare cases in which there is an entire absence of acid secretion, determinations of peptic activity may be advisable.

METHOD OF OBTAINING STOMACH CONTENTS

Several kinds of tubes may be used in this technic, such as the Rehfuss, Ewald, or Levin tube. The Rehfuss tube consists of a small, metal oval tip attached to a very small caliber rubber tube. The tip is designed both for obtaining stomach contents and duodenal contents; i.e., it will slip through the pylorus into the duodenum after a certain period of time with the patient in correct position, lying on the right side.

The tubes are of course cleaned thoroughly and then placed in a basin of ice water before use. The patient should be gowned and in a sitting position, and the neck should be free. Gastric intubation should be performed only by a physician or a specially trained individual.

The cooperation of the patient is very important. He should be told just what is expected of him and what is about to transpire. He should be assured of the lack of pain and discomfort, provided he cooperates. He should be told to "swallow" the tube as soon as he is requested to do so. With the mouth wide open* and the head back a trifle, the head fixed in a steady position by the left hand of the operator, the right hand of the operator, without placing any fingers in the mouth, inserts the point of the tube directly in the middle line over the base of the tongue. The operator rapidly passes the tube into the posterior part of the mouth, almost "throwing" it in. The patient is now directed to swallow. At the same time the tube is pushed along gently and firmly with each swallow. Care must be taken that the tube, when placed over the base of the tongue, does not go into the trachea. The tube should not be oiled or lubricated since this material often causes the patient to vomit. Some individuals have a very active gag reflex, and the slightest pharyngeal stimulation may cause vomiting Between swallows the patient may breath shallowly and rapidly through his mouth (pant), in order to reduce the tendency to vomit. Provided there is no obstruction, the tube will glide rapidly into the stomach.

As soon as the tube is in the stomach, as judged by the mark on the tube, the outside end is lowered so that it will be below the level of the end in the stomach. A siphon is thus created and the material will flow out. If there is any difficulty, a clean glass 20 ml. syringe is attached to the outside end and suction is used. It is sometimes necessary to pull the tube gently in and out so as to remove any blocked food particles which may interfere with emptying the contents. If, in any way, failure occurs in inserting the tube, the patient must be assured that this sometimes happens and is not unusual, and that it is sometimes necessary to try again. The psychic influence of the patient in this procedure is very important. There should be no undue movement on the part of the operator or any signs of concern so that the patient's psyche will in no way be disturbed. The distance from the teeth to the cardiac orifice of the stomach is about 40 cm.

If the operator has any idea at the beginning of the procedure that the tube has gone into the larynx instead of into the esophagus, this idea may be dispelled or confirmed by holding the end of the tube to the ear and listening. If the intake and exhalation of air can be heard, the tube must be withdrawn. The tube does not go into the trachea ordinarily because the opening quickly closes at the approach of a foreign body. If there is considerable disturbance and severe dysphagia and continued strong convulsive coughing during the beginning of the placing of the tube, this indicates that the tube is in the fossa pyriformes at the side of the larynx and the tube is probably rolled up in a spiral. It must be withdrawn and started again. If it is not taken out immediately, it will suddenly be regurgitated after it is drawn up into the mouth.

---

*When a Levin type tube is used, the physician may prefer to pass it through the nose.

After the stomach contents have been removed, the tube should be pinched securely with the fingers and rapidly withdrawn. This pinching of the tube holds any foreign body that may be in the tube securely during the process of withdrawal and thus prevents the dropping of foreign bodies into the posterior pharynx and possible entrance into the trachea.

TUBELESS GASTRIC ANALYSIS (DIAGNEX BLUE)*

Azure A is exchanged from an Amberlite cation resin by hydrogen ions from hydrochloric acid of the gastric juice following caffeine stimulation. The azure A is rapidly absorbed from the small intestine and excreted in the urine. The approximate concentration may be estimated by the intensity of the color when compared with permanent standards supplied with the test material.

Directions to patient: The patient must be in the postabsorptive state until the test is completed.

1. Discard the urine specimen voided upon arising.
2. Take the 2 tablets contained in the small package with 1 glass of water.
3. At the end of 1 hr. void and discard the specimen.
4. Pour the granules from the large package into ¼ glass of water, stir well, and drink. The granules do not dissolve and should not be chewed. Rinse the glass with a little more water for any remaining granules.
5. At the end of 2 hr. collect the complete urine specimen in a clean jar.

The patient may eat at this time.

Procedure:

1. Dilute the urine specimen with water to 300 ml.
2. Fill 3 test tubes with approximately 10 ml. of the specimen.
3. Add approximately 300 mg. ascorbic acid to 2 of the test tubes. This will remove any color so that they may be used as controls by placing them in the comparator slots supplied with the permanent standards. Place the untreated sample in the center slot provided for the test specimen.

If the color intensity of the test urine is equal to or exceeds that of the 0.6 mg. standard, the patient has secreted free gastric hydrochloric acid and the test is complete.

If the test aliquot is less intense in color than the 0.6 mg. standard, acidify with 1 drop of Diagnex blue reagent (or 2 drops of 10% hydrochloric acid). Heat all 3 tubes in a boiling water bath for 10 min. Remove the tubes and allow them to cool for 2 hr. Compare color intensity as before.

If the color of the test specimen falls between the 0.6 mg. and the 0.3 mg. standards, it is presumptive evidence of hypochlorhydria.

If the color of the test specimen is less intense than that of the 0.3 mg. standard, it is presumptive evidence of achlorhydria.

Comments: The color comparator supplied with the test materials has standards that represent 0.3 and 0.6 mg. azure A.

Since azure A may be excreted in the urine in either the blue form or a conjugated colorless form, false positive tests (lack of color) may be avoided by heating in acid solution which oxidizes the conjugate to the colored form.

The blue color, which may disappear on boiling, reappears upon cooling. The full 2 hr. should be allowed for complete color development.

The use of ascorbic acid, which reduces azure A to the colorless form, allows this test to be done with only a single specimen.

Blue or green urine which may be passed for a few days following the test has no significance.

Segal et al.[2] have adapted this test to serum which avoids the difficulties encountered in cases of renal insufficiency or when it is suspected than an incomplete specimen has been submitted.

TEST MEAL EXAMINATION

The usual method of examination of the stomach contents is one examination obtained 1 hr. after a test meal.

Test meals are given to stimulate secretion of the stomach with food. It can be stimulated with various foods, but for the sake of obtaining uniform results certain standard test meals have been adopted.

Test meals are given in the morning because the stomach is usually empty at this time. If there is reason to believe the stomach will not be empty in the morning, it is well to wash it with water the evening before.

Ewald test breakfast: This consists of 40 gm. bread (1 roll or 2 slices of bread) and 400 ml. water or weak tea without cream or sugar. It should be well masticated.

Dock test breakfast: Same as the Ewald breakfast except that a shredded whole wheat biscuit is substituted for the bread. This substitution is carried out because the Ewald test meal introduces with the bread a variable amount of lactic acid and numerous yeast cells, which are completely eliminated by the shredded wheat meal. The shredded wheat biscuit contains no lactic acid.

---

*E. R. Squibb & Sons, New York, N. Y.

Boas test breakfast: This consists of a tablespoonful of rolled oats in a quart of water, boiled to 1 pint, with a pinch of salt added. This should be withdrawn in 45 min.-1 hr. after introduction. It does not contain lactic acid. When this meal is used, the stomach should always be washed with water the evening before.

Riegel test meal: This consists of 400 ml. bouillon, a broiled beefsteak (about 150-200 gm.), and 150 gm. mashed potato. It must be thoroughly masticated; otherwise the tube may be occluded when attempt is made to withdraw the meal.

Fischer test meal: This is similar to the Riegel, consisting of an Ewald breakfast plus ¼ lb. lean, finely chopped Hamburg steak, broiled and lightly seasoned. The Fischer meal and the Riegel meal may be removed in 3-4 hr. They give higher acidity values than the Ewald breakfast.

Histamine test: This is a test to demonstrate the ability of the stomach to secrete free hydrochloric acid under the maximum amount of stimulation. It should be done as an initial test if pernicious anemia is suspected. It should also be done as a control on any patient showing achlorhydria or hypochlorhydria with the Ewald test meal. In other words, if the gastric analysis shows an achlorhydria or hypochlorhydria after using this powerful stimulating agent, the results are much more significant than the lowered value for hydrochloric acid or the absence of hydrochloric acid after an Ewald meal. **This is administered only on order of a physician.**

The test should be performed with the patient under as nearly a basic condition as possible. Remove the stomach contents of a fasting patient by means of a gastric tube. Then administer histamine hydrochloride or histamine phosphate hypodermically. Gompertz and Cohen[3] recommend a total dose of 0.25 mg. This can be most advantageously administered by injecting 0.25 ml. of a sterile 1:1000 solution of histamine subcutaneously. Completely aspirate the stomach contents at 30 min. intervals from the time of injection and determine the volume and total acidity of the samples.

Alcohol test of gastric function: The use of alcohol with phenolphthalein added as an indicator has been suggested as a substitute for test meals. The technic is to have the patient swallow 49 ml. 7% solution of alcohol to which has been added 1 ml. 0.1% phenolphthalein in 90% alcohol.

PRELIMINARY SURVEY

Volume: Normal stomach yields about 20-50 ml.

Color: Normal is colorless. It may be green from bile. Blood is characteristic when present. Color may be altered by blood or drugs.

Consistency: Normally it is clear. It may contain mucus or undigested food particles.

Odor: Normally odorless. In disease the odor is sour or rancid. Watch for the odor of drugs.

Sediment: Normally none. May contain pieces of mucus, food remnants, blood clots, tumor particles.

Starch: Add 1 drop Gram's iodine to the gastric contents. Should starch be present, it will turn blue if undigested. If partially digested, it will turn red.

Reaction: The reaction of gastric contents is normally acid. It may be neutral in some cases of gastric cancer and marked chronic gastritis or when contaminated by a considerable amount of saliva.

Mucus: A small amount of mucus is normally present, but large amounts suggest chronic gastritis.

Bile: Bile is seen in very minute particles as the result of excessive straining while the tube is in the stomach. Large amounts are rarely found but if they are, it indicates upper intestinal obstruction.

CHEMICAL EXAMINATION OF GASTRIC CONTENTS

Routine examination means a qualitative test for free hydrochloric acid and organic acid and quantitative estimations of total acidity and free hydrochloric acid. In routine work qualitative tests are performed before quantitative tests are begun.

Topfer test for free hydrochloric acid

Qualitative

Reagent:

1. Topfer reagent:

Dimethylaminoazobenzol	0.5 gm.
Alcohol, 95%	100 ml.

Procedure:

1. Place a few drops of gastric juice in a test tube.
2. Add 1 drop Topfer reagent.

A bright red color will appear if free hydrochloric acid is present.

Quantitative

Reagents:

1. Topfer reagent (above).
2. N/10 Sodium hydroxide.
    (a) To about 50 ml. distilled water in a 100 ml. volumetric flask add 10 ml. N/1 sodium hydroxide. Dilute to 100 ml. with distilled water.

Procedure:

1. Place 10 ml. gastric juice in a casserole. Add 1 drop Topfer reagent. A bright red color develops if free hydrochloric acid is present.
2. Place N/10 sodium hydroxide in a buret. Add the sodium hydroxide from the buret drop by

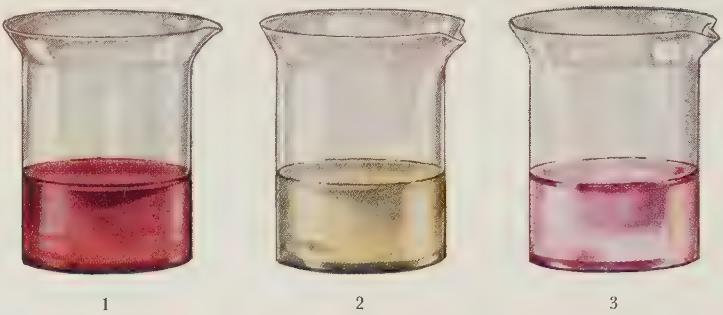

Fig. 680. Titration of stomach contents. **1,** Contents with Topfer's reagent, showing presence of free hydrochloric acid. **2,** End point in titration for free hydrochloric acid. **3,** End point in titration for total acidity in the presence of phenolphthalein.

drop to the solution in the casserole until the red color is replaced by a canary yellow. Stir constantly during the addition of the sodium hydroxide.

3. Read from the buret the number of ml. sodium hydroxide used. Calculate the number of ml. sodium hydroxide required for 100 ml. gastric juice. This gives the degree of acidity.

Example: 2 ml. N/10 sodium hydroxide were used for 10 ml. gastric juice. Ten times 2 ml., or 20 ml., would be required for 100 ml. gastric juice. The degree of free hydrochloric acid is therefore 20.

Normal free hydrochloric acid is 20°-40°.

To change the degree of acidity to percentage, multiply by 0.00365.

Degrees are numerically equal to mEq./L.

It is sometimes advantageous to determine the amount of hydrochloric acid deficiency in cases of achlorhydria. To do this test place 10 ml. gastric contents in a casserole, add 2 drops Topfer reagent, and titrate with N/10 hydrochloric acid until the first red indicative of free hydrochloric acid appears. Calculate the amount of N/10 hydrochloric acid required for 100 ml. gastric contents; this figure represents the degree of hydrochloric acid deficiency. This is not a routine test and is useful only in those cases in which hydrochloric acid therapy can be used to correct the hydrochloric acid deficiency.

Total acidity

The total acidity comprises free hydrochloric acid, loosely combined hydrochloric acid, acid salts, and organic acids such as lactic acid, butyric acid, and amino acids.

Reagents:

1. Phenolphthalein, 1% alcoholic.

Phenolphthalein	1 gm.
Alcohol, 95%	100 ml.

2. N/10 Sodium hydroxide.

Procedure:

1. Place 5 ml. unfiltered gastric contents in a casserole. Add 2 drops 1% alcoholic phenolphthalein.
2. Have a buret filled with N/10 sodium hydroxide. Add the sodium hydroxide from the buret a drop at a time to the mixture in the casserole, stirring constantly, until the mixture remains a deep pink color. This is the end point. Read from the buret the number of ml. sodium hydroxide used. Calculate the number of ml. sodium hydroxide required for 100 ml. gastric contents. This gives the degree of total acidity.

Example: If 3 ml. N/10 sodium hydroxide were used to neutralize 5 ml. gastric contents, multiply 3 ml. by 20 = 60 ml., or the degree of total acidity in 100 ml. gastric contents. **Normal** degree of total acidity is between 40 and 60-70.

Lactic acid

Lactic acid is not found normally in gastric juice. It may be present after ingesting certain foods, e.g., sour milk or foods prepared with it. If emptying of the stomach is delayed or if the secretion of hydrochloric acid is low, lactic acid may be formed from fermentation of carbohydrates by such lactic acid–forming organisms as the Boas-Oppler bacillus. This is a common finding in advanced carcinoma of the stomach.

Reagents:

1. Phenol, 1%.

Liquefied phenol	1 ml.
Distilled water to make . .	100 ml.

2. Ferric chloride, 10%.

Ferric chloride	10 gm.
Distilled water to make . .	100 ml.

Procedure:

1. To 15 ml. 1% solution of phenol in a test tube add 10% ferric chloride until an amethyst color is produced. Usually 1 or 2 drops are enough.
2. Add a few drops of unfiltered gastric contents.

A canary yellow color indicates lactic acid.

Kelling method

1. Fill a test tube with distilled water.
2. Add 2 drops 10% ferric chloride. Mix.
3. Divide the contents of the test tube into 2 parts.

4. In the first half place 1 ml. filtered gastric juice.
5. If lactic acid is present, a deep yellow color develops. Compare this color with the color of the control tube (distilled water plus ferric chloride).

Strauss method

1. Place 5 ml. filtered gastric juice in a small separatory funnel.
2. Add 20 ml. ether. Hold the stopper in tightly and shake thoroughly.
3. Allow to stand in an upright position until the ether separates.
4. Allow the bottom fluid to run out. Retain the upper 5 ml. of ether.
5. Add to this ether extract 20 ml. distilled water and 2 drops 10% ferric chloride solution.
6. Shake gently.

A slight green color indicates the presence of 0.05% lactic acid. An intense yellowish green color indicates the presence of 0.1% lactic acid.

Uffelmann method

Reagent:

1. Add 3 drops liquid phenol to 3 drops 10% ferric chloride. Dilute with distilled water until an amethyst color is produced.

Procedure:

1. To 50 ml. ether add 5 ml. filtered gastric juice. Shake thoroughly for 10 min.
2. Collect the ether by means of a separatory funnel or a dropper pipet.
3. Evaporate to dryness. Add to the residue 5 ml. distilled water.
4. Add the dissolved residue to Uffelmann reagent.

A canary yellow color indicates the presence of lactic acid.

Achlorhydria

The continued absence of free hydrochloric acid in the stomach contents is not in itself a disease entity. There are very few diseases characterized by achlorhydria. In these cases additional clinical and laboratory findings will aid in the proper diagnosis. The lack of titratable acidity in some patients is due to bile and duodenal regurgitation which neutralizes the acid output of the stomach. This kind of achlorhydria can be determined by the estimation of chlorides and trypsin in the gastric contents. Although no free acid may appear in the first hour, the study of an acid curve which appears after 60 min. may be helpful. Achlorhydria is found in the following diseases: pernicious anemia, diabetes mellitus, chronic gastritis, carcinoma of stomach, pellagra, syphilis, amebic dysentery, achylia gastrica, hypothyroidism, rheumatoid arthritis, and pulmonary tuberculosis.

Pernicious anemia: There is very seldom any free hydrochloric acid present in pernicious anemia. The enzymes rennin and pepsin are also absent. The absence of free hydrochloric acid and of the enzymes in the gastric contents may be found long before the blood picture becomes characteristic. Even though liver therapy or vitamin B_{12} may bring about a normal blood count, the achlorhydria remains.

Diabetes mellitus: In certain cases of this disease with lack of appetite there is absence of or great decrease in free hydrochloric acid. The symptoms improve when the patients are given dilute hydrochloric acid.

Chronic gastritis: In this condition the acidity may vary from time to time. Gastritis of the fundus tends toward the absence of hydrochloric acid.

Carcinoma of stomach: Absence of free hydrochloric acid, lactic acid in the gastric contents, occult blood in the stool, defect and slow emptying of the stomach as noted in x-ray examination, all favor the diagnosis of malignancy.

Pellagra: Achlorhydria is often encountered in this disease.

Syphilis: There is sometimes present a gastric subacidity, anacidity, or complete achlorhydria in this disease.

Amebic dysentery: Porgess states that in amebic dysentery the gastric contents frequently show achlorhydria.

Achylia gastrica: Here free hydrochloric acid is absent, and the total acidity rarely rises above 10. The gastric enzymes are absent, due to atrophy of the mucosa. No gastric secretion follows the injection of histamine. Normally 0.1 mg. histamine/10 kg. body weight, injected hypodermically, will stimulate gastric secretion.

Miscellaneous conditions: Hypothyroidism, rheumatoid arthritis, and pulmonary tuberculosis may frequently be associated with achlorhydria.

Hyperacidity

Hyperacidity is a common occurrence. It is found in patients with neuroses, in cases of constipation, and in excessive cigarette smokers. The eating of too many pickles, of foods rich in condiments, or of excessive amounts of carbohydrates may produce it.

Gastric and duodenal ulcers are frequently found in association with high acidity; however, in about 50% of gastric ulcer cases the acidity is normal. In duodenal ulcer the high acidity factor is more constant. The point of high acidity is usually reached in 45 min.-2 hr. after eating the test meal.

Occult blood

Benzidine test

1. Prepare about 3 ml. saturated solution of benzidine (special for blood) in glacial acetic acid in a test tube.
2. Add an equal volume of 3% hydrogen peroxide. Mix thoroughly. Should the solution turn green or blue, it must be discarded.
3. Add a few drops of unfiltered gastric contents and shake.

A green or blue color indicates the presence of occult blood (p. 1835).

Teichmann test for hemin crystals

Disintegrated blood must be examined chemically by the hemin test of Teichmann.

1. Mix a small amount of the suspected material with 1-2 crystals common salt, or place it on the thin layer of salt formed by slowly evaporating a small drop of physiologic salt solution on a slide.
2. Cover with a cover glass and run in enough glacial acetic acid to fill up the space between slide and cover.
3. Warm the slide over a flame for ¾-1 min. until bubbles arise, adding more glacial acetic acid until a faint reddish brown tint appears.
4. Then let the acetic acid evaporate entirely, and run distilled water in from the edge of the cover glass.

Microscopic examination will show dark brown rhombic plates or columns of hemin if blood is present.

Benzidine dihydrochloride test

Follow the method given on p. 1835, substituting gastric contents for urine.

Benzidine test—method of Levin-Watt[4]

1. Mix the gastric or duodenal contents thoroughly with an equal volume of distilled water.
2. Filter through 1 or 2 Whatman No. 5 extraretentive filter papers to obtain a clear filtrate.
3. To 3 ml. clear filtrate add 5 drops 50% acetic acid and 5 drops hydrogen peroxide and shake vogorously.
4. Overlay the mixture with 0.5 ml. 6% alcoholic benzidine solution and rock slightly. The benzidine solution should preferably be 2 or 3 days old.

A positive reaction is indicated by a green ring at the junction of the benzidine solution and the filtrate mixture.

This test can be used for detecting **blood in vaginal washings.** Sterile water irrigation of the posterior portion of the vagina is performed with an Asepto syringe of 10-20 ml. capacity.

Perform the test without filtration, and, if positive, follow by Papanicolaou examination. The test is positive in cases in which there are 4-6 red blood cells/high-power field.

Occult blood in urine:

1. If urine is to be tested, centrifuge 10 ml. at 1500 r.p.m. for 3 min., decant the supernatant fluid, and use the sediment.
2. Add 1 ml. water and 3 drops 50% acetic acid, shake, and add 3 drops of hydrogen peroxide. Shake vigorously.
3. Overlay the mixture with 0.5 ml. 6% alcoholic benzidine solution and observe for a green ring at the point of contact of the liquids.

Occult blood in feces:

1. If feces are used, emulsify a small portion in distilled water, filter as for gastric contents, and use 3 ml. filtrate, 8 drops acetic acid, and 8 drops of hydrogen peroxide before overlaying with the alcoholic benzidine solution.

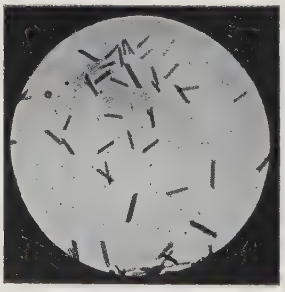

Fig. 681. Hemin crystals. (×100.)

Bile

Break up a match stick in about 5 ml. nitric acid (concentrated). Stratify with a few ml. gastric juice.

A play of colors will develop at the point of contact if bile is present.

Butyric acid

Butyric acid is manifested by the rancid, butterlike odor. If a test is desired, boil the gastric contents to accentuate this odor.

If a piece of moistened blue litmus paper is held in the mouth of the tube, the volatile acid reddens it as it escapes during the boiling. Butyric acid also separates as a drop of oil if a piece of calcium chloride is added to it.

Rennin-renninogen

Rennin is the milk-curdling enzyme of the gastric juice. It is derived from renninogen through the action of hydrochloric acid. Deficiency of rennin has the same significance as deficiency of pepsin and is more easily recognized.

Test

1. Neutralize 5 ml. filtered gastric juice with very dilute sodium hydroxide solution.
2. Add 5 ml. fresh milk and place in an incubator or in a vessel of water at about 40° C.

Coagulation of the milk in 10-15 min. shows a normal amount of rennin. Delayed coagulation denotes a less amount.

Pepsin*

Tests for identity

"An aqueous solution of pepsin (1 in 50) is acid to litmus paper. An aqueous solution of pepsin yields precipitates with solutions of tannic or gallic acid and with solution of the salts of many heavy metals.

"On heating a saturated solution of Pepsin in acidulated water to 100° C., it becomes milky or yields a light, flocculent precipitate, and loses all proteolytic power.

"**Technic:** Mix 25 c.c. of normal hydrochloric acid with 275 c.c. of distilled water. Dissolve 0.1 gm. of Pepsin in 150 c.c. of this acid. Select a hen's egg, which is not less than 5 and not more than 12 days old and has been kept in a cool place, and immerse it in boiling water during 15 minutes. As soon as the egg has sufficiently cooled to handle, remove the shell and pellicle and all of the yolk and at once rub the albumen through a clean, dry, hair or brass, No. 40 sieve, reject the first portion that passes through the sieve, and place 10 gm. of the succeeding portion in a wide-mouthed bottle of 100 c.c. capacity. Immediately add 20 c.c. of the acid and stir the mixture well with a rubber-tipped glass rod so as to separate thoroughly the particles of albumen from each other. Rinse the rod with 15 c.c. more of the acid and, after warming the mixture to 52° C., add exactly 5 c.c. of the acidulated solution of Pepsin. At once cork the bottle securely, invert it 3 times and place it in a bath that has been previously regulated to maintain a temperature of 52° C. Keep the bottle at this temperature for 2½ hours, agitating the contents every ten minutes by inverting it once. Then remove it from the bath, pour the contents into a conical measure having a diameter not exceeding 1 cm. at the bottom, and transfer the undigested egg albumen, which adheres to the sides of the bottle, to the measure with the aid of small portions (about 15 c.c. at a time) of distilled water, until the total amount used measures 50 c.c. Stir the mixture well and allow it to stand for half an hour. The deposit of undissolved albumen does not measure more than 1 c.c.

"The relative proteolytic power of Pepsin, stronger or weaker than that just described, may be determined by ascertaining through repeated trials the quantity of the Pepsin solution made as directed in the assay, required to digest, under the prescribed conditions, 10 gm. of boiled and disintegrated egg albumen. Divide 15,000 by this quantity expressed in c.c. to ascertain how many parts of egg albumen one part of Pepsin will digest.

"Preserve in well-closed containers."

MICROSCOPIC EXAMINATION

To make a microscopic examination place a drop of unfiltered stomach contents upon a slide, cover with a cover glass, and examine with a low dry and a high dry objective with the diaphragm opening much reduced. If a drop of diluted Lugol solution is placed on the edge of the cover glass, it will run under the cover by capillary attraction and will help to bring out certain structures.

Normally we see starch granules with an occasional epithelial cell, yeast cell, or bacterium. Starch stains blue with iodine solution when undigested, and reddish, due to erythrodextrin, when partially digested. These colors, however, are not shown clearly unless the iodine solution is very dilute.

Under pathologic conditions we see remnants of food from previous meals, red blood cells, pus cells, sarcinae, and excessive numbers of yeast cells and bacteria.

Remnants of food from previous meals indicate deficient gastric motility. Red blood cells are recognized by chemical tests, preferably the **benzidine** test. Microscopically the red blood cells retain a fairly normal appearance but are so degenerated at times that only granular pigment is left. The presence of very fresh-looking red cells is highly suggestive of irritation of the stomach mucosa by the stomach tube. Pus cells are rarely seen in gastric contents, although many of them have been seen in cases of gastric cancer. These cells are partially digested, only the nuclei remaining. The nuclei appear as highly refractile bodies.

Swallowed sputum may be present.

Sarcinae are small spheres arranged in cuboid groups, often compared to bales of cotton. They are easily recognized and stain brown with iodine solution. They are rarely found in cases of gastric carcinoma. A few yeast cells may be found under normal conditions with considerable numbers in retention and fermentation. They stain yellow to brown with iodine solution. The bacteria encountered are not very important except the Boas-Oppler bacillus. It is claimed that this is found in the majority of cases of carcinoma of the stomach and rarely in any other condition. This organism belongs to the *Lactobacillus bulgaricus* type. The Boas-Oppler bacillus is large, 5-10μ long, nonmotile, and arranged in clumps or in zigzag chains. It stains yellow to brown with iodine solution, thus distinguishing it from *Leptotrichia buccalis* which is sometimes swallowed and may be found in stomach fluid.

Crystalline elements in stomach lavage: Rafsky[5] reported that crystalline elements were present in the stomach lavage of patients with cholelithiasis. In an effort to corroborate this

Fig. 683. Starch granules. Squamous epithelial cells.

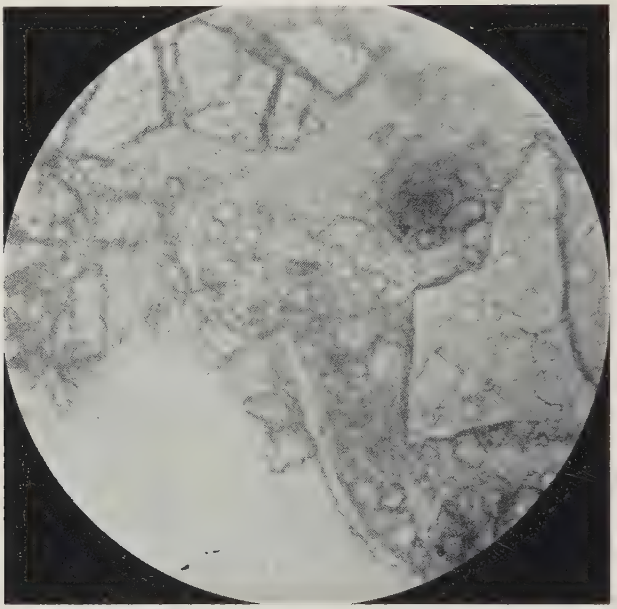

Fig. 684. Cholesterol and carbonate crystals; slight amount of calcium bilirubinate pigment. (Photomicrograph of particle in preoperative specimen of gastric lavage.) (From Rafsky, H. A.: J. Lab. & Clin. Med. **19**:959, 1934.)

finding, this subject was further investigated in a series of patients with and without biliary tract disease. This study was aided by the use of photomicrographs of crystals seen in the stomach lavage before operation, which were compared with photomicrographs of crystals found in the bile and stones removed from the gallbladder and bile ducts at the time of operation.

CONCLUSIONS TO BE DRAWN FROM THE EXAMINATION OF GASTRIC CONTENTS

A number of important points and diagnoses are deducible from examination of the gastric contents. First, the emptying time of the stomach is in a measure determined by this examination. The presence of blood in the gastric contents in visible amount is probably due to hemorrhage from an ulcer or carcinoma. Due consideration, of course, must be given to the possibility of a small amount of blood sometimes caused by the passage of the stomach tube.

If there is no free hydrochloric acid present after a test meal, one should consider the following conditions—pernicious anemia, primary hypochromic anemia, and cancer of the stomach. In pernicious anemia there is complete absence of hydrochloric acid, whereas in cancer a small amount may be present at times, although this is rare.

When increased hydrochloric acid is seen in patients with ulcers, it is due to hypersecretion by the parietal cells of the stomach. That there is a relationship between hydrochloric acid and peptic ulcer is evidenced by the fact that those with histamine achlorhydria usually do not develop either duodenal or benign gastric ulcers.

In **dilatation of the stomach** there is evidence of retention and fermentation, with hydrochloric acid diminished. Pepsin may be normal or slightly diminished. Lactic acid may be detected in small amounts, but is usually absent when the stomach has been washed before giving the test meal. Microscopically we find sarcinae and other bacteria and great numbers of yeast cells.

In **chronic gastritis** free hydrochloric acid may be increased in early cases, but it is usually diminished in well-marked cases and is often absent in advanced cases. Lactic acid may be present in traces. Pepsin and rennin are diminished in marked cases. The presence of large amounts of mucus is very characteristic of this condition.

In **atrophic gastritis** or **achylia gastrica** which is the terminal stage of chronic gastritis, associated with the blood picture of pernicious anemia there is decrease in with sometimes entire absence of free hydrochloric acid and proteolytic enzymatic activity. Total acidity may be down to 1°. Small amounts of lactic acid may be present.

Gastric carcinoma is possibly the most important condition which we have in mind in examination of gastric contents. There is a total absence of free hydrochloric acid and the presence of lactic acid and of the Boas-Oppler bacillus. Exceptions to this have been found where some free hydrochloric acid and no lactic acid were present in undoubted cases of carcinoma of the stomach. It must be borne in mind, however, that the presence of lactic acid is very strong presumptive evidence of the existence of carcinoma. In gastric carcinoma we often find blood, especially when the tumor is located at the pylorus. In these cases occult blood is also likely to be found in the stool.

Gastric ulcer is associated with an excess of free hydrochloric acid in about half of the cases. In other cases the acid is normal or diminished. The presence of blood is a very significant sign of ulcer. It is especially important in these conditions to make an examination of the stool for occult blood, taking care, of course, to have the patient on a meat-free diet for 3 or 4 days before making the test.

Summary: Examination of the gastric contents is of greatest value in the diagnosis of benign gastric ulcer, gastric cancer, and severe anemia of both pernicious and primary hypochromic type. In gastric ulcer, blood, an excess of hydrochloric acid, and perhaps gastric retention are found. In cancer there is very little or no hydrochloric acid; the presence of blood, together with gastric retention and lactic acid if the growth is near the pylorus, is characteristic. Finally, in pernicious anemia and primary hypochromic anemia there will be a complete absence of hydrochloric acid, no blood, no gastric retention or lactic acid.

GASTROSCOPY AS AN AID TO GASTRIC DIAGNOSIS

The following facts were well presented by Deutsch.[6] Gastroscopic study is indicated (1) in x-ray negative dyspepsia, (2) to clarify an indefinite roentgenographic impression or confirm a positive diagnosis of carcinoma, and (3) in all patients with gastric ulcer or polyps.

Gastroscopy can help in distinguishing benign from malignant ulceration of the stomach. In the antrum and middle portions of the stomach, observation of peristaltic waves and segmental tonus changes aids in ruling out an infiltrating rigid neoplastic lesion. Infiltrating lesions in the cardia or fundus show evidence of obstruction at gastroscopy as much as 6 mo. before it is detected by x-ray examination.

Positive biopsies have been taken during gastroscopy. Exfoliative cytology, accomplished by scraping with a polyethylene tube under gastroscopic observation, yields a desquamated mucosa and muscularis mucosa which is quickly aspirated, fixed in formalin, and prepared for cell block.

Attention is here called to the balloon technic of Cooper, described on p. 1781 on the exfoliative diagnosis of gastric lesions.

Radiology and gastroscopy are complimentary aids in the diagnosis of diseases of the stomach. It must be remembered that gastric secretion or mucosal folds in tetanic spasm in a very obese patient occur frequently and make mucosal relief studies by x-ray difficult. At gastroscopy these factors are no obstacle to an adequate examination.

PROTEIN NITROGEN AND NONPROTEIN NITROGEN DETERMINATIONS ON GASTRIC JUICE

Value: A series of papers has been written by Lay Martin[7, 8] on this question.

Normal nonprotein nitrogen is usually found within certain quantitative limits; the fasting juice in normal cases contains more protein and nonprotein nitrogen than the succeeding ones.

Benign achlorhydria, under stimulation with histamine, showed higher values than those of the normal but lower than those of gastric carcinoma or of nephritis with marked increase in blood nonprotein nitrogen.

Does the stomach act as an agent for removal of these products of metabolism from the body? Are they reabsorbed in the lower intestinal tract? Are they destroyed or benignly conjugated? Williams and Dick[9] attempted to answer these questions by establishing standards of normality for intestinal excretions of nonprotein nitrogen products after ingestion of magnesium sulfate. They showed they are quantitatively increased in nephritis.

Withdrawal of contents and precipitation of proteins: A duodenal tube is placed in the dependent portion of the stomach of a patient who has fasted for 15 hr., the position of the tube being verified by fluoroscopy. Entire fasting secretion is removed and placed in a refrigerator.

Gastric juice flow is stimulated by hypodermic injection of histamine (ergamine acid phosphate) in amounts equivalent to 0.005 mg./kg. body weight. Entire flow of gastric juice is collected by continuous siphonage into a narrow container surrounded by ice. All specimens with bile tinge are discarded. After gastric flow stops, all gastric juice is filtered in a refrigerator at 7° C., giving a limpid fluid free of mucus.

Proteins of the gastric juice are precipitated by tungstic acid at pH 3.5. A protein-free filtrate is obtained which can be used by methods described for the estimation of amino acid, urea, ammonia, and nonprotein nitrogen. Total nitrogen for the whole mixture is determined by the Kjeldahl method. The precipitate is redissolved in alkali and the protein nitrogen determined by the same technic.

Normal averages: Protein of the mucus-free gastric juice averaged 22.59 mg. **nitrogen**/100 ml. gastric juice.

The **nonprotein nitrogen** was 25.5 mg./100 ml. gastric juice.

Amino acid nitrogen averaged 7.22 mg. nitrogen/100 ml. gastric juice.

Urea averaged 2.58 mg. nitrogen/100 ml. gastric juice.

Ammonia nitrogen averaged 5.19 mg. nitrogen/100 ml. gastric juice, far more than the negligible amount in blood, suggesting speculation concerning the purpose of the urea-splitting enzyme appearing in the gastric juice and the gastric mucosa.

Uric acid averaged 1.5 mg./100 ml. gastric juice.

Accordingly, there are unaccounted 8 mg. nonprotein nitrogen.

Results in different cases: In benign achlorhydria, protein and nonprotein nitrogen double that of the control group. Compared with 7 cases of pernicious anemia, it was found that there was much more amino acid nitrogen and urea nitrogen in pernicious anemia than in benign achlorhydria with consequent rise in nonprotein nitrogen.

In proved cases of carcinoma of the stomach, protein and nonprotein nitrogen fractions increased from 4-6 times the normal.

Summary:

1. Normal gastric juice shows rather constant figures for protein and nonprotein nitrogen fractions (amino acid, urea, uric acid, and ammonia).
2. In benign achlorhydrias the amounts increased 2-fold.
3. In pernicious anemia the same increase was found plus still greater increase in amounts of amino acid and urea.
4. In carcinoma of the stomach with achlorhydria, very large amounts of protein and nonprotein nitrogen were found.

Methods for determination[8]

Total nitrogen has been determined for normal gastric juice by the Kjeldahl method.

To obtain a protein-free filtrate it was necessary to devise a method for the precipitation of these materials from a medium with a normal pH about 2; in the achylias it was about 7. Blood proteins are precipitated by tungstic acid according to the method of Folin and Wu at a pH of about 7. This method, when applied to gastric juice, in most cases gives no precipitate. Only when the hydrogen ion concentration has been increased to a pH above 4 is one able to precipitate the maximum amount of protein. Routinely this was done in the following manner.

Procedure:

1. To gastric juice add ½ the amount of 10% sodium tungstate. As this solution is gradually added, a cloudy precipitate is formed which is reabsorbed as the pH decreases.
2. Then add ⅔N sulfuric acid drop by drop until the pH of the solution is brought to about 3.5. From many trials it has been found that this is about the optimal point of the heaviest precipitation. This end point can be recognized by means of Congo red paper

which just begins to turn from light to dark blue.

3. Make the material to any required dilution, usually about 1:5. In the achylias, experience has shown that a 1:7 dilution is sufficient.
4. Filter through Whatman No. 42 filter paper which will usually produce a perfectly clear filtrate. If this does not appear at first, refiltering through the same paper will usually bring about the desired result. Standing overnight in a refrigerator will also increase the size of the precipitate particles and make filtration easier.

Biuret tests

Biuret test made on filtrates are negative or show so little color that one feels sure that the amount of protein material can have no significant influence on the findings. A comparison of the biuret reaction on the unfiltered and the filtered portion is sufficient to justify the conclusion that, even when this very faint trace of lavender or pink is seen, the amount of protein therein is certainly negligible.

Nonprotein nitrogenous constituents

Nonprotein nitrogen: The estimation of the total nitrogen on the filtrate is carried out by the usual Folin and Wu nesslerization method. It lies normally between 20 and 48 mg.%. In simple achylias the percentage is higher, up to 30 and 90 mg.%. In achylias complicated by carcinoma the figures have been as high as 60-150 mg.%.

Amino acids: The amount of amino acids was determined by the blood filtrate method of Folin. Because of the higher acidity, much more sodium carbonate must be used before the phenolphthalein will impart a permanent pink color to the solution.

Urea: Urea is determined by first estimating the amount of free ammonia plus the amount of ammonium liberated by the action of urease; from this result subtract the predetermined amount of ammonia.

Ammonia: Ammonia is determined by 2 methods: (1) unfiltered gastric juice, usually 5 ml., by the microaeration method of Folin and MacCallum and (2) upon the filtrate using the method of Folin and Wu.

Chapter 106

Duodenal content

STANLEY REITMAN
SAM FRANKEL

Examination of the duodenal contents, except for research purposes, is primarily indicated to determine whether or not there is an impaction of the common bile duct by gallstones. It indicates the presence or absence of inflammation and stones in the gallbladder. This absence of bile in duodenal contents may be due to a gallstone impacted in the duct or to a cancer at the head of the pancreas. If the bile contains pus cells, it is strongly suggestive of acute inflammation of the gallbladder. Crystals of cholesterol and granules of bile pigment may be found. If both of these are present in considerable amounts, it is presumptive evidence that there are stones in the gallbladder.

METHOD OF WITHDRAWAL

The duodenal fluid is obtained by means of a slender, flexible rubber tube, 3-4 mm. in outside diameter, with a perforated metal tip. It is marked with a series of black rings to indicate the distance from the incisor teeth to the cardia, to the pylorus, and to the duodenum.

If the pancreatic enzymes are to be studied, give a cup of bouillon 30 min. before the tube is introduced. In most of the duodenal contents examinations, however, a test meal is not used. The patient abstains from food for about 12 hr., taking only occasional sips of water. The tube is inserted into the stomach in the manner described for the stomach tube. Place the patient upon his right side with hips elevated 6 or 8 in. The movements of the stomach, aided by gravity, carry the metal tip through the pylorus into the duodenum, usually within 30-45 min. Fluid begins to drip from the free end of the tube soon after the metal tip has reached the stomach. If it does not do so, siphonage should be started by injecting a few ml. warm water. Collect the fluid in portions of about 5 or 10 ml. in a series of test tubes. The fluid that first appears is from the stomach and may be recognized by its acid reaction. When the tube enters the duodenum, the fluid becomes slightly alkaline and is usually clear, light yellow or colorless, and viscid. If one is in doubt as to whether or not the tube is still in the stomach, give the patient a few swallows of milk and aspirate a portion of the fluid through the tube. If the milk appears, the tube is still in the stomach. If the flow should at any time be interrupted, inject a few ml. warm water. If, after the tube is in the duodenum, the fluid is somewhat cloudy and opalescent, less alkaline, and less viscid, this is the result of admixture with stomach fluid which may have passed through the pylorus. Such fluid is to be discarded.

Examination of duodenal fluid should be done as soon after withdrawal as possible since many of its characteristics quickly change. **Normally** it is clear, colorless or light yellow, distinctly viscid, and slightly alkaline. Admixture of acid gastric juice causes it to become somewhat cloudy and opalescent. Cloudiness due to bacteria and pus cells may be present in inflammation of the duodenum or biliary passages.

LYON-MELTZER METHOD OF DUODENAL DRAINAGE[10]

Drainage of the gallbladder by inducing a relaxation of the sphincter of Oddi, through the introduction of a 25% solution of magnesium sulfate, has attracted a great deal of attention. Lyon claims that by adhering closely to his technic many cases of early biliary tract disease can be diagnosed from the examination of the duodenal contents. It has been proved, however, that the so-called A-, B-, and C-bile, presumably originating from three different parts of the biliary tract, have no clinical significance. (The A-bile is supposed to originate in the common duct; the B-bile, a dark viscous bile, in the gallbladder, and the C-bile, a golden yellow bile, in the hepatic duct.) Lintz reported a case that has dealt quite a blow to the A-, B-, and C-bile contention. His patient had congenital absence of the gallbladder and yet, upon injection of magnesium sulfate the 3 typical specimens of bile, including the dark B-bile, which is supposed to come from the gallbladder, appeared. Nevertheless, a careful microscopic examination of duodenal sediments may be of diagnostic value.

According to Jones, bile-stained leukocytes and epithelial cells, when found in any quantity, indicate an inflammatory condition of the biliary tract. It is not possible, though, to determine from the type of cell found in the duodenal sediments the exact level of the inflammatory process. Too much importance should not be attributed to the finding of these cells; they should be regarded merely as confirmatory evidence.

The presence of many crystals of cholesterin, bilirubin, and calcium bilirubinate may be of diagnostic value in cholelithiasis. It has been claimed by Bockus and associates that the finding of cholesterol crystals and bilirubin calcium pigment in the same bile is pathognomonic of cholelithiasis.

CHEMICAL EXAMINATION OF DUODENAL CONTENTS

Enzymes

Estimation of the pancreatic enzymes, amylopsin, steapsin, and trypsin, in duodenal contents gives the same information as their estimation in feces but is more reliable. Absence of or great decrease in the quantity of one or all of these enzymes points to deficiency of the pancreatic secretion or occlusion of the pancreatic duct. Pancreatic fluid from a fistulous tract shows little or no proteolytic activity. The following methods, although not absolutely accurate, give important clinical information.

Amylopsin (pancreatic amylase): Amylopsin should be studied along with amylase of urine and blood (p. 111). Carry out the technic for amylase in feces but use pure duodenal fluid, 5 ml. 1% starch, and bring the volume in each tube to 7 ml. Express the amount of amylase in units (the number of ml. 1% starch digested by 1 ml. duodenal contents). For example, if the digestion of starch is complete in the tube containing 0.2 ml. duodenal fluid, 25 units amylase are present. According to Myers and Fine, the average is about 40 units, with extremes of 5 and 200 units in different specimens.

Steapsin (pancreatic lipase)—Myers-Fine:

1. Place 1 ml. duodenal fluid in each of 2 test tubes.
2. Boil the contents of 1 tube to destroy enzyme activity.
3. Add to each tube 1 ml. neutral ethylbutyrate, 10 ml. distilled water, and a few drops of toluol.
4. Incubate at 38°-40° C. for 24 hr., shaking occasionally. If lipase is present, the ethylbutyrate will be split, the resulting fatty acid giving an acid reaction in the tube that was not boiled.
5. Add 2 drops phenolphthalein indicator to each.
6. Titrate to a pink color with N/20 sodium hydroxide.

The index of lipolytic activity is the difference in the number of ml. N/20 sodium hydroxide required for the 2 tubes. According to Myers and Fine, this is 0.3-4.3 ml., averaging 1.5 to 2.

Trypsin:

1. If the fluid is acid or neutral, render it slightly alkaline with a weak solution of sodium carbonate.
2. To 5 ml. fluid in a test tube add 1 gm. fibrin and a few drops of toluol.
3. Incubate at 38°-40° C. for 24-48 hr. Tyrosin and tryptophan can be found if trypsin is present. Neutralize the fluid and examine microscopically for tyrosine crystals. Test for tryptophan by adding very dilute bromine water a drop at a time. If tryptophan is present, a reddish violet color develops, which disappears upon the further addition of bromine.

Amylase:

1. To 10 ml. 1% solution of freshly prepared starch add 1 ml. pancreatic juice and 1 ml. toluol.
2. Allow the mixture to digest at 40° C. until duplicates no longer show blue with iodine solution. Place the bottles in boiling water to stop digestion at the same moment.
3. Dilute the contents to 50 ml.
4. Titrate from a buret against 10 ml. of boiling Fehling solution, using acetic acid and potassium ferrocyanide to determine the end point.
5. Ascertain the number of ml. of digestive mixture required to reduce 10 ml. Fehling solu-

tion, which is equivalent to 0.05 gm. dextrose, or its equivalent of maltose.

6. If the amount of sugar in the digestive mixture is less than that required to reduce the copper, add a standard dextrose solution and compute the amount of dextrose equivalent in the juice used.

Amylase values are reported as the number of ml. of the digestive mixture, which, when made up to 50 ml., would be equivalent to 0.05 gm. glucose. Normal values are given above.

Lipase:

1. Place in a bottle 1 ml. pancreatic juice.
2. Add 10 ml. distilled water, 1 ml. neutral ethyl butyrate, and 1 ml. toluol.
3. Allow mixture to digest at 40° C.
4. After 24 hr. determine the amount of acidity developed, using N/20 sodium hydroxide aqueous solution, with phenolphthalein indicator. From the amount of sodium hydroxide used subtract the amount of acidity, if any, in the duplicates containing 1 ml. juice plus 10 ml. water and 1 ml. toluol.
5. Shake the digestive mixture 10 times during the 24 hr. period.

Express the lipase values as the amount of N/20 sodium hydroxide necessary to neutralize the acidity developed. Normal values are given on p. 1923.

Alkali-protease (trypsin):

1. Dissolve 10 gm. gelatin in 100 ml. 1% solution of sodium fluoride and color with methyl violet.
2. Draw this solution into capillary tubing 1 mm. in diameter.
3. Quickly place the tubing under cold water to solidify the gelatin.
4. Cut the tubing into 2 cm. lengths.
5. Place 10 ml. juice in a small bottle.
6. Close with a perforated cork through which the gelatin tubes can be inserted.
7. Keep the digestions at room temperature for 48 hr. to determine the alkali-protease.
8. Add 1 ml. toluol to each digestive mixture and enough 0.2% sodium carbonate solution to make the mixture alkaline in reaction.

Express the alkali-protease (trypsin) values in the number of mm. gelatin digested. **Normal value** is 25-50.

Quantitative methods of determining pancreatic enzymes—Einhorn[11]

Principle: Agar tubes, mixed with albumin, starch, or fat, allow the enzyme action to take place in them by osmosis. If the test substances added are colored with indicators, which undergo a change when acted upon, it is easy to ascertain the presence of the enzymes and also to estimate their approximate activities by the volume of tube changes given in mm.

Starch tubes:

Agar powder	2.5 gm.
Starch	5 ml.
Distilled water up to . . .	100 ml.

1. Rub the starch and agar in a mortar with sufficient water to make a smooth paste; then add the rest of the water.
2. Place in a flask and heat to boiling point.
3. Draw by suction into a capillary glass tube, inside diameter 1.5 mm., which has previously been warmed in the flame. Allow tube and contents to cool. Cut into 2 cm. lengths. Seal at each end with melted paraffin.

Olive oil tubes:

Olive oil	25 ml.
Agar powder	2 gm.

Aqueous solution of Nile blue sulfate (1:2000), sufficient to make 100 ml.

1. Rub the olive oil and agar together.
2. Add sufficient water to make a thin paste.
3. Add the Nile blue sulfate solution to make the balance of 100 ml.
4. Then proceed as with the starch tubes.

Hemoglobin tubes:

Hemoglobin powder . . .	1 gm.
Agar powder	2.5 gm.
Distilled water sufficient to make	100 ml.

1. Rub the hemoglobin with about 10 ml. water until it is smooth; then add the agar powder and the balance of the water.
2. Then proceed as with the starch tubes.

Keep the agar tubes on ice until ready to use. They retain their efficiency for 4-6 wk., when they begin to deteriorate; they should not be used when they become dry.

Procedure:

1. Use one each of the starch, olive oil, and hemoglobin tubes.
2. Scrape off the paraffin at both ends.
3. Put vertically into a small bottle containing about 0.5 ml. duodenal secretion.
4. Add 1-2 drops of toluol and keep the bottle at 37° C. for from 16-24 hr.

Examine as follows: Take the agar tubes from the bottle, wipe the outside, and inspect. Hemoglobin tubes show a change of appearance due to action of trypsin, with a clearing up of the end part, becoming more or less transparent. Olive oil tubes manifest a bluish appearance at the end because steapsin activity splits the oil into fatty acids, which affect the indicator. Measure the lengths of transparency in the hemoglobin tube and of the bluish color in the oil tube in mm. Examine the starch tube by pushing out the agar column and dipping it into a weak iodine solution. The portion of starch column remaining colorless indicates the part changed by the amylopsin activity into sugar. This is expressed in mm. lengths.

By these tests the hemoglobin serves to gauge the trypsin activity, the olive oil measures the steapsin activity, and the starch measures the amylopsin activity.

Bilirubin

Bile pigment is usually present in the duodenal contents in sufficient amount to impart a tinge of yellow to the fluid. The depth of color is a useful guide to the amount present. Report as +, ++, +++, i.e., a small, moderate, or large amount, respectively. If bile is present, the diagnosis of complete obstruction of the hepatic or common bile duct is ruled out. Its absence does not exclude the possibility of bile reaching the duodenum at some time.

Urobilin

Urobilin is a derivative of bilirubin. It is doubtful whether or not the former idea of its identity with hydrobilirubin is correct. Urobilin is normally found in the duodenal contents just as it is in urine.

When we find an increase of urobilinogen and urobilin in the duodenal contents, it has the same significance as an increase of these substances in the stool. The amount of these substances in the feces and duodenal content reflects the extent of blood destruction. In other words, they are extremely important in the diagnosis of the hemolytic anemias. In the study of anemias in general the estimation of urobilin, when possible, is interesting but not necessarily important.

The most satisfactory clinical method for urobilin is that of Wilbur and Addis, which Schneider applies to the duodenal contents as follows.

Procedure:

1. To 10 ml. duodenal contents add 10 ml. saturated solution of zinc acetate. Shake well and filter.
2. To 10 ml. filtrate add 1 ml. Ehrlich reagent (p. 1827).
3. Mix and let stand in a dark place for 15 min.
4. Examine with a spectroscope and dilute with 60% alcohol until the bands of both urobilin and urobilinogen have disappeared exactly as is described for urobilin in feces.

Calculate the dilution value for 1000 ml. duodenal contents, remembering that the filtrate used represented 5 ml. duodenal fluid. If, for example, the urobilin and urobilinogen bands disappeared when the 10 ml. filtrate were diluted to 80 ml. and to 40 ml., respectively, then the dilution value of 5 ml. duodenal fluid is 16 for urobilin and 8 for urobilinogen; and for 1000 ml. it would be 200 times this, or 3200 and 1600, with a total dilution value of 4800.

Schneider found that the maximum value for healthy medical students is about 1000 dilutions and that urobilinogen is never present. In pernicious anemia and hemolytic jaundice urobilinogen is generally present, the total dilution value usually reaching 3000-5000. Giffin and associates found a striking decrease following splenectomy, particularly in pernicious anemia.

Schneider used these figures in the following formula, which aims to express the relation between blood regeneration and blood destruction in the form of an index number which he designated as the H-H (hematopoietic-hemolytic) Index:

$$\frac{Z + Y}{6} = \text{H-H index}$$

Z representing the total duodenal urobilin-dilution value in thousands and Y the red cell count in millions. Under normal conditions (urobilin dilutions 1000, red cell count 5,000,000) the index is 1. When hemolysis is very active, it will be above 1 unless counterbalanced by very deficient blood formation. When blood regeneration fails, the index will be below 1. Such an index is artificial and arbitrary but is useful in stressing the importance of considering the ratio of blood formation to blood destruction in the course of an anemia.

Fractional examination of duodenal contents[12]

Einhorn recommends a test meal of one cup of beef broth, usually made by putting one bouillon cube in a cup of hot water. The duodenal contents are examined first in the fasting condition, then one cup of buillon is given by mouth, and the duodenal contents are aspirated every ½ hr. for a period of 2 hr. This is carried out as follows: Give patient the duodenal tube in the evening after a light supper. Note the length of tube which has entered the buccal cavity before retiring. The tube used is that recommended by Einhorn with 3 marks, mark I, mark II, and mark III. Mark III should have reached the mouth; if not, the patient is given milk or water and the tube in this way made to go in beyond the III mark before going to sleep. Attach the tube, lying outside the mouth, with a piece of adhesive tape to the cheek. By early morning the capsule end of the tube has usually reached the duodenum.

Einhorn states that in normal patients there was an alkalinity of the duodenal contents of 30, whereas ½ hr. after the bouillon test meal it was 10, then it rose to 20, 25, and ultimately to 30. The enzyme activities were strongest in the fasting condition, whereas they were weakest ½ hr. after the test meal, to increase in strength later on. In pathologic cases the degree of alkalinity of the duodenal contents appeared to be dependent to a certain extent upon the state of gastric secretion. Einhorn states that cases of hyperchlorhydria showed a lowered alkalinity whereas cases of subacidity manifested an increased alkalinity. Other factors play a role, chief of which are pancreatic and duodenal juices and the bile. He differentiates 4 types of alkalinity curves: **type I**—decrease of the alkalinity during the first ½ hr. after the bouillon test meal, then a steady increase; **type II**—increase of alkalinity between ½ and 1 hr. after the bouillon, then slight decrease; **type III**—increase of alkalinity during the first ½ hr. after the bouillon, then slight decrease up to 1 hr., then again increase to 1½ hr., thereupon again a decrease; **type IV**—at first a steady increase of alkalinity up to 1½ hr. after the bouillon test meal, then an abrupt descent of the curve, so that at 2 hr. after the bouillon the contents are acid instead of alkaline.

Einhorn[13] gives the following 4 types of reaction in **peptic ulcers:**

1. Duodenal contents are always alkaline in the fasting state as well as at any time after the bouillon test meal.
2. The duodenal contents are alkaline in the fasting state and at times acid after the bouillon test meal.
3. The duodenal contents are acid in the fasting condition and at certain periods after the bouillon test meal.
4. The duodenal contents are always acid in the fasting state as well as at any time after the bouillon test meal.

Type I represents the normal. In a number of peptic ulcers the abnormal types (II, III, and IV) were found. The severity of the disturbance is least in type II, greater in type III, and greatest in type IV.

MICROSCOPIC EXAMINATION OF DUODENAL CONTENTS

Unless the duodenal fluid is examined within a few minutes after it is secured, the cellular elements may be damaged or destroyed by the enzymatic action. The method is the same as for fresh urine. Normally only an ocasional leukocyte or epithelial cell can be found. Pathologically these may be present in increased numbers, but no definite diagnostic inferences can be drawn. A great excess of pus cells suggests inflammation of the duodenum or biliary tract. *Strongyloides stercoralis* and *Giardia lamblia* have been found, sometimes in great numbers. Cystic and vegetative forms of *Entamoeba histolytica* have also been found, and in such cases infection of the liver or bile passages is inferred.

BACTERIOLOGIC EXAMINATION

At the present time very little of clinical value can be learned from a bacteriologic study. Normally the fluid is sterile or contains only a few gram-positive cocci. Bacteria seen in the direct microscopic examination are mostly dead.

For bacteriologic examination the duodenal fluid is obtained in the usual way, with the following precautions to prevent contamination:

Sterilize the tube by boiling. Slip over the metal tip a gelatin capsule which has been soaked in alcohol for several days. Dip the gelatin-covered tip in thin shellac several times, letting it dry after each coating. Introduce the tube in the usual way. When it has entered the duodenum, the gelatin bag may be removed by forcing in a little air or a few ml. sterile water.

Section Three

CEREBROSPINAL FLUID

Chapter 107

Cerebrospinal fluid

JOHN D. BAUER

The examination of spinal fluid is a very important procedure in connection with many medical and surgical cases. For the method of withdrawing spinal fluid from the living subject, we are indebted to Heinrich Quincke who first treated 2 cases of hydrocephalus by means of withdrawal of the spinal fluid. In 1893 Lichtheim called attention to spinal puncture as a valuable aid in diagnosis, and in 1895 Fubringer reported 107 punctures in 80 cases. Since that time spinal puncture has been generally adopted as a routine procedure for diagnostic and therapeutic purposes.

The ventricles of the brain which contain fluid slightly different in composition from that of the spinal fluid were first tapped by Middeldorpf in 1856. Occipitoatlantoid drainage of the cisterna magna in man was first performed by Parker in 1893. Cistern puncture has been developed mainly in this country. In 1919 Wegeforth, Ayer, and Essick performed the operation in man, using a needle for the puncture. Sicard in 1923 was the first to introduce Lipiodol into the cistern as a roentgenographic aid in the diagnosis of cord tumors.

The cerebrospinal fluid is contained in the ventricles of the brain and in the subarachnoid space of the brain and cord. There are 5 ventricles, 2 lateral, and the third, fourth, and fifth. They are intercommunicating. The cerebrospinal fluid in the ventricles of the brain communicates with the fluid in the other ventricles through the various apertures connecting them. The only exception to this is the fifth ventricle which contains very little or no fluid. The fluid in the lateral ventricles flows into the third through the foramina of Monro; the fluid in the third communicates with that in the fourth by means of the aqueduct of Sylvius. The cerebrospinal fluid of the subarachnoid space communicates with the fluid in the ventricles of the brain through the foramen of Magendie, which opens into the posterior part, and the 2 foramina of Luschka, which open into the lateral recesses of the fourth ventricle, and through numerous other apertures which open into the lateral ventricles.

In order to understand the diagnostic features of cerebrospinal fluid, something must be said of the physiology of this fluid. No one has yet determined the rate of formation under normal conditions. Equally uncertain are the data on the rate of absorption of the spinal fluid, but it has been shown that absorption probably occurs through the perivascular lymphatics directly into the blood stream.

The function of the cerebrospinal fluid is mechanical. The fluid forms a water bed around the cord and brain and prevents jarring from external trauma. It also equalizes the pressure between the brain and the cord. It is probable that the chorioid plexus, which is in the ventricles of the brain, is responsible for the secretion of the cerebrospinal fluid.

CHARACTERISTICS OF CEREBROSPINAL FLUID

Amount: The amount of fluid normally present in the ventricles and in the subarachnoid space varies according to different authors from 60 to 150 ml.

Color: Normal cerebrospinal fluid is clear and colorless, provided no blood has been removed with it during the puncture.

A very interesting condition which is called xanthochromia may sometimes be found. In this condition the spinal fluid is a clear yellow color with rapid and marked coagulation, large amounts of globulin, and no blood pigments by chemical tests. It is generally the result of compression by a tumor of the cord or vertebrae with interruption to the flow of cerebrospinal fluid and formation of a pocket of greater or lesser extent in which the fluid stagnates. Xanthochromia also follows old brain hemorrhage and is thought to be due to bilirubin bound to albumin.

Transparency: Normal spinal fluid is clear. In acute meningitic infections the fluid may vary from slight cloudiness to almost pure pus. It is absolutely clear in tuberculous meningitis.

Pellicle formation: In many acute cases of meningitis a pellicle or a net of fibrin and blood cells forms in the fluid on standing. In suppurative meningitis the pellicle forms in a very short time; in tuberculous meningitis it takes 12-24 hr. to form. Pellicles have been observed in poliomyelitis and in general paresis only rarely. The pellicle is formed by the separation of the heavier elements of the cerebrospinal fluid, so that microscopically one sees in the pellicle many leukocytes on a fibrinous background. Fig. 685 shows the forms of pellicle in various diseases as observed early, before autolysis takes place. The pellicle is dependent for its formation upon the presence of fibrinogen.

Lack of sediment: Normal fluid forms no pellicle or sediment. This lack of sediment is helpful in differentiating normal fluid from fluid in cases of meningitis in which a sediment is often present.

Specific gravity: The specific gravity varies according to different authors from 1.006 to 1.010.

Reaction: Reaction of cerebrospinal fluid is alkaline.

Levinson[1] states that the hydrogen ion concentration ranges from pH 7.4 to 7.6.

Total solids: Total solids vary between 1.200 and 0.876 gm./100 ml.

Calcium: Calcium content of the spinal

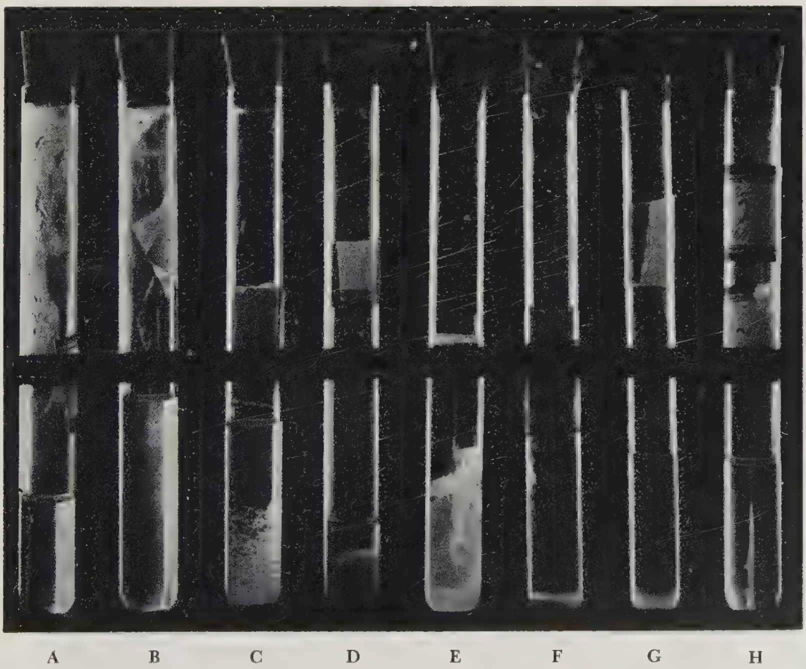

Fig. 685. Pellicle formation in meningitis. **A,** Normal. **B,** Meningococcus meningitis, fairly early. **C,** Meningococcus meningitis, advanced (sulfurlike granules). **D,** Meningococcus meningitis, late in disease. **E,** Meningococcus meningitis, severe, on road to recovery. **F,** Pneumococcus meningitis, fatal. **G,** Pneumococcus meningitis, fatal. **H,** Tuberculous meningitis. (From Levinson, A.: Cerebrospinal fluid in health and in disease, St. Louis, The C. V. Mosby Co.)

fluid varies from 2.3 to 2.6 mg.% (1.13-1.3 mEq./L.).

Magnesium: Magnesium content of spinal fluid is greater than that of blood (0.82-1.08 mEq./L.).

Chlorides: Normal spinal fluid contains more chloride than does blood plasma. The normal value for adults is 123-133 mEq./L. spinal fluid. In children the normal range is 110-130 mEq./L.

In acute meningitis the amount of chloride may be reduced in adults to 105 mEq./L. and to 98 mEq./L. in children. In tuberculous meningitis still smaller amounts are found. A fall in plasma chlorides will produce a corresponding fall in C.S.F. chlorides. High values may be found in conditions in which the value for the plasma chloride is increased.

For quantitative determination of chloride in spinal fluid see p. 176.

CYTOLOGY OF SPINAL FLUID

Most writers are of the opinion that the normal cell count in spinal fluid varies from none to 2/c.mm. As a rule, we consider anything up to 5 normal.

Type of cells found: The cells of spinal fluid are leukocytes, principally small lymphocytes. The nucleus of the lymphocytes of normal spinal fluid is round or slightly oval, seldom irregular. Large lymphocytes occur very rarely. Polymorphonuclear or segmented leukocytes are usually absent in normal fluids. The origin of the cells in normal spinal fluid has not been fully determined.

Method of cell counting in spinal fluid

The cell count should be made as soon after withdrawal as possible. Always shake the tube before diluting the spinal fluid.

Reagent:

1. Spinal fluid counting solution (Tuerk solution).
   Glacial acetic acid . . . . . 1 ml.
   Distilled water . . . . 99 ml.
   (a) Add a few drops of alcoholic gentian violet to color.
   (b) Filter several times.

Procedure (with any counting chamber):

Diluting spinal fluid:

1. Draw the spinal fluid counting solution to the 0.5 mark and the spinal fluid to mark 11 in a white counting pipet, making a dilution of the spinal fluid of 19:20.
2. Mix thoroughly.

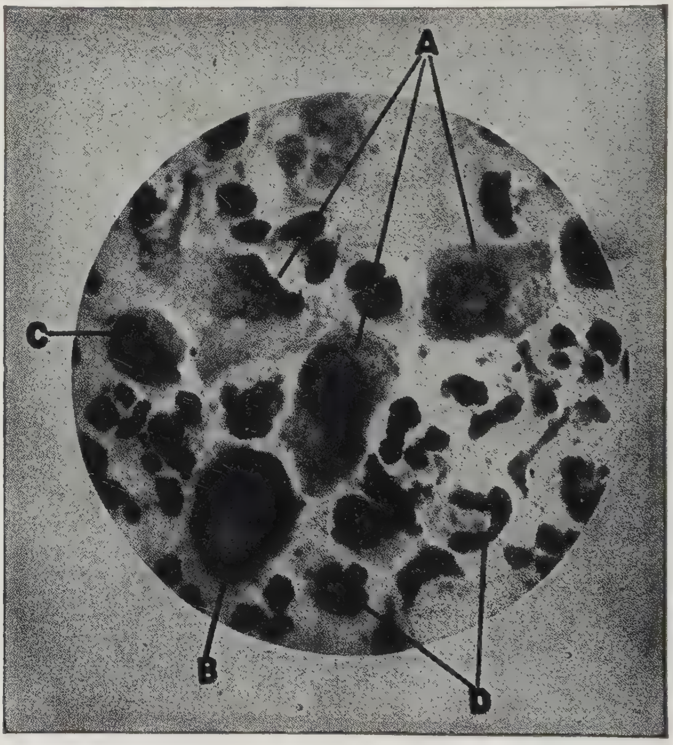

Fig. 686. Photomicrograph showing types of cells in pathologic cerebrospinal fluid. **A,** Desquamated endothelial cells. **B,** Monocyte which has engulfed a polymorphonuclear leukocyte. **C,** Large mononuclear cell. **D,** Polymorphonuclear leukocytes. (×1000.) (From Levinson, A.: Cerebrospinal fluid in health and in disease, St. Louis, The C. V. Mosby Co.)

Filling counting chamber:

1. Blow out 2 or 3 drops of the diluted spinal fluid before filling the counting chamber. Place the cover glass over the ruled area.
2. Allow the diluted spinal fluid to run under the cover glass so that it exactly fills the space between the cover glass and the counting chamber.

Making count:

1. Focus under the low-power dry objective without the Abbé condenser.
2. Count all the cells in the entire ruled area which represents 9 fields.
3. Divide by 9 and multiply by 10 to obtain the number of cells/c.mm.
4. Make similar counts on 2 more drops of diluted spinal fluid.
5. Average the 3 counts for the report.
6. To correct for the slight dilution of the spinal fluid, divide the final result by 19 and multiply by 20. Do not report a fraction of a cell.

Example:

1st drop	2nd drop	3rd drop
9 | 18	9 | 20.0	9 | 18
2	2.2	2
10	10	10
20	22.	20
22		
20		
3 | 62		
19 | 20.6		

1.08 × 20 = 21.6 or 22 cells/c.mm. spinal fluid

Normal: 0-5 cells/c.mm. (see below).

Counting of spinal fluid contaminated by blood

The problem of whether or not an accurate cell count can be made of bloody spinal fluid may be answered in the following words—to date no reliable or absolutely accurate method can be recommended for estimation of pleocytosis in the cerebrospinal fluid if the fluid is contaminated by blood. An attempt has been made to do this by staining the fluid lightly with Unna polychrome methylene blue and calculating all of the red cells and all of the white cells present in 1 c.mm. Correction for the number of white cells present in the fluid as a result of the blood can then be made on the basis of the red and white blood count in the peripheral vessels. According to Merritt,[2] "while this method is not absolutely accurate there is usually no trouble determining a pleocytosis in the cerebrospinal fluid of twenty-five or more cells."

Making the differential count of spinal fluid

This count can be made if there is a total blood cell count of over 500 cells/c.mm. If the cell count is below this, the sediment may be procured by centrifuging the fluid.

Technic of procuring the cells is to discard the supernatant fluid and spread the cells on a glass slide. In either case, whether the direct count or count of this centrifuged specimen is to be made, proceed in exactly the same manner in which a differential count of the leukocytes in blood is made.

Interpretation: As stated above, the normal cell count in the spinal fluid is 0-5 cells/c.mm. in adults.

Increased cell count is due to inflammatory lesion of the brain, spinal cord, or meninges. An increased count is found in cerebral tumors. An acute process will show an increase in the segmented neutrophils. In chronic infections and toxic conditions there is usually an increase in lymphocytes. A slight increase, say 10-100, especially of the lymphocytes, occurs in early tuberculous meningitis, neurosyphilis, anterior poliomyelitis, encephalitis lethargica, and multiple sclerosis. As many as 1000 cells, principally lymphocytes, have been found in late tuberculous meningitis, poliomyelitis, and acute syphilitic meningitis. Naturally, over 1000 cells are found in purulent meningitis and brain abscess.. There is no increase in cells to any extent in uremic or diabetic coma.

The **Papanicolaou technic** in conjunction with the Millipore filter* has also been applied to the examination of the cerebrospinal fluid for tumor cells. In primary tumors of the brain the results are disappointing, but they are somewhat improved in metastatic tumors with meningeal involvement.[3]

TESTS FOR PROTEIN

These tests are commonly called tests for globulin, but they are really tests for protein since the methods used depend upon the precipitation of both albumin and globulin.

Normal concentration of cerebrospinal protein is between 15 and 40 mg./100 ml. fluid. In inflammatory conditions of the meninges the choroid plexus, which is the barrier of the passage of the proteins, breaks down and permits these to enter the spinal fluid. In some other conditions such as typhoid fever, uremia, and convulsive states, elevated proteins are found. The increase in the proteins of the spinal fluid in suppurative diseases of the meninges is due to the accumulation of the protein of the exudate. In acute suppurative meningitis protein concentration values may be as much as 1300 mg./100 ml. Tuberculous meningitis shows values between 200 and 1000 mg. In tetanus there is an increase in the protein concentration, and an increase has been noted shortly after epileptic seizures. In such syphilitic diseases as paresis, tabes dorsalis, and other forms of cerebrospinal syphilis, values between 20 and 200 mg. have been reported. In epidemic encephalitis, protein concentrations vary between 50 and 300 mg./100 ml. In cerebral hemorrhage, thrombosis, or embolism there is an increased protein content. There are increased protein contents in brain abscesses and brain tumors and also in multiple sclerosis. In the disease known as the Froin syndrome, in which there is complete obstruction of the meninges of the spinal cord, there is a difference noted in the protein concentration above and below the point of obstruction. For instance, a lumbar puncture may show in such a case as much as 1000 mg./100 ml. (due to absorption of water below obstruction), and fluid taken from a cisternal puncture may show practically normal values. In myxedema, protein varies between 30 and 220 mg. Table 367 shows the changes in the pathologic conditions in respect to protein concentrations. It is important to note that the normal range varies according to the location from which the specimen is obtained.

---

*Millipore Filter Corp., Bedford, Mass.

Table 367. *Cerebrospinal fluid proteins**

Condition	*Changes in spinal fluid protein to be expected*	*Concentrations observed (in mg./100 ml.)*
Normal	0	20-40
Pathologic		
Brain tumor or abscess	+	30-100
Cerebral hemorrhage†	+	20-220
Cerebral thrombosis†	+	20-140
Cerebrospinal syphilis†	+	20-160
Epilepsy	+	20-80
Epidemic encephalitis†	+	50-300
Froin syndrome†	++	100-2100
Meningitis

Tetanus	+	
Uremic convulsions	+	

*From Andes, J. E., and Eaton, A. G.: Synopsis of applied pathological chemistry, St. Louis, 1941, The C. V. Mosby Co.

†Diseases in which the determination may be of clinical value.

‡Values as high as 1000 have been reported, but such concentrations are rarely found.

Normal:

Ventricular fluid .	10-15 mg./100 ml.
Cisternal fluid . .	15-25 mg./100 ml.
Lumbar fluid . .	20-40 mg./100 ml.

The first test described below, the Nonne-Apelt or Ross-Jones test, is a test for globulin as are the Pandy and Noguchi tests.

Qualitative tests

Nonne-Apelt method (Ross-Jones)

Reagent:

1. Nonne-Apelt (Ross-Jones) reagent. Saturated solution of ammonium sulfate, filtered after saturation has been reached.

Procedure:

1. Place 1 ml. Nonne-Apelt (Ross-Jones) reagent in a test tube.
2. Stratify 1 ml. spinal fluid on the reagent.

A white ring at the point of contact indicates the presence of globulin. If the spinal fluid contains blood, the test should not be made.

Pandy method

Reagent:

1. Pandy reagent.
   (a) Dissolve 10 gm. carbolic acid crystals in 150 ml. distilled water.
   (b) Place in the incubator and shake frequently for several days. Filter. The reagent must not become turbid upon shaking. It may become pink.

Procedure:

1. Place 1 ml. Pandy reagent in a test tube.
2. Add a few drops of spinal fluid and shake.

A turbidity develops if globulin is present.

Noguchi method

This test is so delicate that it often detects globulin in normal spinal fluids.

Reagent:

Butyric acid	10 parts
Sodium chloride, 0.9% . . .	90 parts

Procedure:

1. In a small test tube place 0.5 ml. Noguchi reagent.
2. Add 0.1 ml. spinal fluid.
3. Bring to a boil over a flame.
4. Add 0.1 ml. N/1 NaOH.

A flocculent precipitate appears in a few minutes if globulin is present in large quantities. The precipitate may take a few hours to form if the quantity of globulin is low.

Normal spinal fluids show a slight opacity. Traces of proteins are normally present in spinal fluid. A great increase occurs in acute inflammations in tuberculous meningitis, and in syphilitic affections.

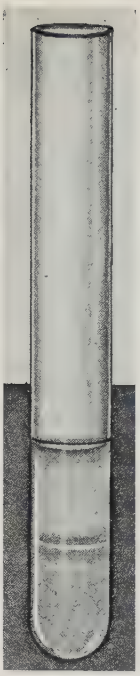

Fig. 687. Nonne-Apelt test for globulin in spinal fluid, positive reaction.

The chief protein is globulin, tests for which are outlined above. Because of the presence of serum globulin in blood, a globulin test is valueless if the spinal fluid is contaminated with blood.

Alcohol test

A drop of cerebrospinal fluid is added to a test tube containing 0.5 ml. 95% alcohol. A very slight turbidity is normal, but a heavy white cloud or flocculation indicates a high protein content.

Lange colloidal gold test

This test is based on changes in spinal fluid protein. The method that is recommended for the preparation of Lange colloidal gold solution is that suggested by Levine.[5] He had previously[6] described a method for this preparation using gold chloride, potassium carbonate, and formaldehyde. At that time he suggested the use of triply distilled water and a block-tin or resistant-glass distilling assembly. In 1934 Borowskaja[7] found that sodium citrate could be used in the preparation of gold sol instead of the potassium carbonate and the formaldehyde. She found, further, that sodium citrate stabilized the reaction sufficiently so that once-distilled water could be employed with safety. Levine made a study of Borowskaja's reaction and found that the time which it took for the reaction to reach its completion varied in duration from 5-30 min. and occasionally even longer, and that the sensitivity of the final sol to precipitation by positive spinal fluids varied accordingly. But he found that by the addition of a few drops of a fresh solution of 3% hydrogen peroxide instead of bubbling air or oxygen through the hot water, the reaction began immediately and reached completion within a few seconds. The method which is here advocated is that originated by Levine.

Glassware should be chemically cleaned. Although it is recommended that once-distilled water be adjusted to pH 7.2 to 7.4, this is not essential.

Preparation of colloidal gold:

1. To prepare 500 ml. gold sol the following formula is recommended:

Distilled water	460 ml.
Gold chloride, 1% solution .	5 ml.
Sodium citrate, 1% solution .	25 ml.
Hydrogen peroxide, fresh 3% solution, 3-5 drops, diluted in distilled water	10 ml.

2. Heat the distilled water to brisk boiling.
3. Remove from the hot plate.
4. Add the 5 ml. 1% gold chloride solution.
5. Shake for a few seconds.
6. Add the 25 ml. 1% sodium citrate solution.
7. Shake for 10-15 sec.
8. While shaking, add the 10 ml. distilled water which contains the 5 drops hydrogen peroxide. Continue shaking for a few seconds. Let the flask rest on the table until the reaction is completed. This usually takes ½-1 min.

The advantages of this method are resident in the fact that (1) it is not necessary to use triple distilled water; (2) the reaction of the water does not have to be adjusted; (3) this method can be used to make as little as 100 ml. and can be made with the same ease and with as high a degree of reliability as larger volumes. In Levine's experience, however, the reaction proceeds in a more regular manner in large volume manufacture, say, 500 or 1000 ml.

The colloidal gold reagent is commercially available.

Note: The prepared solution ordinarily requires no special treatment for neutrality. It is advisable, however, to test it with known normal and known paretic spinal fluids. It must give no reactions beyond the red-blue color with a known normal spinal fluid, and a typical paretic zone curve with the known paretic spinal fluid. The neutrality of the colloidal gold solution must be controlled; this may be carried out with alizarine red. Place 10 ml. colloidal gold fluid in a clean flask, add 1 or 2 drops 1% solution of alizarine red in 50% alcohol. Titrate with N/50 sodium hydroxide until neutral. With this solution of alizarine, acid reaction shows lemon yellow; neutral, brown red; alkaline, reddish purple. After estimating the quantity of acid or alkali necessary to neutralize the 10 ml. sample, add enough of one or the other to neutralize the entire amount of colloidal gold reagent that has been prepared.

A special set of glassware should be kept for the making of the reagent and the test. This glassware should be chemically cleaned, and care should be exercised in preventing contamination of the spinal fluid with dyes or chemicals before it is tested. Glassware should also be cleaned in 50% **aqua regia** (3 parts HCl, 1 part HNO_3, 4 parts water) to remove precipitated gold.

Glassware:

1. 1000 ml. Pyrex beaker, free from scratches.
2. 1000 ml. cylinder graduated in 10 ml.
3. 1000 ml. brown glass-stoppered bottle for storing the reagent.
4. 100 ml. cylinder graduated in 1 ml.
5. 25 ml. volumetric pipet.
6. 10 ml. pipet, graduated in 0.1 ml.
7. Two 1 ml. pipets, graduated in 0.01 ml.
8. Two 5 ml. volumetric pipets.
9. Several test tubes, kept especially for use in testing the reagent.
10. Eleven test tubes for the actual test, 1 cm. in diameter and 10 cm. long.

Procedure: Test tubes, 1 cm. in diameter and 10 cm. long, the same size as Wassermann test tubes, are needed for the test. In addition, two 1 ml. pipets, graduated in 0.1 ml. and one 5 ml. volumetric pipet are required.

1. Dilute physiologic saline to double volume for the test since a 0.4% sodium chloride solution is used.
2. Place the 11 test tubes in a Wassermann test tube rack.
3. Leave one space between the tenth and the eleventh tube. Tube 11 is a control over the glassware and the reagent. It receives no spinal fluid.
4. Place 1.8 ml. 0.4% sodium chloride solution in tube 1 and 1 ml. in each of the remaining tubes, including tube 11.
5. Add 0.2 ml. spinal fluid, free from blood cells, to tube 1.
6. Mix by drawing in and out of the pipet many times.
7. Withdraw 1 ml. of the mixture in tube 1 and place in tube 2. Mix the contents of tube 2 in the same manner; withdraw 1 ml. and place in tube 3. Mix the contents of this tube; withdraw 1 ml., and place in tube 4. Continue in this manner through tube 10.
8. After mixing the contents of tube 10, withdraw 1 ml. of the mixture and discard. Tube 11 receives no spinal fluid.
9. Place 5 ml. Lange colloidal gold in each of the 11 tubes.
10. Mix thoroughly and allow to stand at room temperature for 24 hr. Record the results according to Fig. 692 or record the numbers represented by the color changes in each tube according to Fig. 692. The color scale, with corresponding numbers, is as follows:

5 colorless
4 pale blue
3 blue
2 lilac or violet or purple
1 red blue or very slight change
0 red, no change in color of reagent

The **principle** upon which this test is based is as follows: if a cerebrospinal fluid is diluted in geometrical progression with a weak neutral electrolyte and 5 vol. clinical colloidal gold are added to each successive solution, a series of precipitation colors may be obtained which when ascribed numerical values from 0 to 5 and the values plotted as ordinates against the dilutions as abscissae will give a curve whose contour is characteristic for certain of the infectious diseases of the central nervous system.

The recording of the color values or ordinates is then plotted on coordinated paper against the dilutions or abscissae. Multiply the abscissae values by some convenient factor to elongate the curve formed by connecting the points in a continuous line. A convenient factor is 5/3.

The color of the colloidal gold is red. No change in the color of the reagent is therefore red, or "0" on the color scale. Complete precipitation of the gold is accompanied by a change in color of the reagent from red to colorless, the color changes between red and colorless depending on the amount of precipitation.

Interpretation: It has been generally believed ever since Lange brought out this reaction in 1912 that it is diagnostic of syphilis of the nervous system and particularly that various types of neurosyphilis could be distinguished by changes in this reaction. The weight of opinion at the present time, however, is to discard the terms "paretic," "cerebrospinal luetic," and "meningitic curves" and replace them by terms that indicate the tubes in which the greatest precipitation of the colloidal suspension occurs—"first-zone," "mid-zone," and "end-zone." This test indicates an abnormality in the protein content of the cerebrospinal fluid and does not necessarily have any particular diagnostic value. Kafka[8] and others have shown that the changes produced in colloidal suspensions of spinal fluids are related to the albumin-globulin ratio and to the total protein content of the fluid. In other words, the globulin fraction of the protein of the cerebrospinal fluid is most active in the precipitation of the colloidal suspension, whereas the albumin fraction has a protective action; this protective action depends not only on the albumin-globulin ratio but also on the total amount of protein in the fluid. A fluid with a high protein content and a high albumin-globulin ratio would produce no change in the colloidal suspension, but dilutions of it would cause a precipitation.

A normal spinal fluid results in no change of the colloidal gold suspension except possibly a slight change to lilac.

The first-zone curve is seen in cases of paresis but is not necessarily diagnostic of this condition because it has been seen in multiple sclerosis and other conditions (Fig. 692).

Text continued on p. 1940.

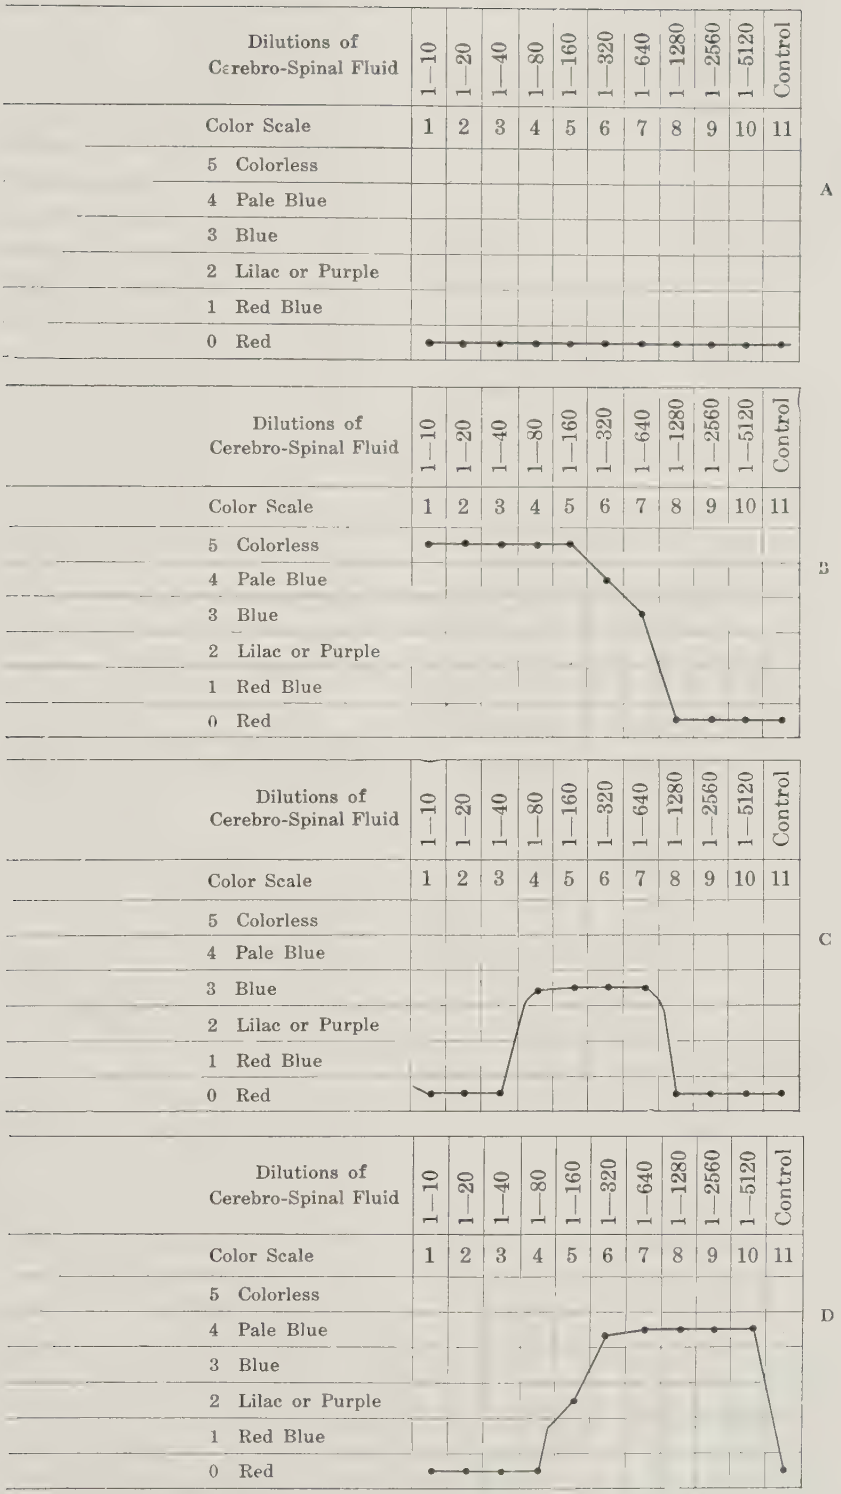

Fig. 692. Interpretation of results. **A,** Normal curve 0000000000. **B,** First-zone curve 5555543000. **C,** Mid-zone curve 0003333000. **D,** End-zone curve 0000244440.

The mid-zone curve (Fig. 692) may be found in any abnormal fluid and cannot be used as a specific indication of any particular type of cerebrospinal syphilis.

The end-zone curve (Fig. 692) was formerly called the meningitic curve but really means a fluid with a very high protein content with an especially high albumin-globulin ratio. It is naturally found in cases of acute purulent meningitis, subarachnoid block, and extravasation of blood in the subarachnoid space.

It is perfectly reasonable, therefore, to find changes in the colloidal gold test without any other signs of syphilis in the nervous system. Too much emphasis has been laid in the past on the specific value of this test alone as a differential diagnostic measure in cerebrospinal syphilis.

Precautions: It must be remembered that the colloidal gold solution contains only 1 part of gold in 20,000 parts of water, and therefore the presence of even a minute trace of contaminant may have a disastrous effect on the proper precipitation color. It was shown by Zsigmondy[9] that when 0.5 ml. 10% solution of sodium chloride is added to 5 ml. gold solution containing 0.25 mg. gold, more than 0.0025-0.005 mg. gelatin or 0.003-0.02 mg. alkali albumin[10] will prevent the change from red to violet.

Probably all the errors made in connection with this test are due either to inadvertent protection of the gold solution before or after use or to inadvertent precipitation afterward. One must be sure to prevent the intrusion of even traces of foreign disturbing substances into these solutions. The spinal fluid must be received into specially prepared test tubes which contain no traces of gelatin or albumin. Concerning the use of salt solution in this test, it is advisable to pour out the quantity that is going to be used from the stock bottle into a separate clean container so that repeated insertion of the same pipet or different pipets into the stock bottle can be avoided. The same precaution should be followed with the colloidal gold solution; namely, pour out about 60 ml. of this material from the stock bottle and reject the surplus.

Attention must be called to the fact that the smallest amount of saliva flowing into the pipet and touching the gold solution will inhibit normal precipitation of the colloidal gold solution. It has been found, too, that the soluble sizing from toweling used to dry a beaker has pronounced protective powers.

In order to check the gold solution and the salt solution, the addition of 0.4 ml. 1% salt solution to 5 ml. gold solution should produce no precipitation after standing at room temperature 18 hr., whereas the addition of 1.7 ml. should produce complete precipitation of the gold in the same period of time. The addition of 1 ml. 1% solution of sodium chloride to 5 ml. gold solution should produce, upon standing overnight, a color change adjudged to be midway between a 1 and a 2 reading. The ultimate test, of course, is to use the spinal fluid from a known paretic, which will give the typical first-zone curve. If the gold solution should exhibit evidence of protection, a fresh 0.4% salt solution must be prepared with which the gold solution must again be tested. If the same results are obtained, it is probable that the gold solution has become protected through contamination; if an improved result is obtained, contamination of the original salt solution by a protectant is indicated; on the other hand, if an undue tendency for the gold solution to precipitate is found and an improvement is then noted with the fresh salt solution, the presence of a precipitant in the original salt solution may be inferred.

Mastic test—method of Cutting

The mastic test has been proposed as a substitute for the gold test, but it is not as useful a test in the differentiation of the various types of syphilitic diseases of the nervous system. Complete precipitation of the mastic corresponds to complete decolorization of the colloidal gold reagent, whereas partial precipitation of the mastic corresponds roughly to the purple or blue of the colloidal gold test. The method used by Cutting follows.

Reagents:

1. Mastic solution.

Gum mastic, U.S.P.	0.2 gm.
Absolute alcohol	20 ml.
Freshly distilled water . . .	80 ml.

   (a) Dissolve the gum mastic in the absolute alcohol and centrifuge to clear.
   (b) Pour the filtrate rapidly into the distilled water and mix well.

2. Alkaline saline solution.

Potassium carbonate, reagent grade . .	5 mg. (0.005 gm.)
Sodium chloride . .	1.25 gm.
Distilled water . . .	100 ml.

   (a) Dissolve the salts in the water.

Procedure:

1. Arrange a series of 6 small test tubes. In the first, place 1.5 ml. alkaline-saline solution and in each of the others place 1 ml. To the first tube add 0.5 ml. of the spinal fluid, which must be completely free from blood. Mix by

sucking the fluid up into the pipet and expelling it; then transfer 1 ml. to the second tube. Again mix and transfer 1 ml. to the third tube and continue down to the fifth tube, discarding the 1 ml. portion which is removed from this and leaving the sixth tube with alkaline-saline solution alone to serve as a control.

2. Finally add 1 ml. of the mastic solution to each tube. Mix well and set aside at room temperature for 12-24 hr. or in the incubator for 6-12 hr.

Tubes in which the reaction is complete will show a heavy precipitate with clear supernatant fluid.

Interpretation: As stated before, this reaction is read as one reads the Lange colloidal gold test reaction. If there is no precipitation of the colloidal suspension in any of the tubes, this is a negative reaction. Any precipitation is considered a positive reaction and the characteristics of the precipitation in the various tubes determine the interpretation; e.g., most precipitation in the first tubes is read as paretic zone, precipitation in the center tubes as syphilitic zone, and in the last tubes as meningitic zone.

Quantitive test for protein

See p. 49.

SUGAR ESTIMATION IN SPINAL FLUID

It is generally believed that the sugar values in spinal fluid vary between 50 and 75 mg./100 ml. Estimation of the amount of sugar in spinal fluid is important because a low sugar content is diagnostic of certain conditions. For instance, there is a low sugar content in acute and subacute meningitis due to the glycolytic action of the organisms present. It also has been noted that there is a low sugar content in cerebrospinal fluid containing blood. This is due to the action of glycolytic enzymes which are present in the blood, which serve to reduce the normal sugar content of the fluid. A low sugar content has been seen in cases of so-called aseptic meningeal reaction due to the glycolytic action of cells in vivo. The level of the spinal fluid glucose should always be measured together with a blood sugar specimen obtained immediately prior to the spinal puncture since the procedure in itself may increase the C.S.F. glucose contents. If possible, the patient should be fasting and there should be no delay in performing the test (or in preparing the filtrate).

The lumbar and cisternal fluid sugar amounts to 10-20 mg./100 ml. less than the blood sugar but still reflects blood sugar fluctuations. The ventricular fluid sugar approaches the blood sugar level.

Cerebrospinal fluid sugar:

- Increase:
  - Diabetes
  - Encephalitis (some forms)
- Decrease:
  - Infections
    - Bacteria
    - Fungi
  - Hypoglycemia
  - Metastatic tumor
- Normal:
  - Viral infections
  - Encephalitis (some forms)

For procedure see clinical chemistry, p. 83.

Section Four

FECES

The examination of the feces, while generally stressed by clinical teachers as a very important means of diagnosis in medical and surgical cases, is seldom thoroughly performed. The leading gastroenterologists are undoubtedly examining stool, just as they are giving barium enemas, and making roentgenologic examinations of the canal, but most physicians are not adequately utilizing this type of examination. A routine chemical, bacteriologic, and microscopic examination of the stool of every patient is not indicated, but in certain selected cases, this examination will be of considerable aid. The microscopic examination and the more important chemical tests can be quickly performed. A search for pathogenic amebae is frequently indicated.

Physicians make exhaustive examinations of all parts of the patient except the anus and rectum; in most cases this part of the physical examination is superficial, and consequently much valuable information is overlooked. The indifference to the possibilities of help from routine stool examinations, lack of concise information as to technic and interpretation, and esthetic objection to handling the material, all have conspired to make this field of laboratory work practically a terra incognita to most workers and students.

In southern states one finds more interest and more real work being done on stools than in any other section of the country because of the prevalence of intestinal parasitism in that district and the impossibility of making a definitive diagnosis in any other way. We find a growing interest in stools, too, on the part of pediatricians, but we believe much more emphasis must be placed on this subject.

Chapter 108

Laboratory examination of feces

STANLEY REITMAN

NORMAL FINDINGS

It must be remembered that what constitutes the normal stool is quite a variable factor. There is no normal standard regarding either the frequency or absolute character of the stools. The number, character, weight, consistency, and color of the passages must be accurately ascertained in the individual case before one can draw reasonable and proper deductions.

In order to appraise the individual case, certain fundamentals must not be overlooked. The feces consist of the indigestible and undigested remnants of food, certain constituents such as material secreted by the intestinal wall, and myriads of bacteria that may or may not belong to the normal intestinal flora.

The usual amount of stool is 100-200 gm./day, but this quantity is dependent upon the amount and character of food ingested. Besides the diet, the amount of feces passed depends upon the adaptability of food to the peculiarities of the individual's digestion, the rapidity of intestinal absorption, the amount and character of the digestive juices, such as the bile and pancreatic fluids, the amount of mucus discharged by the intestinal mucosa, and the biologic characteristics of the bacterial flora of the canal. The age of the patient, his habits, whether he leads an active or a sedentary life, his occupation, etc., all influence the number and weight of the stools.

The stools of patients with diarrhea lasting several days show undigested muscle tissue if they have been eating meat, also unchanged connective tissue elements. The predominant ingredient of a stool that is associated with inflammation of the small intestine is mucus, thoroughly mixed with food remnants.

COLLECTION OF THE SPECIMEN

In order to gain the maximum information, the stool specimen must be properly collected and submitted to the examiner as rapidly as possible. This is particularly true with respect to examination for parasites, when, in order to detect their motility, the stool should be examined while still warm. For routine bacteriologic and chemical examinations this is not vital. The best results for all purposes are obtained when conditions are such that preservatives are not needed. For long distance transportation a chemical preservative must be added, and this sacrifices some of the data obtainable from the fresh, unchanged specimen.

Physicians, as well as laymen, are prone to send both sputum and feces specimens in unwieldly, impracticable, and dangerous containers. The Post Office regulations in this country very properly compel one to take precautions against transmitting disease via infectious material in the mails. Specimens may safely be mailed if they are placed in double, tightly closed metal containers. The stool should be collected in a wide-mouthed, chemically clean and sterile bottle. (We recommend the sterilization of all glassware at 170° C. for 2 hr. in the dry heat sterilizer.) The container must be chosen with the following ideas in mind: (1) to keep the material in much the same condition as it was when passed from the patient and (2) to withstand the rough handling to which it may be subjected in

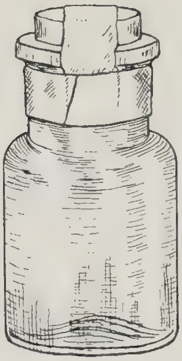

Fig. 693. Taped bottle for collecting specimen of feces.

transit. Despite reasonable care in transit many very severe strains are placed upon such containers; they must be carefully packed so as to withstand the severest of ordeals in shipment.

The receptacle and its packing must be so prepared that it will be neither a menace to the health of those handling it nor offensive to the sensibilities of those who must examine it. Containers leaking fecal material from all sides, as from a Mason jar, for instance, require great care and time on the part of the laboratory worker to prevent infection and contamination of laboratory material. Above all, paper receptacles are to be condemned and never used.

Fill the bottle only about ⅓ full so as to allow ample space between the stopper and the top of the fecal contents to prevent the stopper from being forced out by gas formation. The stopper should be of cork and should fit tightly enough to prevent leakage. It should be long enough to project well above the bottle so as to facilitate removal. It is well to secure the cork with adhesive strips.

The use of 20% glycerin in physiologic saline has been suggested by Cumming, who claims that it has an inhibitory effect on the growth of the colon bacillus and other fecal microorganisms. His solution is made by adding 20 ml. glycerin to 80 ml. 0.9% sodium chloride. To 20 ml. of this solution a mass of feces about the size of a split pea is added. Shake well to make a uniform suspension. Do not use a larger amount of feces since the inhibition of *Escherichia coli* might not be controlled when larger amounts are used. According to Hazeltine[1] this method gives admirable results on specimens artificially contaminated with laboratory cultures of *Salmonella typhosa* and should be applicable in practice.

When the stools are to be examined in a hospital laboratory adjacent to the hospital-domiciled patient, they may be received directly into a clean sterile granite-ware bowl and taken immediately to the laboratory.

Stools submitted for examination for living amebae should be examined while still warm. Patients with dysentery due to pathogenic amebae may show these parasites only during the activity of the process when the patient has frequent bloody or purulent passages. The material should be examined at once, using a warm stage. If the patient cannot come to the laboratory, or the laboratory worker cannot take his microscope and other material to the bedside, then it is best to have the attending physician make half a dozen slides from the fecal matter, allow them to dry, and ship them to the laboratory. An examination of the stained specimen can be made for cysts; this is the most reliable method of diagnosis. In cases in which an examination is being made of the feces for amebae in a fresh state, the bottle or receptacle containing them should be placed in an incubator and kept warm while the technician is adjusting the microscope and warm stage. Refer to Chapter 55 for details relative to examination of stools for intestinal protozoa.

In general, feces should be examined as expeditiously as possible because of the rapid tissue and bacterial changes. The isolation of *Salmonella typhosa,* for instance, increases in difficulty in proportion to the age of the stool. A specimen that has been quickly examined for typhoid bacilli will often show a good culture, whereas the same stool kept for a while and then cultured will show no growth of the organism. Certain changes of decomposition take place in the stool; the overgrowth of one or more hardy microorganisms prevents the

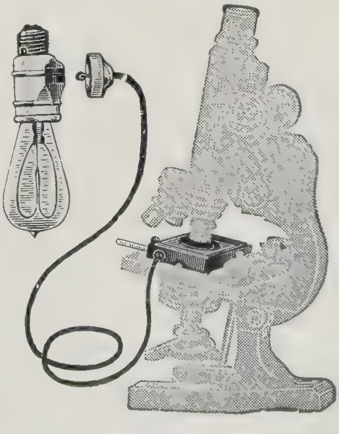

Fig. 694. Warm stage. (Courtesy E. H. Sargent Co., Chicago, Ill.)

growth and recognition of *Salmonella typhosa* in the stools of suspected carriers. The administration of a cathartic increases the number of bacilli in the stools. It is good practice, therefore, to precede the search for typhoid bacilli in suspected carriers by the administration of a saline cathartic. Bacteriologic examination of stools is discussed in detail in Chapter 31.

As Cammidge has pointed out, the feces of infants must generally be scraped off diapers and are therefore contaminated more or less with material derived from dusting powders or ointments which have been applied to neighboring parts. This must be taken into account in the chemical and microscopic examinations of infants' stools. The feces should be free from urine to prevent interference with the reaction, the ammonia content, chloride estimation, etc. With adults it is not difficult to prevent the contamination of stool with urine. In the case of infants the nurse may prevent contamination by placing a large pad of absorbent cotton over the urethral orifice while collecting the stool for the analyst. A stool that is strongly alkaline or that has an ammoniacal odor with a well-marked reaction for chlorides can be instantly proved to be contaminated with urine because the stool never shows more than a bare trace of chlorides. The **presence of urine** can be quickly proved as follows.

Make an aqueous extract of the stool with boiling water. Filter. Acidify with nitric acid and add 10% silver nitrate drop by drop. An uncontaminated stool will show only a slight opalescence due to formation of silver chloride. Stool containing urine will give a heavy white precipitate, indicating a large amount of chloride.

Only a small amount of feces is necessary for the usual routine stool analysis. In most cases in which a quantitative chemical analysis is desired, the stool must be collected for 3 days and the entire specimen submitted. A complete chemical analysis of stools is unnecessary except under special conditions. To determine the metabolic changes in a given case, one might make such a chemical analysis in conjunction with the estimation of the chemical intake of food, the study of the blood chemistry of the individual, and the chemical study of the urinary constituents. As a rule, the stool examination should consist of a determination of certain essential factors, macroscopic and microscopic. Under special conditions this examination may be varied to include a complete bacteriologic study, qualitative and quantitative.

EXAMINATION OF STOOLS

The examination of stools is divided into 5 studies: (1) macroscopic, (2) microscopic, (3) microchemical, (4) chemical, and (5) bacteriologic.

MACROSCOPIC EXAMINATION

The macroscopic identification of parasites may be summarized as follows: the proglottids of the tapeworms, *Ascaris lumbricoides,* and *Enterobius (Oxyuris) vermicularis* are likely to appear spontaneously in the stools. *Ancylostoma duodenale* and *Trichuris trichiura* appear only as a result of definite therapeutic attempts to expel them. Rarely one finds insects and their larvae. Workers must be sure that stools are not contaminated **after** their expulsion either accidentally or purposely by malingerers or psychopathic individuals.

The number and variety of foreign bodies that have been found in stools are legion. They may vary from meat skewers, splinters of wood, eggshells, garden earth (from imperfectly cleaned vegetables), kernels of nuts and fruits, pieces of tobacco leaf, tea leaves, etc. It is remarkable to note that sharp instruments such as needles, pieces of a knife blade, and glass balls may pass the entire length of the canal and may be expelled without injury to the wall. It must not be forgotten that some of these foreign bodies may be placed in the rectum by psychopathic persons.

The macroscopic examination is very important.

Place a portion of the stool on a flat dish. Note the color, consistency, quantity, and mixture with large mucous particles, blood, and undigested food remnants. For closer examination some of the stool should be mixed with water and this diluted material put in a Petri dish with a dark background. The brown particles that will then be noted should be examined microscopically.

Pathologic macroscopic findings are as follows:

1. Undigested food remnants, such as connective tissue, remnants of potatoes and meats, and pieces of fat.
2. Mucus, pus, or blood.
3. Pieces of human tissue.
4. Intestinal stones and gallstones.
5. Worms.

The **physical characteristics** of the stool should be investigated.

Color: Under normal conditions the color of the stools may be light yellow to blackish blue, dependent in a measure upon the character of the food ingested. Exposure to the air and to light causes the stool to become blacker. The fecal color is due to bile pigment plus the presence of foreign pigments of foods and drugs. The ingestion of blackberries or huckleberries causes black stools; chocolate gives them a dull gray color; cocoa makes them light gray. The effect of starchy food is to produce a yellow stool; of chlorophyl from vegetable material, a greenish shade. Fats produce the classical clay-colored stool. Certain drugs, such as bismuth and iron, produce a black stool; senna, rhubarb, santonin, and calomel give a yellowish green cast.

The normal color of the fecal material is due to the presence of urobilin and stercobilin derived from the bilirubin of bile; the intestinal bacteria convert bilirubin into the urobilins. Neither of the bile pigments, bilirubin nor biliverdin, is ever normally encountered in a stool unless the bile is passed unchanged down the intestinal tube by unduly rapid peristalsis. The darkening of the stool after exposure to the air is probably due to the conversion by bacteria of urobilinogen into the urobilins. The color of stools is mainly dependent upon the character of the diet. If one is to be influenced by color of the stool in estimating a fault in health, then he must inquire very carefully as to the diet taken, whether mixed, whether it contains vegetables or fruit, etc. An inquiry of this kind will usually explain the color.

Blood: Blood is not easy to identify visually in the stool because the bright red color is lost after the blood remains some time in the intestine, changing in color to the brown of hematin. A large quantity of blood gives the appearance of cooked tea. If blood comes from the lower bowel, it will usually appear on the surface of the stool and can be detected. It is always red if it comes from the rectum and is darker if it comes from a higher point. When summarizing the evidence presented by either the macroscopic or the chemical analysis for blood in stools, one must know whether there are any hemorrhoidal changes present, also whether there is a rectal fissure, as well as polyps, rectal adenomas, carcinoma, or ulcer. Attention should be called to the gross appearance of stools contaminated with large quantities of blood coming from points higher up, notably the tarry color due to a bleeding duodenal ulcer, typhoid stools with bleeding, or in severe dysenteric conditions.

Blood mixed with pus is seen in dysentery. Mucus and blood are seen in mixed cases of intussusception and polyposis intestinalis. Blood is found, too, in cases of embolism of the mesenteric arteries.

Form: The form of the fecal material gives an idea of certain conditions. The stools in prolonged constipation are hard and often ball-shaped, sometimes grooved by the intestinal bands. There is a characteristic scybala formation called "goat droppings" seen in cases of spastic constipation, or one may see pipestem or ribbon-shaped stools. In general, it may be said that the formation of scybala, due to small bulk of feces and lack of moisture, is evidence of spastic constipation.

Liquid and semisolid stools are indicative of irritation in the intestinal tract, and the passage of this type of stools is termed diarrhea. There are varieties of these liquid formations, sometimes spoken of as characteristic of certain definite disease states, such as the "pea-soup" stools of early typhoid and the brilliant red stool of the later period. In cholera the so-called "rice-water" stools are seen.

Odor: The odor of feces is due to the presence of indole and skatole which are formed as a result of the putrefactive processes that normally occur in the intestine. These putrefactive processes result from the action of bacteria upon protein present in intestinal contents. The most important products formed are indole, skatole, paracresol, phenol, *p*-oxyphenyl-propionic acid, *p*-oxyphenylacetic acid, volatile fatty acid, hydrogen sulfide, methane, methylmercaptan, carbon dioxide, proteoses, peptones, peptides, ammonia, and amino acids. Of these products indole and skatole in the feces give the disagreeable odor, whereas indole, skatole, phenol, and paracresol appear in the urine as ethereal sulfuric acids. Methane, methylmercaptan, and hydrogen sulfide may add to the disagreeable odor produced by indole and skatole. The more meat digested by the patient, the more the odor; it is less marked in stools from a vegetable diet and hardly noticeable in stools from a milk diet. This explains the fact that stools of infants on milk diets are practically odorless except under pathologic conditions.

Casts: Casts of the bowels are occasionally found. They may be passed in shreds or in the form of a complete cast of the intestine. This condition has been designated by Nothnagel as enteritis membranacea or colica mucosa. They may be a foot or more long and may be passed, accompanied by severe tenesmus, without any fecal material. These cases are seen more commonly in women than in men. They are found, according to Greene,[2] associated with 2 conditions aside from the causes mentioned, namely, impairment of general nutrition and spastic constipation. The nature of these casts may be determined by the **Pariser method:**

Treat them with sublimate alcohol and then with Ehrlich triacid stain; they turn green if mucoid, whereas they turn red if fibrinous. Details of the test are given below.

Undigested food particles: These particles may be seen and identified by the naked eye. Pour liquid stools into Petri dishes. Thick pasty stools are best stirred with water and then poured over a fine-shred sieve. The sieve described by Einhorn is very useful to detect concretions. Another method without the use of a special sieve consists of tying a double thickness of cheesecloth over a ring of wood or on to the edge of a pail. Kemp has described a method that is simple and practical. A circular wire is fitted to the toilet seat and to this is attached a bag made of double thickness of cheesecloth which dips into the pail. The patient defecates into the bag. Water is poured through until only the more solid parts remain. These are then scraped off and examined. The same thing may be accomplished by means of a colander over which is laid a fine meshed wire screening.

Mucus: Mucus that appears in the stool is usually visible macroscopically. In very small quantity it is difficult to find, but in larger quantity it can readily be seen and grasped with forceps. Cases in which it is found only with the aid of a microscope are rare, but they do exist. Our interest therefore is in mucus that can be found macroscopically.

Tests for mucus may be made as follows: Wash a few particles of the supposed mucus in water and stir in a test tube with 2½% mercuric chloride in alcohol, using a glass rod. The larger particles are thrown down by the hardening effect of the mercuric chloride in alcohol. Sediment the specimen, add distilled water with a few drops of Ehrlich triacid stain, sediment again, wash in water, and examine microscopically. The mucus particles, provided they are not too rich in cells or fat, are stained bluish green or green; all the animal cells are stained red.

Mucus is precipitated with acetic acid. The precipitate is not redissolved by an excess of this acid. Mineral acids added slowly cause a precipitate; added rapidly they dissolve the mucus. Alkalies cause it to swell and dissolve. Alcohol causes shrinkage. Thionine stains mucus violet; other material remains blue. In order best to obtain this reaction, take care that there is not too much mixture with other material and that the reaction of the specimen is neutral. Other aniline dyes stain only the cells present. Iodine stains mucus a diffuse yellow color. The **Hecht method**[3] is a mixture of brilliant green (2%) with neutral red (1%). Stain a few minutes. This gives a light red color to mucus, which is in sharp contrast to the rest of the field, which is green. Nuclei and cell membranes appear reddish violet.

The amount of mucus present in stools may range from very small particles to enormous masses.

The mucus is usually present in clumps or small masses which, in water, appear to have irregular edges. At times there are the so-called boiled sago nodules, the composition of which has been much in dispute. The consistency of mucus masses varies from extreme softness to leatherlike hardness. Pure mucus masses are usually soft, the harder particles consisting of other material as well as mucus, namely, albumin, fat, and many cells. Mucus is transparent, but when contaminated with other substances, such as fat or albuminous material, it becomes cloudy. It imitates the color of the fecal mass in which it is found, varying from the brown color of hydrobilirubin to the orange red and green color of bilirubin and biliverdin; blood elements, of course, make mucus reddish or red brown.

Washing the stool gently with water makes it comparatively easy to find the smaller particles. Mucus appears under the microscope as structureless material, more or less transparent, in which may be embedded epithelia, pus cells, red blood cells, bacteria, protozoa, air bubbles, detritus, food remnants, and crystals. Mucus from the upper tract is more likely to be entwined with food residue than when it originates from a lower point. The bacterial contents vary, being very scant from cases of mucous colitis. Note 2 points, the irregular lines that traverse it and the irregularity of its boundaries.

Only visible mucus is found under pathologic conditions. The exceptions to this are the meconium and the stools of young infants.

The most important consideration in the study of mucus is its **source.** Usually, mucus comes from the large intestine. The small intestine does not produce mucus with the same facility as does the large bowel. If mucus is found in diarrheal stools very finely subdivided, as in typhoid fever, tuberculosis, and cholera, it may be assumed that it comes from the small intestine. Further proof of the small intestine as the source of the mucus is the impregnation of the mucus with unchanged bilirubin.

The manner in which mucus is mixed with stools may indicate the source; if the well-formed stool is covered with mucus or if the mucus dips down between the scybala, it is coming from the lower end of the large intestine. The ribbonlike masses that are called membranous colitis mucus come from the sigmoid flexure of the colon. If mucus is intimately mixed with a "soupy" stool, the material comes from the upper part of the large intestine; in fact, the smaller the particles and the more intimately they are mixed, the higher their source.

The pathologic process underlying the undue pouring out of mucus into the intestinal canal is usually a catarrhal process, with increase in the glandular activity and a diffuse inflammatory change in the entire mucosa.

The degree of inflammation may in a measure be determined from the transparency of the particles of the mucus. Our conception of a very severe attack is a mucus that is very cloudy, due to the content of epithelial and pus cells. There may, however, be a catarrhal inflammation without mucus in the stool, so that absence of mucus does not exclude inflammation. The appearance of the sagolike clumps of mucus occurs in the stools of children as an evidence of severe mucous inflammation. Heubner, in explaining this formation, thinks that the nodules of mucus are formed from the follicles in the intestinal wall, whereas Kelsch believes they are pieces that are squeezed out of the Lieberkühn follicles. The presence of a large amount of pus with mucus indicates ulcerative inflammation; with blood, a diagnosis of ulcerative enteritis (dysentery).

Fibrin: It is difficult to identify fibrin in the stools either visually or even chemically. Autopsy findings of fibrin are common in dysenteric patients, but there it is attached to the walls of the intestine. It is logical to assume that it is cast off and appears in the stool, but it cannot be proved by an examination of the stools. Fibrin masses are found especially in membranous colitis.

Tissue remnants: Tissue remnants emanate either from tumors of the intestinal wall or from necrotic mucous membrane changes. In the first group we note polyps, pieces of hemorrhoidal nodes, carcinoma, and occasionally lipoma. Necrotic pieces are seen in ulcerative processes, such as invagination cases, typical dysentery, twisted off pieces of adenomatous polyps, or pieces of ulcerated neoplasms.

Very small necrotic masses have been seen in the stools of patients with typhoid fever in the second or third week.

The greatest stumbling block to an attainment of a good working knowledge of the material commonly seen in stools is the presence of nonpathologic substances or artifacts. These are fly larvae, unusual pieces of food, pieces of goods, pieces of apparatus, and other objects that may come in contact with the stools or containers. This must constantly be borne in mind; in fact, a microscopic study of all such foreign matter is very good preliminary practice in preparing oneself for coprologic expertness.

Other organic material: Other organic material may be parasites or various calculi. Among **calculi** are gallstones which are identified by their smooth and facetted surfaces and their light weight. Chemical means will fully identify them. Although all sizes of gallstones may be found, the 2 extremes, very large and very small stones, are rare: the very large stones lead to obstruction and are not passed; the small stones are so easily broken up that they are no longer recognizable when they reach the lower end of the canal. The rare pancreatic stones have no known characteristics to make their identification with the naked eye easy. According to Fleiner of Heidelberg, their surfaces are facetted and rough.

MICROSCOPIC EXAMINATION

The microscopic examination of the stool may be made either a very simple procedure or a very complicated one. It depends upon how far we wish to go and upon the object of our investigation. We may simply wish to survey the crystals present, or the food remnants, or to verify our naked eye judgment or to prove the presence or absence of eggs of the more common parasites such as the hookworm or the tapeworm; we may wish to make a simple smear for tubercle bacilli or to make a smear for other microorganisms; in short, our microscopic examination may be directed to the solution of one problem or a great many. We usually are given a clue from the clinician as to what he particularly wants investigated.

Preparation of specimen

In general, the following material is needed for a microscopic examination of stools: glass slides and cover glasses; teasing needles; a good centrifuge; test tubes and small funnels, pieces of sterile gauze for filtration; sterile Petri dishes; and culture media for identification of the more common varieties of bacteria such as the colon and typhoid bacilli.

It is inadvisable to add any chemical substance to the stool to reduce the odor since these substances always cause a distortion of the picture and render the examination of doubtful value.

The simplest examination consists in taking a small piece of the stool on a toothpick and rubbing it on a glass slide, covering with cover glass and examining. Portions from various places should be taken, from the solid parts, and from softer and more liquid parts. Be sure the specimen is as fresh as possible to eliminate the question of alterations from standing. If the stool is not particularly fresh, take the specimen from the inside of the masses rather than from the outside. In exerting pressure on the cover glass elastic tissue and watery material will not remain pressed out, mucus and fat containing stools remain pressed out. If a grittiness as of glass against glass is noted, crsytals or sand may be present. Thin watery stools may be sedimented and thicker heavy stools may be slightly diluted with water or saline in making this examination. The mixture may be made on the slide. Examine with the low- and high-power dry lenses. To isolate certain parts of the stool, wash repeatedly, shake, sediment, and pour off the supernatant fluid. Remove the large particles which are visible to the naked eye and examine the sediment.

Sedimentation can best be accomplished with the use of a centrifuge tube very much like that devised by Hopkins for the counting of bacteria. Run the centrifuge at moderate speed. Note a sharp line of separation between the sedimented portion and the supernatant fluid. In the cloudy portion just above the sediment the various bacteria and the fatty acid needles are found in fatty stools. Note foamy fat on the surface in cases with much fat in the stools. In this upper portion are seen small particles of vegetable material, mucus with air bubbles, and particles of connective tissue cells. In the deeper portions of the sediment are crystals of large size such as triple phosphates, and the hair-like covering of vegetables, and the large muscle remnants.

There are a number of other more elaborate methods of washing and sedimenting the stool for microscopic study, but the above method will generally suffice.

Microscopic findings

Epithelia: Epithelial cells from all portions of the tract are likely to find their way into the stool. The character of the cell points to the origin, but pure histologic pictures as they occur in the mucosa do not exist in the stool because the digestive juices have a powerful effect in changing the morphology. There may be pure unchanged stratified squamous epithelial cells from the region of the anus, but even this is rare. They appear, however, less changed than cells from points higher up; for instance, the cylindrical cells from the small and large intestines. These squamous cells closely resemble the cells that fall into saliva from the mucosa of the mouth. They are very large nucleated cells and are not to be confused with the nuclear-free cells of meconium and infant stools which have originated from the vernix caseosa. Pure types of squamous cells are rubbed off, unchanged, from the anal orifice by passage of the stool. Cylindrical cells from points higher up are seen as slightly distorted cells, found in washings of the gut or in thin soupy stools of typhoid, diarrheas of children, tuberculous enteritis, and cholera. They have clear nuclei and granular cytoplasm. They may appear singly or grouped as they are in the intestinal wall, arranged side by side. These cells are sometimes swollen with fat droplets. One may see the cells described by Nothnagel as "vanishing" or epithelial cell "ghosts" bound up with mucus particles. They

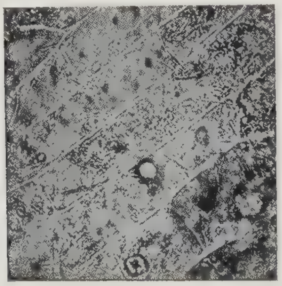

Fig. 695. Vegetable cells in feces.

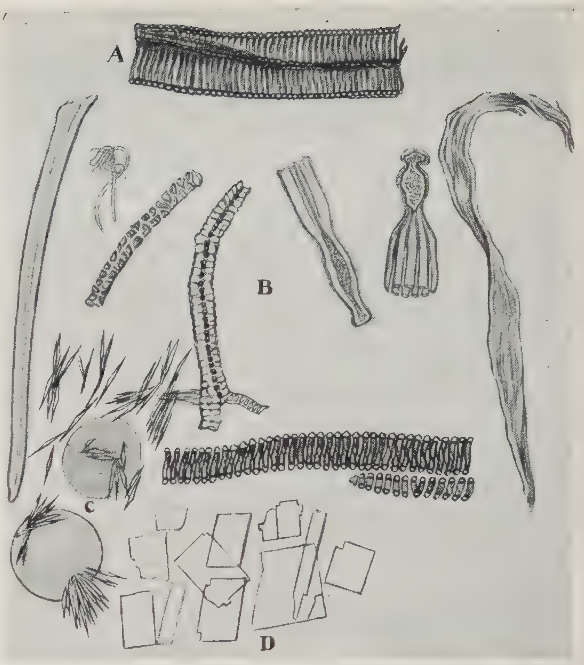

Fig. 696. Microscopic findings in feces. **A** and **B,** Vegetable fiber remnants, banana (**A**) commonly mistaken for tapeworm section; **C,** fatty acid crystals; **D,** cholesterol crystals.

are supposedly degenerated cells according to Leube, or amyloid cells according to Lambl. They are small and homogeneous and have no nuclei. They are refractive and apparently have lost their granules. They are frequently spindle shaped. Nothnagel believes they are cells that are changed by abstraction of water. Kitagawa, however, stated that he found these cells in watery stools in diarrhea and that they are the result of a degenerative process, either hyaline or coagulation necrosis. Epithelial cells in the feces are usually not stained. Rarely are they yellow colored from bile. Nothnagel believed that the staining with bile is an intervital process and does not occur post mortem.

A sharpness in outline of the cytoplasm of the epithelial cells may be produced in the usual way by the addition of acetic acid. Osmic acid will stain fat granules black.

The diagnostic significance of epithelial cells in abundance is their indication of the existence of catarrhal processes. The occurrence of a large amount of mucus and a paucity of cells evidently shows that the derangement is more a result of a nervous irritability of the intestine than a true inflammatory process. This is especially true in cases of enteritis membranacea. Toxic disturbances of an intense nature, as in cholera, cause a great exfoliation of cells. One cannot conclude simply because the epithelial cells are bile stained that the disturbance is in the small intestine. Other signs must be at hand to make this diagnosis. The presence of the "vanishing ghost" cells does not prove their source the large intestine; when mucus is present as well, this is probable. The presence of half-digested cells with mucus indicates a small intestine disturbance, especially if the cells are bile stained. This picture is seen in typhoid fever and tuberculous enteritis, in which pus cells are also present.

Leukocytes: Leukocytes are not commonly found in feces. They are abundant naturally where there is pus formation, as in ulcerative conditions in the tract. One may have difficulty in identifying them under the microscope, but they may present a perfect contour, with granular cytoplasm and single or multiple nuclei. Eosinophilic granules may be seen; particularly is this true when Charcot-Leyden crystals are found in cases of parasitism. Leukocytes that are large enough to be designated giant cells have been seen in feces. They are much larger than the flat cells found in the mucosa of the mouth. They show vacuoles. They are seen in tuberculous enteritis. Schmidt noted phagocytes in a case of dysentery. The shadows of leukocytes are sometimes seen. Small, broken down leukocytes are frequently seen enmeshed in mucous particles. The presence of a few leukocytes in conjunction with epithelial cells in infantile stools indicates an irritation process.

Pus: Macroscopically the grayish masses which microscopically prove to be collections of pus cells may be observed. If yellow material which is unmistakably pus is present, one must think of para-intestinal pus pockets in the region of the large intestines. Pus coming from a higher point in the small intestine would undergo changes before being expelled with the stool mass so that it would not be readily recognized macroscopically. In the various ulcerative processes of the large intestine and even of the small intestine, such as dysentery, colitis ulcerosa, syphilis, neoplasms, tuberculosis, and typhoid, pus may be intimately mixed with the stool and is difficult to recognize as such.

Pus cells do not appear in feces in abundance in catarrhal states, as is the case in sputum of catarrhal inflammation of the respiratory tract. The presence of much pus always indicates an ulcerative pathology with but one exception, namely, colitis with severe inflammatory changes, with pus, blood, and mucus in the stools, without ulceration. One must remember that there are certain types of ulceration without pus, e.g., the perforation of typhoid ulcers.

Erythrocytes: Blood must be very fresh in order that the cells be seen intact under the microscope. Even then the crenated or crab-apple form are usually seen because of the acid reaction of the stool. Only a large number, as expected in an ulcerative or intensely inflammatory condition, will yield shadow forms which show no color. The finding of red cells in feces usually indicates ulceration. Exceptionally they are found in venous stagnation. Well-preserved corpuscles are seen in cases of hemorrhage from stasis low down (hemorrhoidal vein bleeding).

Detritus: Besides the various elements already described, there are found in stools microscopic particles that are extremely small and impossible to identify. This material is called detritus. It is intimately digested muscle remnants, plant cells, bacteria, epithelia, and isolated nuclei too far changed by the digestive juices to be recognizable. The presence of a large quantity of detritus is a good indication of the chemical and mechanical efficiency of gastrointestinal digestion.

Crystals: Many crystals are found in feces, some derived from food, others from chemical changes in the intestine.

Triple phosphate or ammonium magnesium phosphate crystals are the commonest. They vary in size, some so small that they can be covered by calcium oxalate crystals, others very large. The best developed crystals are seen in fluid stools. Their shape is that of the "knife rest" or "coffin lid," but some are more or less irregular (Figs. 635 and 636). Some are so large that they cover 2 microscopic fields, in which case they can be seen in the specimen with the naked eye, as a small white point on the slide. They sometimes appear as 3- or 4-cornered splinters representing breaking down of the "coffin-lid" formation. Triple phosphates are never bile stained. They are freely soluble in dilute acetic and other acids. They are insoluble in ammonium carbonate solution which distinguishes them from neutral phosphate crystals which they closely resemble. Some claim that they are found in normal and abnormal stools. Szydlowski found them absent in but one condition constantly, i.e., icterus. Lynch states that they are never found in meconium. When found, we must be sure that there is no urine contamination.

Di-calcium phosphate or neutral phosphate of lime crystals appear in the form and size of those found in urine, larger or smaller sheaves with the points lying together. They may occur as rosettes. They are occasionally bile stained, whereas triple phosphates are never bile stained. A homogeneous transparent variety is seen in milk stools, this form being a combination with fatty acids. They are freely soluble in acids and in ammonia, as well as in ammonium carbonate solution. They are found in normal stools, particularly when alkaline stools have been allowed to stand for some time. They have no diagnostic importance.

Neutral magnesium phosphate or trimagnesium phosphate crystals are found in stools showing ammoniacal decomposition. They occur as irregular sheaves, never as in urine as light refracting long rhombic plates. They are soluble in acetic acid and become opaque when ammonium carbonate solution is added.

Calcium carbonate crystals appear as round or dumbbell-shaped crystals or amorphous granules. The addition of acetic or other mineral acids dissolves them with gas formation. Sulfuric acid causes them to assume a sheaflike form. These crystals are commonly seen in the stools of milk-fed children.

Calcium oxalate crystals are found in ingested vegetables that contain them, such as rhubarb, tomatoes, spinach, etc. They are not seen on a milk or meat diet. With a **large** amount of vegetables a moderate number have no significance, but with a **small** quantity of vegetables an enormous quantity of calcium oxalate crystals indicates an intestinal catarrh, showing that cellulose disintegration has been retarded, with an escape of the crystals from the plant cells. In hyperchlorhydria an abundance of vegetables will not result in the appearance of many of these crystals, for these are dissolved by the excess acid in the stomach; consequently there may be an increase of these crystals in the urine. They appear in various forms in feces, as envelope shape, as typical rosettes, and as rhomboid and acicular varieties (Fig. 637). They are insoluble in acetic acid and alkalies but are soluble in mineral acids.

Crystals from medicaments are sometimes found. Dark bismuth crystals are found after ingestion of bismuth subnitrate. The use of salicylate of bismuth gives peculiar crystals of this drug; iron, charcoal, and manganese pass as black amorphous granules.

Cholesterol may at times appear as flat superimposed plates, often with re-entrant angles, but as they rarely show typical forms they must be identified chemically. They are easily soluble in hot alcohol, ether, and chloroform. They are insoluble in water, alkalies, and acids. On adding iodine followed by sulfuric acid there is a play of colors, yellow, yellow red, carmine red, violet, green, blue, with melting of the crystals from the edges. Cholesterol appears particularly in children where there is a large amount of mucus passed. It is commonly seen in meconium.

Charcot-Leyden crystals appear as they do in sputum, as colorless octahedra with sharp margins and generally broken angles. They are commonly seen embedded in mucus. Leichterstern spoke of them as especially characteristic of helminthiasis. His pupil, Buckler, further emphasized this relationship together with the presence of eosinophilia in the blood, but other authorities disputed this as constant or as sufficiently noteworthy to be of value in diagnosis. Charcot-Leyden crystals are found in abundance, it is true, in cases of helminthiasis, but they are absent in other cases. They have also been found in abundance in other conditions, e.g., in the mucus of enteritis membranacea, by Akerlund and Schmidt. They are no more characteristic of any disease when found in feces than when found in sputum, even though they are present in abundance in cases of bronchial asthma.

Hemin crystals are not seen in feces except after ingestion of blood sausage, but **hematoidin** crystals are common. They occur as reddish yellow rhombic plates, columns, needles, or bundles of needles, at times as amorphous masses. Uffelman reported them in infant feces, and Lynch reported them in meconium. Von Jaksch found them in intestinal stagnation hemorrhages or free hemorrhages in adults. They are soluble in ammonia, the solution turning yellow. They are not soluble in potassium or sodium hydroxide solutions. Nitric acid turns them blue.

Bilirubin appears like hematoidin as rhombic needle-shaped crystals or golden yellow kernels. It is found more frequently in infantile stools than in adults.

Uric acid and uric acid salts are not found except as a result of contamination with urine.

Intestinal parasites: Parasites are living organisms which take up residence in another living organism. They may be of plant or animal origin, i.e., phytoparasites or zooparasites. We are here more especially interested in those parasites which take up their residence in the intestinal canal or structures adjacent thereto and that may be detected by systematic stool examinations. Parasites might be occasional or permanent.

Parasitism is relatively common in this country. It is much more common in tropical countries because of certain customs, failure to cook food thoroughly, and ingestion of many foods in a raw state. With the advent of rapid transport by air, many cases are directly imported into this country and are direct centers for infection of other persons. The spread of World War II into tropical lands resulted in many new cases among our military forces who were sent to these places for duty.

A full description of intestinal parasites may be found in the section on medical parasitology.

MICROCHEMICAL REACTIONS

Microchemical reactions are elicited by simply allowing 1-2 drops of a reagent to run in by capillary attraction between a cover glass and a slide after having made a smear of the feces. If the fecal mass is not fluid, it is impossible to do this, in which case drop the reagent directly on the preparation before placing the cover glass in position.

The following reagents are necessary:

1. Saline solution, 0.6%.
2. Glycerin.
3. Alcohol, ether, and chloroform.
4. Acetic acid, 30%.
5. Hydrochloric acid, 3-5%.
6. Concentrated sulfuric acid.
7. Potassium hydroxide, 15%.
8. Millon reagent (p. 1809).
9. Modified Lugol solution
    - Iodine . . . . 1 gm.
    - Potassium iodide . . . . . 2 gm.
    - Distilled water . . . . 50 ml.
10. Osmic acid, 1%.
11. Sudan III (Herxheimer). Equal parts of 70% alcohol and acetone saturated with Sudan III.
12. Glacial acetic acid . . . . . 90 ml.
    - Alcohol, 95% . . . . 10 ml.
    - Pinch of Sudan III.
13. Weak watery solutions of eosin, methylene blue, and safranin.
14. Ziehl-Neelsen carbolfuchsin.
15. Concentrated aqueous solution of Nile blue.
16. Friediger polychrome solution:
    - Saturated alcoholic solution of dimethylaminoazobenzol . 2 ml.
    - Absolute alcohol . . . . 2 ml.
    - Eosin, 0.5% alcoholic . . . . 20 drops
    - Mucicarmine, saturated aqueous solution . . . . . 20 drops

Preparation of specimens

Although it is not necessary to use all these reagents in all cases, one may adopt as a routine the following microchemical procedure in examination of stools.

Make 3 preparations, 1 of the plain diluted feces, 1 mixed with acetic acid, and 1 treated with iodine solution. The first gives a good general picture. In the second the striation of any muscle fibers is rendered more distinct; connective tissue is swollen in contrast to elastic tissue which is unchanged; mucus is coagulated and rendered more distinct; cells are cleared and their nuclei appear sharper; albuminous granules are dissolved; some crystals, such as triple phosphate, disappear, whereas others, such as oxalates, are not affected. In the third preparation undigested starch granules are colored deep blue; partially digested ones are brown or red.

Findings and confirmatory tests

Most of the material found in feces may be identified microscopically. However, there are certain very minute ingredients representing the breakdown of food remnants, called detritus, which cannot be identified.

Meat fibers: It is natural to find a certain amount of fibrous residue in the stool. Outside their mere presence, the quantity on certain diets is of great importance in drawing a conclusion as to the status of intestinal digestion. It is difficult to differentiate meat fibers from flesh, fowl, or fish; the coincident finding of scales of fish would suggest the fibers are of fish origin, whereas the presence of small pieces of feather would suggest fowl origin. The manner of cooking meat plays a part in the finding of meat fibers: well-roasted beef is more likely to remain in the stool than is raw meat. Muscle remnants appear as isolated polygonal pieces devoid of sarcolemma. At times they lie together as if bound by the skeleton sarcolemma. They may be stained yellow from bile and thus attract one's attention immediately on looking through the microscope. Long and cross-cut striations are easily identified in the fibers. The size of these fibers varies from minute forms to pieces that entirely fill the field, under which latter circumstances they can be seen with the naked eye. The longer pieces have parallel sides with cross striations.

Better digested pieces do not show these sharp contours. The cross striations may be seen with the medium-power dry lens. Schmidt states that cross striations in the fibers from fish disappear more rapidly than do those from mammalian flesh. The color of fibers is dependent upon admixture of bile, the usual color being yellow or yellowish green. Nuclei can never be detected unless there is an absolute disappearance of pancreatic juice, in which case there is macroscopic evidence of unchanged meat in the stool.

Microchemical tests: It is difficult to identify meat fibers by microchemical methods because of the admixture of bile elements and the presence of certain unknown factors. One may attempt to remove bile elements by the use of alcohol; bilirubin-stained meat may be freed of this interfering factor with chloroform. Acetic acid swells the fibers and brings out the cross striations fairly well. The addition of potassium hydroxide causes the fibers to dissolve. If a little copper sulfate is added to the potassium hydroxide and the picture watched under the microscope, a slight violet color (the biuret reaction) may be observed. The addition of concentrated nitric acid with warming of the specimen gives a yellow color of xanthoprotein. Millon reagent causes a disappearance of structure, with a red coloration. Picric acid and iodine-potassium iodide solution gives a yellow color. Eosin solution causes the appearance of a red color in meat fibers more quickly than in other parts of the stool.

There are a number of very elaborate methods for exactly determining the amount of meat fibers present in any given stool, together with an estimation of the meat ingested after selected test meals. These methods are of doubtful usefulness. Certain conclusions may be drawn, however, from the presence of a large number of meat fibers in the stool. The process of digestion of meat occurs mainly in the small intestine, due to action of the pancreatic juices. No further digestion of meat occurs beyond the ileocecal valve. Hence the appearance of unchanged or slightly changed fibers in the stool is an indication not of large but of small intestine dysfunction. The disturbance in digestion in the small intestine may be motor or secretory. Unduly rapid peristalsis may be based upon a secretory disturbance in the pancreas and the intestinal glandular apparatus. In some cases, whether catarrhal, ulcerative, or purely neurotic in origin, all factors may be deranged.

Connective tissue: It is very easy to identify connective tissue in the stools with the naked eye, but it is still easier with the microscope. The connective tissue fibers are not found so constantly in feces as are muscle fibers. The finding of connective tissue fibers depends upon the manner of cooking.

Protein: There are casein clots found under pathologic conditions in stools to which Nothnagel gave the name of "yellow mucus" bodies. They consist of casein clumps which resemble short pieces of muscle fibers; but they are not muscular in origin, for they are found 3-4 wk. after the patient ceases to take meat, as in typhoid convalescent states when no meat has been taken for weeks. They appear as minute yellow round bodies; under the cover glass they give an impression of sandy particles. Microscopically they appear as yellow particles or cells lying close together. There is no differentiation of structure with higher power. They contain no formed elements whatsoever.

They are dissolved by the addition of a mixture of warm water and potassium hydroxide. Acetic acid causes partial precipitation of the clump which is insoluble in an excess of this acid. The addition of potassium ferrocyanide solution causes a white precipitate; Millon reagent stains them red. They are not found in normal stools. Their presence, according to Nothnagel and others, indicates a disturbance in small intestine activity, usually an inflammatory condition.

Pieces of ingested egg may at times be seen in the stool as small particles of the skin or coagulated material (fried egg remnants). Meconium "corpuscles," so called, are found under the high-power magnification. They appear as weakly stained, greenish yellow, homogeneous, round or oval bodies lying near epithelia and cholesterol crystals. Schmidt believed they are shrunken epithelia of vernix caseosa.

Fat: Fat substances are frequently found in the stool as neutral fat, free fatty acid, or soaps.

(1) **Neutral fat:** Neutral fat appears in droplets or in scales of irregular form. The fat scales are usually unstained. The fat droplets appear round. Fat droplets are often stained yellow. In stools of infants fat appears just as it does in a microscopic picture of milk.

Microchemical reactions: All neutral fats when heated melt and run together; when cooled, they resume their individual shapes. Fats are insoluble in water, weakly soluble in cold alcohol, soluble in hot alcohol, ether, and chloroform. They are unchanged by the addition of potassium hydroxide. Osmic acid stains fat black but not necessarily all neutral fats: olein and oleic acid are stained black; palmitin, stearin, and their corresponding acids are not stained except with the addition of alcohol. Fat in the animal body contains all these components. Therefore, osmic acid stains fat black but with varying shades dependent upon the proportions of the ingredients just set forth. Substances other than fat may be stained black by osmic acid. The addition of a few drops of Sudan III stains fat red. The Friediger reagent stains fat yellow. Concentrated Nile blue reagent produces a rose red color.

(2) **Fatty acids:** Fatty acids appear as drops or scales and are difficult to distinguish from neutral fat, at times showing characteristic crystals. The crystals appear as fine needles with pointed ends, similar forms being seen in sputum. They also appear as lancet-shaped plates, occasionally seen in infantile stools or as needles that resemble soaps.

Microchemical reaction: They differ from neutral fats in that they are soluble in potassium hydroxide and cold alcohol. They are not bile stained in the stool nor do they take the stains. They are, however, colored by osmic acid and Sudan III like the neutral fats. They stain intensively with dilute carbolfuchsin whereas neutral fats remain unstained. This is the best differential stain.

(3) **Soaps:** Soaps appear as scales or crystals. They show less luster than neutral fats or fatty acids. They may be unstained or stained slightly yellow by urobilin or bilirubin. They usually appear as unstained needles. One variety is round with fine radial striations.

Microchemical reactions: The basis of these soaps is alkali. They are soluble in hot water and alcohol. They are mainly calcium salt combination. Upon heating the preparation they do not melt as do neutral fats and fatty acids. They are not stained by osmic acid or Sudan III.

(4) **Significance of fat in stools:** Infantile stools show a great deal of fat, as neutral fats, fatty acids, and soaps. Adult stools show fat but usually only soaps as scales. They are not found in healthy persons after a test meal. Naked eye appearance of fat means an undue quantity. This fat can be seen as grayish, shining particles of a smeary consistency. Fatty acid crystals are never found in normal stools, but, according to Muller, they are always seen in the stools of starving people. Fat as a pathologic entity is seen in stools in connection with disturbances of the biliary function, affections of the neighboring mucosa, or the mesenteric lymph nodes, where there is increased peristalsis without anatomic changes in the mucosa. Gastric and large intestine disease does not seem to have much influence on the undue appearance of fat in stools. Pancreatic disease does not necessarily show fat in the stool.

Fatty stools are sometimes seen in breast-fed infants, a mass of fat droplets with increased fatty acids and soap needles. Biedert called this fatty diarrhea. The addition of acetic acid and heat causes the entire microscopic picture to appear as fat droplets. The appearance of visible neutral fat in the stools of adults, of course, is pathologic except where castor oil has been taken.

Starch: Unchanged or slightly changed starch granules with concentric or eccentric markings seldom appear in the stools of adults. They are never stained by bile pigments; they are of varying size; and they are usually changed by the process of digestion so that, except in stools of infants, one does not see starch that has not been subjected to chemical or physical agents. The microscope reveals bodies that are of different size from the original starch granule as it was ingested, granules that fail to show the classical markings. Even the ingestion of raw potato gives a starch residue that is not classical, with a corrosion or unevenness of the periphery.

Microchemical reactions: Cold water has no effect on starch granules, but warm water produces a slow swelling. Acetic acid has no effect. Iodine produces the well-known blue color on unchanged starch granules. Lugol solution is recommended for this test (described on p. 467). Rub the solution well into the fecal mass. The cellulose fiber present often hinders penetration of the iodine solution and prevents a reaction. Semidigested starch gives a mahogany red color, indicating it has changed to erythrodextrin. In the final stage of digestion starch gives no color at all with iodine. Certain spores of fungi give a blue color with iodine. As stated above, unlike muscle fibers, starch is never stained by bile pigments.

As starch is present in some of the undigested vegetable remnants, care must be taken in the preparation of specimens to prevent these fibers from giving up their starch granules with consequent false interpretations. The presence of starch granules intact in the stools of adults points very definitely to derangement of the activity of the small intestine; hence one must be sure that the granules seen are eliminated as such and are not pressed out of vegetable residue. Starch in vegetable residue is found after the ingestion of peas and beans, especially in dried forms. Pancreatic insufficiency alone does not cause starch granules to appear in the stool. The activity of the intestinal bacteria is responsible for this fact; they evidently digest the starch when the pancreatic juices fail to do so. When, however, there is increased peristalsis with this insufficiency, starch is found in the stool mass. The appearance of starch granules, unchanged or only slightly swollen, therefore indicates a much more severe grade of insufficiency of small intestinal digestion than does the appearance of muscle fibers.

After the ingestion of oily seeds such as almonds, in place of starch or with it, are seen granular structures of a rounded or angular form known as **aleurone grains.** These are albuminoid in nature and give no blue color with iodine. They are freely soluble in water and pass out of the cell in which they occur in the intestine. As they are insoluble in serum they are seen frequently in stools of serous diarrhea and dysentery.

Cellulose and vegetable tissue: Recognition of plant cells and cellulose is important in examination of stools because they may be mistaken for animal remnants and parasites. There is some obscurity as to the exact changes that take place in the process of digestion of vegetable matter. Plant cells are covered or enclosed with cellulose which is commonly supposed to be quite resistant to the action of digestive juices. This is not altogether true, for Moeller has shown that thin cellulose walls are readily broken down in the digestive tract; the pectinlike material that forms the middle lamellae of plant cells is attacked in the intestine and the cells fall apart and are thus exposed to further digestive activity. Cellulose found in stools is not chemically the same as when ingested, for, instead of the faint blue which they give with iodine and sulfuric acid before digestion, they show a faint purple coloration. They are also much more freely soluble in copper oxyammonia after digestion than they are before digestion. The nature of the change is probably a hydrolysis brought about by the action of bacteria, the alkaline contents of the intestine, and the intestinal enzymes. The enzymes from certain molds have the power of breaking down the toughest kind of cellulose, e.g., that of wood. The digestion of cellulose is aided by constipation because the bacteria have a longer period of contact under these circumstances, whereas in diarrheal states with rapid peristalsis the cellulose is passed almost unchanged. Modifications of cellulose, such as the cutinized peripheral walls of stems and leaves and corky cells, are much more difficult to digest than unaltered material. For this reason they are seen more often in stools. Flat epithelial cells with the intervening stomas of leaves and also plant hairs are characteristic. The plant detritus most often seen is the lignified cells forming the spiral pitted and scariform vessels and the vast fibers of the fibrovascular bundles. Young green vegetables give only spiral vessels, pitted and reticulated ducts appearing chiefly in old and overripe plants. Woody tissue, fruit envelopes of vegetables and fruits, pass through the intestinal canal practically unchanged and appear in stools as such.

CHEMICAL ANALYSIS

Fresh stools are usually used in chemical researches, but one may use dried stools satisfactorily. Chemical analysis is not commonly performed because of the time necessary for its completion and because not every case requires such an analysis. However, an occasional chemical analysis gives information to the internist which cannot well be otherwise obtained.

Reaction

Stools are ordinarily neutral in reaction, although acid and slightly alkaline stools apparently may occur under normal conditions. This acid reaction is due to the presence of lactic or butyric acid and usually is indicative of fermentation in the intestinal canal.

Litmus is the usual indicator. Moisten red and blue litmus paper with distilled water, place on a glass slide, and rub on a fragment of feces, observing the change of color from the other side. Or place a small amount of stool in a test tube, add sufficient water to make a suspension, and shake well. Into another small test tube introduce a few ml. of a watery solution of tincture of litmus and add a few drops of the fecal suspension. Observe the color change. If the cloudiness of the fecal suspension interferes with the reading, centrifuge the suspension first and use only the supernatant fluid.

A method published by Bruce[4] follows: Make a 1% solution of alizarin. Place 2 small drops of the indicator on a glass slide about 1½ in. apart. Dip a stirring rod into the fluid part of the specimen or, if the feces are formed, merely puncture the mass. Mix thoroughly in one of the drops, using the other drop as a control. An alkaline reaction is indicated by a reddish violet to violet color; neutral, no change; and acid, a light yellow. The density of the colors depends upon the amount of acid or alkali present. By placing the slide upon white porcelain, the depth of color may be more easily determined. After a few observations, it is easy to detect any abnormality in the reaction.

Changes in reaction: Meat diet gives an alkaline reaction; the more meat ingested, the stronger the alkalinity. Blood, mucus, and pus change the reaction. As putrefaction increases alkalinity and fermentative changes increase acidity, the reaction must be taken soon after passage of the stool. Excess fat increases acidity from the presence of fatty acids. Catarrh of the upper intestine increases the acidity if peristalsis is rapid. Chronic processes of this kind, however, produce an alkaline state, e.g., in chronic enteritis, whether tuberculous or amebic. If there is a block in the pancreatic juice outflow, there are fatty stools with marked acidity. The presence of much protein may be masked by the ammonia formed, giving an alkaline stool.

Reaction of infants' stools is dependent upon the diet. Breast-fed children have faintly acid stools. Bottle-fed children have neutral or slightly alkaline stools. The reaction is dependent upon the proportion of fat and protein present; i.e., when fat predominates, the reaction is acid; when protein predominates, it is alkaline. Therefore persistent alkaline stools from a breast-fed child may indicate that the mother's milk is deficient in fats.

"Dry" constituents of stools

Normally the stool consists of liquid parts, 65-85%, and dry solids, 15-35%. This is largely dependent upon diet, a meat diet increasing the solids and a vegetable diet increasing the liquid parts. Under pathologic conditions the relative proportions of dry to liquid constituents change; i.e., the dry part decreases when there is a block and the liquid constituents increase, the most extreme condition occurring in cholera, in which, according to the statistics of C. Schmidt, only 1-2% of dry substances is found. Increase in liquid constituents of stools is due to decreased resorption and increased secretions within the intestines. It might be termed a combination process, with the increase in transudation in the principal role. Schmidt believed that the extreme condition just noted, Asiatic cholera, is an example of blood transudation. An analogous condition obtains when senna or other purgatives are taken. The exact mechanics of these drugs is still in dispute, however.

Bile and biliary constituents

The pigment of feces which gives it its color is urobilin or stercobilin, formed from the bilirubin of the bile by reduction processes in the intestine. This conversion of bilirubin into urobilin does not take place in man until bacteria appear in the intestine in early infantile life.

Schmidt sublimate test for urobilin

Place a portion of fresh feces the size of a walnut in a mortar and rub up with a small quantity of concentrated solution of bichloride of mercury (25 gm. bichloride of mercury, 2.5 gm. sodium chloride, 500 ml. distilled water). Allow to stand for 24 hr. in a covered Petri dish. If urobilin is present, a deep red color develops in a few minutes. If only a trace is present, it may take 24 hr. to develop this color. This reaction may be obtained only if stools are quite fresh. Stools containing much fat must be extracted with ether before applying this test.

Schlesinger test

This is substantially the same as that for urobilirubin in urine.

Shake a sample of feces with ether to remove the fat. Extract the residue with acid alcohol (5 ml. hydrochloric acid and 95 ml. alcohol); neutralize the yellow fluid that results with ammonia or sodium hydroxide solution. Mix with an equal quantity of 10% zinc acetate in alcohol. Remove the precipitate, if any forms, by filtration through a dry filter paper. Examine the clear filtrate against a black background for the green fluorescence that indicates urobilin. Examine the red fluorescent solution with the spectroscope; it will show an absorption band between F and B which moves nearer to F when the fluid is acidified. No bands can be seen if feces contain blood.

These tests are used to determine whether stools are really acholic. A negative result with the zinc acetate test shows that no bile is reaching the intestine, and when associated with deep painless jaundice and progressive loss of weight and strength, is strongly suggestive of malignant disease causing obstruction of the biliary system.

Bilirubin alone or mixed with biliverdin is encountered normally only in stools in the first week or two of life.

Gmelin test for bilirubin

Add a few drops of nitric acid containing nitrous acid to a smear of feces on a piece of white porcelain; a play of colors, green, blue, violet, red, and yellow develops. If the stools are already green from the presence of chlorophyl or bacterial pigments, extract with water and test the aqueous extract.

Bilirubin is seen under pathologic conditions in diarrheal states, especially the jejunal diarrhea described by Nothnagel.

Bile acids, glycocholic and taurocholic, are completely reabsorbed from the intestine so that only a very small quantity appears in the lower part of the bowel. There, under the influence of putrefactive bacteria, they are split up into glycocoll, taurine, and cholalic acid. The cholalic acid combines to form cholate of soda which, under normal conditions, is the only representative of bile acids in the stool. If the intestinal contents pass so rapidly that the usual fission processes do not have time to take place within the large intestine, unaltered bile acids may be present.

Test for biliary acids

Extract a small quantity of feces with alcohol and filter. Distill the filtrate to drive off the alcohol, take up the residue with water rendered faintly alkaline with sodium hydroxide. Treat the watery solution with a trace of cane sugar or a few drops of a dilute solution of furfural, and add concentrated sulfuric acid. In the presence of bile acids a crimson color develops. The sulfuric acid must be added a drop at a time, shaking after each addition. Care must be taken that the temperature does not rise above 70° C., the test tube being cooled in water from time to time.

Watson test for urobilinogen

This is fully discussed on p. 1827.

Spectroscopic and chemical tests for occult blood

We have already discussed the presence of blood in the gross examination of stools, as well as its presence microscopically. Blood in extremely small amounts can be detected as occult blood by chemical or spectroscopic methods. These tests all depend upon the detection of one of the constituents of blood, hemoglobin.

The finding of occult blood in feces is of the greatest importance in the diagnosis of ulceration of the digestive canal. Hemorrhage from the nose, throat, esophagus, and hemorrhoids must be excluded. The finding of occult blood may establish whether an ulcer in the digestive tract is or is not healing.

Significance of occult blood: One must be guarded in the interpretation of a positive benzidine test for blood because it is difficult to differentiate exogenous from endogenous blood. The smallest amount of meat in the diet is likely to give a positive benzidine blood reaction. The patient must be kept on a meat-free diet for at least 3 days before making this test if the results are to be meaningful. The physician who interprets this test must make certain that there has been no bleeding from the hemorrhoidal vein. A positive reaction means bleeding from any portion of the tract. Blood may be found in either benign or malignant disease. During the suckling period blood is encountered in melena vera, hemorrhagic enteritis, from fissures, polyps, rectal papilloma, trauma, the hemorrhagic diatheses, invagination, and typhoid perforation. Duodenal ulcers occasionally occur in children and of course may lead to bleeding.

Spectroscopic test

Snapper's method is the best.

1. Extract the feces in a mortar with acetone to remove the coloring matter. This leaves a dry mass.
2. Transfer the dry residue to a clean mortar and rub up with a mixture of 1 part glacial acetic acid and 3 parts ether, preferably ethyl acetate.
3. Filter. Add ¼ vol. pyridine, and then a drop of ammonium sulfide solution.
4. Examine spectroscopically. If blood is present, a hemochromogen band will be found on the boundary between yellow and green.

Chemical tests

The chemical tests are simpler. These are the guaiac, aloin, benzidine, and others.

Boas-Weber test

1. Mix 1 gm. feces with 10 ml. 70% chloral hydrate in 95% alcohol.
2. Add 1 ml. glacial acetic acid and filter.
3. To 1 ml. filtrate add 1 ml. 2% guaiac resin in equal parts of chloral hydrate solution and hydrogen peroxide (3%).

A **blue** color indicates blood.

Kuttner-Guttmann modification of Weber test

1. Stir 8 gm. feces with acetone. Let stand and pour off the supernatant fluid.
2. Treat the residue with 5 ml. glacial acetic acid in 10 ml. 7% sodium chloride solution.
3. Extract with ether by adding the ether to the mixture, allowing it to settle, and then decanting the ether.
4. Add a few drops of glacial acetic acid to the ether.
   (a) Mix 1 ml. of this with 2% guaiac resin,
   (b) Mix 1 ml. of this with 0.2% guaiac resin,
   (c) Mix 1 ml. of this with 0.02% guaiac resin.

All 3 resins are dissolved in equal parts of alcohol and oil of turpentine.

The solution becomes **purple** if blood is present.

The different concentrations are necessary because one cannot tell how much blood is present before making the tests.

Objection to the test: Less than 10% of blood in feces will not show a reaction.

Boas phenolphthalein test

Reagent:

Phenolphthalein	1 gm.
Potassium hydroxide	25 gm.
Distilled water	100 ml.
Zinc powder	10 gm.
Hydrogen peroxide, 3%	5 drops
Alcohol	2 ml.

Procedure:

1. Stir 1 gm. feces in a mortar with 5-6 drops glacial acetic acid and 10 ml. alcohol.
2. Filter.
3. Pour the filtrate on a mixture of 15 drops Boas phenolphthalein reagent.

A **red** color denotes blood.

Boas thymolphthalein test

Reagent:

Thymolphthalein	10 gm.
Potassium hydroxide	1 gm.
Distilled water	25 gm.
Zinc powder	100 ml.

Procedure:

1. Stir 1 gm. feces with 10 ml. alcohol and 10 drops glacial acetic acid.
2. Filter.
3. To 30 drops filtrate add 30 drops Boas thymolphthalein reagent and 15 drops 3% hydrogen peroxide.

A **blue** color denotes blood.

Benzidine test—Levin-Watt

To make the benzidine reagent dissolve 6 gm. benzidine base, c.p., powder in 100 ml. 95% ethyl alcohol and preferably allow to age 2 or 3 days before using.

1. Collect fecal material in clean containers. Emulsify a small portion of the feces in distilled water; then pass through filter paper (Whatman No. 5 or more retentive paper) into a clean test tube to obtain a clear filtrate. If clouded due to breach in filter paper, refilter.
2. To 3 ml. filtrate add 8 drops 50% aqueous acetic acid or glacial acetic acid, with mixing.
3. Add 8 drops hydrogen peroxide (c.p., 3%) to the resulting mixture and shake.
4. Overlay the final mixture with an alcoholic benzidine solution, drop by drop, to obtain a contact ring. Tilt to bring about slight mixing at the ring. A positive reaction is indicated by the appearance of a greenish ring at the area of contact of the benzidine solution and the filtrate mixture, spreading into the benzidine solution either immediately or up to 2 min. time, the intensity or gradient of color being in relation to the concentration of blood.

When testing for blood in vomitus and gastric contents, add water in half the volume of material used, filter, and carry through the test as previously. In urine, when only a few red blood cells are found microscopically, centrifuge or sediment the specimen. Transfer the bottom 0.1 ml. containing the sediment, to a clean test tube, add 0.4 ml. distilled water, and continue as previously described.

This method eliminates most of the substances producing false positive reactions as follows: (1) filtration of the stool suspension eliminates blood-containing particles of meats, oxidase-containing particles of foods, particles of animal charcoal, and insoluble metal salts (of iron, copper, etc.) and (2) the acetic acid destroys soluble oxidases. In the contact layer or ring test the soluble hemoglobin compounds give true positive blood reactions in dilutions up to 1:100,000; meat-free days are unnecessary preceding this test for occult blood.

Benzidine dihydrochloride test

This is described on p. 1835.

Hematest

See p. 1841.

Protein substances

Coagulated albumin is not found in stools under normal conditions. Soluble albumin and proteoses are present only under pathologic conditions. Inasmuch as nucleoprotein is always present, being derived from the nuclei of the mucosa and food remnants, always remove it before testing for albumin.

Biuret test for albumin

1. Mix the feces with water to a consistency of thin syrup. Test with litmus paper and add to each 10 ml. a quantity of 10% acetic acid and alcohol, varying with the reaction: if the stool is strongly acid, add 0.15 ml.; if faintly acid or neutral, 1 ml.; if slightly alkaline, 1.5 ml.; if strongly alkaline, 2-2.5 ml. Mix well.
2. Rub 5 ml. chloroform into the mixture. Place in a test tube and let stand until the chloroform and the larger particles sink to the bottom.
3. Decant the upper yellow and faintly tinted fluid into another test tube and add a disk of copper sulfate agar. After 1 hr. take out the disk, wash with water, and examine.

If the feces contain a large amount of albumin, the disk retains its bright blue color, but if no albumin or only a trace is present, it will be brownish blue. On pouring over it a little diluted solution of potassium hydroxide, the color will change to blue violet if albumin is present.

Copper sulfate agar is made by boiling 2 gm. agar in 100 ml. distilled water until dissolved, and then adding 10 ml. 10% solution of copper sulfate. Pour the hot mixture into a glass tube 0.8-1 cm. in diameter, 20-30 cm. long, closed at one end by a plunger. Close the other end with a rubber cap. To make a test remove cap, push in the plunger, and cut off a disk about 1 cm. long.

Caution: Urobilin also gives the reaction. Ury noted that other pigments and the remnants of paranuclein and casein give misleading results.

A simple test will be found on p. 1818.

Dissolved albumin is found pathologically only with inflammatory conditions. Proteoses are found only under rare conditions and always in association with albumin. They are found more frequently in stools of babies, but here they undoubtedly arise from the food ingested and not from the intestinal wall.

Casein: No satisfactory test for casein has been devised. It is better to rely upon macroscopic test than upon chemical analyses.

Mucin: Mucin is a compound protein radical and a nitrogen-containing carbohydrate, glucosamin. Boiling with acids makes mucin yield a copper-reducing substance like a sugar. Mucin dissolves in weak alkaline solutions and is precipitated by acetic acid. It may be identified by acetic acid, with microscopic study. The mucin becomes cloudy and develops lines. This is a better method than the chemical methods.

Protein derivatives

Amino acids: The digestion and putrefaction of protein substances in the intestine yields a number of amino acids. Among these are leucine (amino-isobutyl acetic acid), tyrosine (oxyphenyl-amino-propionic acid), and tryptophan (indole-amino-propionic acid). These undergo further changes, breaking down into phenol, paracresol, indole, and skatole, which appear partly in urine with sulfuric and glycuronic acids and partly in feces in an unchanged state. Lack of pancreatic action causes leucine and tyrosine to appear in feces.

Gelatin film test for stool trypsin—Schwachman et al.

The gelatin film test estimates roughly the proteolytic activity of stools by determining their ability to liquefy gelatin. Fecal suspensions are placed upon gelatin film (unexposed and unfixed), and the extent of removal of the gelatin film is noted.

In determining the significance of the test, Schwachman et al.[6] studied 2 groups of patients: (1) 500 normal and sick individuals and (2) 50 patients with pancreatic fibrosis. In group 1, less than 5% of the infant group lacked this proteolytic power. As one advanced into the older age groups, this percentage increased. The administration of a laxative for some older children without tryptic activity resulted in stools possessing tryptic activity.

A total of 220 separate stool specimens was examined from patients in group 2. In 209 specimens there was no tryptic activity. The remaining 11 specimens from 7 patients showed definite tryptic activity. In this group 3 patients had minimal tryptic activity in the duodenal fluid.

When oral pancreatin was given to patients with pancreatic fibrosis, the stools became positive for trypsin. When laxatives were given to a few patients with pancreatic fibrosis, the stool trypsin remained negative.

Conclusions and interpretations based on a single examination are hazardous. At least 3 specimens should be studied to eliminate or to make probable the diagnosis of pancreatic insufficiency, and whenever doubt arises, duodenal intubation is indicated.

There are 2 procedures, a test tube method and a gelatin film method. The test tube method is more reliable and reproducible because the film substrate in the gelatin film method might change its properties when exposed to different temperatures and if stored for varying periods of time. However, the film method offers the advantage of simplicity and convenience and can be used as an office test. Photofilm is less reliable than gelatin film.

(1) Test tube method

Reagents:

1. Sodium bicarbonate solution, 5%.
   - (a) Dissolve 5 gm. sodium bicarbonate ($NaHCO_3$) in distilled water and dilute to 100 ml. with distilled water.
2. Gelatin solution, 7.5%.
   - (a) Dissolve 7.5 gm. gelatin in 100 ml. distilled water heated to about 37° C.

Procedure:

1. Place 4 ml. distilled water in a test tube graduated at 5 ml.
2. Add feces to the 5 ml. mark.
3. In another test tube graduated at 10 ml., place 9 ml. distilled water.
4. Add feces to the 10 ml. mark.

This gives two samples of fecal material diluted, respectively, 1:5 and 1:10 with distilled water. Further dilutions can be made as desired.

5. Mix the contents of the 2 tubes thoroughly.
6. Place 1 ml. of 1:5 dilution in one tube and 1 ml. of 1:10 dilution of feces in another tube.
7. Add 1 ml. 5% sodium bicarbonate and 2 ml. 7.5% gelatin solution, previously warmed to 37° C., to each of the 2 tubes.
8. Mix well and place the tubes in a 37° C. water bath for 1 hr.
9. Then transfer both to an ice bath for 30 min.
10. At the same time prepare a control tube containing all the ingredients except the feces and carry it through the same procedure.
11. Examine all tubes at the end of the 30 min. period of ice bath incubation.

If the contents remain liquid, record the tryptic activity as 4+. A rigid gel indicates no activity. Compare the tests with the control.

(2) Gelatin film method

1. Prepare stool dilutions in water as described in method 1.
2. Place 1 large drop (approximately 0.1 ml.) of the well-mixed specimen on an unexposed,

unfixed gelatin film such as is used in routine hospital practice. The film strip may be clipped to a cardboard to prevent curling.

3. Incubate the film at 37° C. for 1 hr. Although 37° C. is the recommended temperature, room temperature is satisfactory if the incubation period is prolonged to 1½-2 hr.
4. Wash the film in a stream of cold water with gentle rubbing.

The result is now apparent. A clearing at the site of the drop indicates enzyme activity. A complete clearing is designated as 4+, and a slight clearing only at the periphery of the drop as 1+.

If the drop is small or if the concentration of the specimen is too great, the material will dry and cake.

Proper bacteriologic precautions should be taken when dealing with cases suspected of enteric infections.

Both a 1:5 and a 1:10 dilution of stool are used routinely.

When performing the test for the first time or when using new gelatin film, adequate controls should be run. Determination of the end point using normal infant stools or a standard trypsin solution is suggested.

Discrepancies between the film and tube methods occur in less than 1% of the tests. The tube method is more sensitive. For example, a specimen showing a 2+ reaction in the 1:10 dilution and a 4+ reaction in the 1:5 dilution on the film will be strongly positive by the test tube procedure using a 1:10 dilution.

Fischer-Bergell test for amino acids

Rub up feces with water and then with acetic acid; boil and filter. Concentrate on the water bath, cool, and shake 8 hr. with ether in a shaking machine to remove the fat. Decant the ethereal portion and mix the residue with potassium hydroxide; add 25% sulfuric acid and 20% phosphotungstic acid. Filter. Add barium hydroxide to the filtrate, concentrate it on the water bath, and for every 500 ml. of the original fluid add 2 ml. 10% solution of naphthalene-sulfo-chloride. Make slightly alkaline and shake for 12 hr. in the shaking machine. Every 3 hr. add 1 ml. reagent and a little potassium hydroxide. Flood the product at the end of the shaking with ether, acidify the supernatant fluid, and allow to stand 24 hr. At the end of that time a crystalline deposit of naphthalene-sulfo-tyrosine is formed. It is readily crystallizable from alcohol, melting at 129° C. The watery portion gives a strong Millon reaction.

Fat

In a consideration of fat in stools we refer actually to the higher insoluble fatty acids. To the casual reader the fat in stools is closely related to the fat ingested and the ability or lack of ability of the normal physiologic processes to handle it. This is true in the main; yet, according to Williams' researches, there may be a general metabolic disorder that throws on the intestine the onus of eliminating some of the fatty acids, calcium salts, etc.; i.e., some of this fat is endogenous and not exogenous The most important conclusion to be drawn from the presence of a large amount of fat in stools is a block in the outflow of bile into the intestinal canal.

According to Biebert, the presence of more than 40% of fat in stools indicates a condition of fat diarrhea. In normal dried stools of infants the fat should not exceed 20%. Increase in fat content to a marked extent is always a biliary or pancreatic affair. Pancreatic juice has for a principal function the digestion of fats, which is markedly increased by the presence of bile and still more by the presence of both bile and hydrochloric acid. Bile of itself can do nothing with fat, but a mixture of bile and pancreatic juice can digest 3 times as much fat as pancreatic juice alone. Wohlgemuth states that the lipase of the pancreatic fluid exists in an inactive form and that it is activated by the bile. The bile also helps to dissolve the free fatty acids formed by the action of the pancreatic lipase on neutral fats, for these acids are insoluble in water but very soluble in bile: bile therefore assists in the absorption of fats.

No data of any value can be obtained from a chemical analysis for fat unless dried feces are used.

Place a required quantity of feces in a shallow porcelain dish of known weight and carefully weigh. Transfer the dish and contents to a water bath kept at 50°-60° C. After most of the water has been driven off, break up the residue with a glass rod. Return the dish to the water bath and heat for another 30 min. Remove the feces from the dish, transfer to a porcelain or glass mortar, and grind to a fine powder. Return the powder to the dish and heat for another 30 min. Cool the dish and weigh, repeating the process. Two consecutive weighings must give the same results. This figure gives the weight of the dried feces from which to deduce the water content. If the stool contains much fat, it is difficult to dry it because the fat forms a film on the surface which interferes with evaporation. To avoid this, lower the boiling point by the addition of alcohol from time to time. Heat on the water bath for 3-4 hr. in a porcelain casserole. Add 50 ml. absolute alcohol, stir with a glass rod, and again heat. In 1 hr. add 25 ml. more alcohol, stirring well, and evaporate as before. Add a third portion of alcohol, stir, and evaporate for another hour. Heat on the water bath at 108° C. for a short time, thus removing all the water. When a constant weight is obtained, there is no more water present.

Another rapid method of drying for fat estimation only: Mix the stool with 10 vol. of silver sand

(Merck's purified sea sand) which has been successively washed in hydrochloric acid, water, and alcohol and dried. Dry at 100° C.

Test for total fat

Neutral fats and free fatty acids are soluble in ether; combined fatty acids or soaps are not. To include both in the analysis, one must break down the latter and set free the fatty acids with a mineral acid.

1. Place 0.5 gm. dry powdered feces in the lower bulb of the Schmidt-Werner milk tube with the use of a funnel.
2. Pour 10 ml. diluted 30% hydrochloric acid into the tube to carry down the particles that may adhere to the sides.
3. Heat in a boiling water bath for 15 min., rotating occasionally to mix contents. Cool, fill to the 50 ml. mark with ether, securely cork, invert 40 or 50 times, rotate between hands to get rid of air bubbles, fix in upright position, and allow to stand a half hour to give time for all the solid particles to settle to the bottom of the tube. Rotation of the tube occasionally hastens this process.
4. Pipet off 20 ml. of the clear supernatant fluid and place in small weighed beaker. Evaporate the ether, dry the residue on a water bath, cool, and weigh.
5. The difference in weights is the weight of the fat contained in 20 ml. of the ether. Read off the height of the liquid in the tube after the 20 ml. have been withdrawn.

Calculate the percentage of fat as follows:

If w = the weight of the feces taken
x = the weight of fat found in 20 ml. ether
y = the number of ml. left in the tube

then (y − 10) will be the amount of ether left in the tube, for 10 ml. were dilute hydrochloric acid, and 20 + (y − 10) = (y + 10) will be the total bulk of the ether in which the fat from "w" grams of feces was dissolved.

$$\frac{x\ (y + 10) \times 100}{20 \times w} = \text{percentage of fat in stool}$$

Besides the total fat, the ether extract of the feces contains the lower fatty acids, cholesterol, lecithin, cholalic acid, pigments, etc. These exist in quantities so small that they are negligible.

Tests for neutral fat, free fatty acids, and soaps

Neutral fat and free fatty acids are soluble in ether, whereas the combined fatty acids or soaps are not and must be broken down by the addition of a mineral acid to make them soluble.

Test for **neutral fats** in the following manner:

1. Place 0.5 gm. dried feces in the lower bulb of the Schmidt-Werner tube; add 10 ml. distilled water.
2. Heat the tube for 15 min. in a boiling water bath, rotating the tube occasionally to get a good mixture.
3. Cool; fill to the 50 ml. mark with ether; carry on the remainder of the test of the feces for total fat and the fatty acids and neutral fats side by side, labeling the tube "A" that has been treated with acid,* and the tube "B" that has been treated with water. The ether extract of tube B gives the sum of the neutral fats and the fatty acids (free). The contents of tube B gives the unsaponified or, as Cammidge speaks of it, the "unsoaped fats," whereas the difference between the 2 gives the combined fatty acids or soaps.
4. To determine the relations between the neutral fats and free fatty acids, dissolve the ether extract from tube B in an excess of ether (about 20 ml.), add a few drops of an alcoholic solution of phenolphthalein; then titrate with N/10 sodium hydroxide in alcohol.

The number of ml. used to neutralize the solution multiplied by 0.0284 gives the weight of the free fatty acids contained in the quantity of feces originally used. The difference between this and the weight of the ether extract gives the quantity of neutral fat (and lipoids).

There are a number of other tests for fat that are sufficiently important to be carried out in certain cases.

The **acid test** is the number of mg. potassium hydroxide necessary to neutralize 1 gm. fat; this is a measure of the degree to which the fat has been hydrolyzed. Weigh a small amount of the fat, dissolve in neutral alcohol or alcohol-ether; add a few drops 1% alcoholic phenolphthalein, or if the fat is dark colored, a 2% solution of alkali blue 6 B; titrate with N/10 or N/2 aqueous potassium hydroxide.

The **saponification value** is obtained by determining the number of mg. potassium hydroxide necessary to neutralize the fatty acids split off from 1 gm. fat on saponification.

1. Boil a weighed quantity of fat with alcoholic potassium hydroxide on a water bath for 30 min.
2. Titrate the alkali in the flask with 0.5N hydrochloric acid, using phenolphthalein as an indicator. Compare the result with that given by a control experiment in which the alcoholic potassium hydroxide only was used. The difference gives the amount of alkali neutralized by the fatty acids liberated from the weighed quantity of fat, and from this the saponification value can be calculated. As the soaps formed are hydrolyzed by water and therefore react alkaline, it is necessary to add neutral alcohol from time to time in sufficient amount to keep it at over 40% since hydrolysis of soaps does not occur in this strength of alcohol.

The saponification value is a measure of the mean molecular weight of the fatty acids entering into the composition of the fats. By means of it the nature of the fat present is suggested. Fats such as tallow or lard give a saponification value of about 195, butter 220-233, cocoanut oil 250, and cod liver oil about 171-189.

The **ester value** is the difference between the saponification and the acid values of the fat and is therefore the number of mg. potassium hydroxide necessary to neutralize the fatty acids present in the form of neutral esters.

---

*Test for total fat.

The **iodine value** of a fat is the amount of halogen, expressed as iodine, that the unsaturated fatty acids of this fat will absorb, expressed as a percentage of the weight of the fat. The iodine value of a fat or a mixture of fats is therefore an index of the proportion of unsaturated or saturated fats present, for the latter do not absorb iodine. In feces, oleic acid, with an iodine value of 90.1, is the most important unsaturated fatty acid. Feces of children fed on cow's milk have a lower iodine value and a higher melting point than of those fed on mother's milk. The first stools of the latter after the meconium has been passed are particularly rich in this substance. They have an iodine value of 48% and a melting point of 40° C. At the end on the first week the proportion of oleic acid falls, and the melting point and iodine value approximate those of older children; namely, 47° C. for the former and 20% for the latter. In cases of dyspepsia the iodine value rises and the melting point falls.

Method: A titrated solution of iodine monochloride, obtained by mixing solutions of iodine trichloride and iodine in glacial acetic acid, is added to a solution of the fat in carbon tetrachloride. This, after standing in the dark for 1-2 hr., is mixed with a 10% solution of potassium iodide and is then titrated with a standard solution of sodium thiosulfate. From the amount of iodine absorbed by the known weight of fat taken the iodine value can then be calculated.

Hehner's value is the percentage of fatty acids insoluble in water upon saponification of the fat. For triolein, the Hehner value is 95.7; for lard and most fats and oils, 95; for butter, between 86 and 88; and for cocoanut oil, still lower.

Saponify a weighed quantity of fat with alcoholic potassium hydroxide, evaporate the alcohol, dissolve the soap in hot water, and make the solution acid with hydrochloric acid. Heat until the aqueous layer is clear; then filter. Wash the fatty acid with boiling water as long as any acid reaction can be detected; then dry and weigh.

The **Reichert-Meissel value** is the number of ml. of N/10 potassium hydroxide necessary to neutralize the volatile acids produced by the saponification of 5 gm. fat and is a measure of the amount of lower molecular weight fatty acids (which volatilize in a current of steam) that enter into the composition of the fat. To obtain comparative values the experiment must be carried out under certain prescribed conditions, which vary somewhat in different countries.

The **acetyl values** gives the number of mg. potassium hydroxide necessary to neutralize the acetic acid liberated when 1 gm. acetylated fat or fatty acids, formed by heating the fat with twice its weight of acetic anhydride, is saponified. Animal fats do not give an acetyl value unless they are mixed with cholesterol or some alcohol soluble in water, but certain vegetable oils have high acetyl values; thus for castor oil it lies between 153 and 156.

Total nitrogen

Use the Kjeldahl method. The ammonia nitrogen and protein nitrogen are converted into ammonium sulfate by heating with sulfuric acid in the presence of a catalyst. The ammonia is set free with an alkali, and the steam distillate is titrated with a standard acid. Use dry stool or about twice the weight of fresh stool.

Weigh 2 gm. dried feces and place in the bottom of a Kjeldahl flask.

Add 800 ml. pure sulfuric acid, 200 ml. fuming sulfuric acid, and 100 gm. of anhydrous phosphoric acid free from nitrogen. Add about 0.1 ml. mercury from a pipet; place flask aside for 12 hr. after shaking it, as it will foam too much if heated at once. Heat in the usual inclined position on a sand bath or asbestos mat with a small flame, and later with a full flame, until the fluid is clear. This takes 3-4 hr. Shake down any particle that comes up on the neck of the flask. Cool and wash the contents into a 500 ml. distillation flask with 50 ml. water. Wash the residue into this flask with fresh portions of water, keeping the total contents below 200 ml. Cool the flask, add 50 ml. 10% sodium hydroxide solution, 40 ml. 4% potassium sulfate solution, and a spoonful of talc or a few zinc filings. Add 60 ml. sodium hydroxide solution; connect quickly with the condenser. The delivery end of the condenser dips into a small flask containing 50 ml. N/5 sulfuric acid. Heat and distill. Disconnect and stop the heating in 20 min. Wash the delivery tube with a little distilled water into the receiving flask, adding a little cochineal or methyl orange solution. Titrate with N/5 sodium hydroxide. The number of mg. nitrogen in the dried stool is obtained by multiplying the number of ml. of N/5 sulfuric acid bound by the distilled ammonia by 2.8.

An alternate method is described on p. 41.

The interpretation of the amount of total nitrogen found is difficult: The nitrogen comes from the proteins of food, from the secretions and metabolism of the gastrointestinal tract, and from bacteria. Schmidt and Strassburger consider that on a diet yielding only a small amount of residue, bacteria furnish no less than ¼ or even ½ of the total nitrogen of stools. In general, very little help is obtained in the diagnosis of pathologic conditions from total nitrogen determinations.

Carbohydrates

Sugars do not ordinarily appear in stools of adults. Interference with absorption may cause them to appear in stools of children. Sugars can be determined by the usual reduction processes. It is more important to determine, however, whether the normal process of fission has taken place. Orban proved the absence of lactose in the acute stages of several intestinal affections of children, and Pfaundler found that the inversion of milk sugar does not take place in marasmic children, thus accounting for the lactosuria that has been reported in such cases.

Extract the dried stool with water; filter; test the filtrate, with or without evaporation, with Fehling, Trommer, Nylander, phenylhydrazin, or

Benedict reagent. Proteoses and peptones are interfering substances; therefore, it is preferable to extract with alcohol, filter, and evaporate the alcohol, dissolve residue in water, and apply the reduction tests.

Starch may best be determined by the microscopic or the microchemical methods already described.

Of pure chemical methods we shall describe the well-known Schmidt fermentation test. This test depends upon the fact that the dissolved carbohydrates, as well as those starches that lie free and are easily acted upon, are inverted by the diastase which is always present in the feces and are then fermented by the intestinal bacteria, with the formation of gas.

Procedure: Place 5 gm. stool, well mixed with water, in the receptacle of the Schmidt apparatus and close with a rubber stopper, excluding air bubbles. Connect the outlet tube with a closed graduated tube filled with water in which the gas that is formed collects. Join this in turn to a tube where the displaced water passes. Fill and set up and place in the incubator at 37° C. for 24 hr. If gas has collected in the tube, cool the apparatus to the temperature of the room and measure the gas. Test the reaction of the fecal mixture with litmus. An acid reaction plus gas indicates the presence of fermentable carbohydrates. Only a positive result is of value.

Schmidt claims that a patient should take a test diet for several days, and if the gas fills ¼ of the tube, intestinal dyspepsia can be proved. Rice, cellulose, and fat should be excluded from the diet.

Concretions

Our interest in the various kinds of concretions found in stools lies mainly in distinguishing coproliths from real concretions such as gallstones, pancreatic calculi, and intestinal sand. It is comparatively simple to distinguish between a stone composed of organic material from one of inorganic structure; heat on a platinum dish causes the organic material to carbonize and crumble away, while the inorganic substance remains unchanged or blackens a trifle. Furthermore, organic pancreatic stones, according to Minnich, on heating give off an aromatic odor and are easily soluble in chloroform.

Gallstones: Gallstones consist of a mixture of the constituents of the fluid in which they are produced. They are always "mixed"; that is, they have more than one constituent. Cholesterol is found in all stones. Calcium salts of the bile pigments are commonly present; sometimes they form the chief part of the stone. Naunyn divided them into the following classes: pure cholesterol stones, laminated cholesterol stones, common gallbladder stones, mixed bilirubin-calcium calculi, and rare forms.

Pure cholesterol stones: These are smooth, white to yellow, rarely green or brown on the surface, crystalline, oval or spherical, and seldom faceted.

Laminated cholesterol stones: These contain calcium salts of the bile pigments, found in yellow, brown, or green layers, alternating with the white layers of cholesterol. Cholesterin forms 75% of the stone. They are often faceted.

Common gallbladder stones: These are chemically like the former; physically they show an external firm laminated crystalline crust which surrounds a softer pigmented nucleus, frequently containing a cavity filled with a yellow alkaline fluid. They are seldom larger than a cherry. Surface is yellow, sometimes white or brown. They are usually faceted.

Mixed bilirubin-calcium calculi: Calcium bilirubinate is the chief constituent, but there is also found biliverdin, calcium bilifuscin, oxidized bilirubin, and always some cholesterol. These stones are small and occur in 2 forms, one of waxlike consistency, with round irregular surface, the other hard and brittle, steel gray in color, with a metallic luster.

Rare forms: Rare forms are found, to wit, amorphous and incompletely crystalline cholesterol gravel with a nucleus of calcium bilirubinate, surrounded by cholesterol, varying in size from a grain of sand to a pea; calcareous stones consisting of calcium carbonate with calcium bilirubinate, rare in man, but common in cattle and herbivorous animals; concretions with included foreign bodies such as ligatures, needles, plum stones, around which gallstones are formed.

Test for stones

We have already noted the test in a platinum dish. Boil 2 gm. powdered stone in a flask with distilled water to remove the bile acids and other water-soluble substances. Divide the filtered extract into 2 parts. (1) Evaporate one to dryness and weigh, giving the weight of the water-soluble material in the amount of dry material used. Incinerate and again weigh, this weight being the quantity of water-soluble ash. Evaporate the other half (2) to dryness and extract the sodium glycocholate with a mixture of alcohol and ether from the dry residue.

Dry the residue from the water extract and extract with warm alcohol, thus separating the fats along with a small proportion of the cholesterol. Extract the residue with ether, which dissolves the cholesterol. Evaporate the ether, weigh the cholesterol, and examine for crystals of cholesterol, which are best seen by recrystallizing from warm alcohol; also try the chemical reactions for cholesterol.

1. Crystals treated with sulfuric acid (5 parts of concentrated sulfuric acid with 1 part water) melt at the edges and turn crimson. Add a small quantity of iodine and note a play of colors: violet, blue, green, and red. Evaporate a small quantity on the edge of a porcelain crucible with hydrochloric acid and add a trace of ferric chloride; this gives a blue color.
2. Dry cholesterol dissolved in chloroform and mixed with an equal volume of concentrated sulfuric acid gives, on shaking, a blood red upper layer of chloroform, which changes to cherry red and finally to purple, and a lower green fluorescent layer of sulfuric acid. With dilute solutions the chloroform solution is yellow to rose red, whereas the sulfuric acid is yellow with a greenish fluorescence.
3. A small quantity of cholesterol mixed with acetic anhydride gives a rose color changing to blue and then to blue green on addding concentrated sulfuric acid drop by drop (**Liebermann-Buchard** reaction). A specimen, purified by repeated crystallization from hot absolute alcohol and dried, melts at 145° C.

After treatment with ether, extract the residue with dilute hydrochloric acid (1:3) and filter. (Calcium, if present, is shown by making a portion of the solution alkaline with ammonia and adding acetic acid and ammonium oxalate solution. Copper may be detected by adding a few drops of potassium ferrocyanide, when a brown color develops.)

1. Wash the residue on the filter with water until free from hydrochloric acid. Dry the filter, cut into pieces, and warm in a dry flask with chloroform. Filter and examine for bilirubin, evaporate a small portion spontaneously on a watch glass, showing microscopically small, ill-defined rhombic plates, or indistinct crystalline grains which on being moistened with nitric acid give the colors of Gmelin reaction (p. 1957). Again shake the chloroform mixture with dilute sodium hydroxide; the pigment goes into alkaline solution, whereas the chloroform remains decolorized. The separated alkaline solution left to stand in the air turns green from the formation of biliverdin. Detect the presence of urobilin by the spectroscope.

Examine the stools carefully for stones, especially after washing in a sieve. Many of the objects commonly called gallstones are not real stones; they are intestinal sand coproliths. Chemical and microscopic study of all stones must be made to verify the diagnosis. With the aid of the roentgen ray, too, much information about the gallbladder region is obtainable which will substantiate the stool findings. An artifact is sometimes seen after the administration of large quantities of olive oil in suspected cholelithiasis. It is a concretion composed of fatty acids, fats, and soaps; it is soft, greasy, and transparent. Microscopic and chemical examinations will reveal its true nature.

Pancreatic calculi are rarely found, less than a hundred cases having been reported. They are small, gray white, with no facets on the surface. Heated on a platinum dish they yield a large amount of white ash and give off an aromatic odor, as previously stated. They are soluble in chloroform. Chemically they consist of 50% lime, as carbonates, phosphates, or even oxalates. Pigments and cholesterol in a very small amount are found in the external layers. Cammidge presents a very good illustration of these stones.

Intestinal sand has been previously described.

BACTERIOLOGIC EXAMINATION

When bacteriologic methods are applied to a study of stools, a never-ending task is encountered. The variety and number of bacteria normally found in stools are so great that ordinarily, unless there is some special reason, we do not make a thorough bacteriologic test. There are certain occasions, however, when a bacteriologic study must be made. Some mathematically inclined bacteriologist has shown that a normal individual passes out via the stool every day some 126 billion bacteria of many varieties and kinds.

Detailed methods for bacteriologic examination of the feces are found in Chapter 31.

In searching for bacteria, feces should be examined as soon after passage as possible. They should be passed in a sterile vessel, and rapidly smeared, stained, plated, and inoculated on special media or placed at once in a preserving or transport medium.

BASAL METABOLISM AND ELECTROCARDIOGRAPHY

SECTION ONE BASAL METABOLISM

Chapter 109 Apparatus for measuring basal metabolic rate

SECTION TWO ELECTROCARDIOGRAPHY

Chapter 110 Use of the electrocardiograph
111 Unipolar lead electrocardiography
112 Interpretation of the electrocardiogram

Section One

BASAL METABOLISM

The terms basal metbolism and basal metabolic rate (BMR) refer to the heat production of an organism at the lowest level of cell chemistry in an inactive, awake, fasting state. This may be determined directly by means of a calorimeter or indirectly by calculating the heat production from an analysis of the end products of oxidation within the organism or from the amount of oxygen utilized.

Basal metabolism determinations are primarily used to evaluate thyroid function. Other laboratory tests that reflect thyroid activity are the measurement of serum protein-bound iodine, radioactive iodine uptake, and serum cholesterol. Elevated basal metabolic rates are seen in patients with toxic goiter. If any degree of thyrotoxicosis is present, tests done after 5-10 days of iodide therapy will reveal a lowering of the BMR by 15% or more.

Conditions other than hyperthyroidism that are frequently associated with an elevated BMR are pregnancy, hyperpituitarism, pheochromocytoma, polycythemia, and leukemia.

Diseases other than hypothyroidism that are often associated with a low BMR are Addison's disease, myotonia atrophica, and the nephrotic syndrome.

Fever increases the basal metabolic rate about 5% per degree. If the patient is febrile, it is preferable to postpone the test until the temperature has returned to normal.

Normal range: –10% to +15%.

GENERAL INSTRUCTIONS

The patient is instructed to eat or drink nothing except water after midnight prior to the morning of the test. If the patient is in the hospital, as soon as possible after awakening he is wheeled into the room in which the test is to be performed. Undue exertion is avoided.

If the patient reports to the laboratory for the test, he must rest for 30-60 min. During this time he is not to be disturbed by conversation, loud noises, or strong lights.

The basal metabolism apparatus should be prepared before the patient enters the room. Do not set up the machine in the patient's presence.

The procedure should be briefly explained to the patient before the rest period begins. It is necessary to explain that he is to breathe naturally into the apparatus and that the technician is simply going to measure the quantity of oxygen that is consumed. Frequently it is advisable to make 1 or 2 preliminary tests to acquaint the patient with the procedure.

The mouthpieces should be washed with warm water and soap, thoroughly rinsed, and then placed in boiling water for 30 min. They are then dried and stored. Different directions are given for the Jones apparatus (p. 1978).

Only the soda lime specified by the manufacturer of the basal apparatus should be used.

An extra tank of oxygen should be available. All the labels on the tank should be read to make certain that oxygen is being used. Other gases, such as nitrous oxide, have been sent to laboratories by mistake, with serious consequences.

Chapter 109

Apparatus for measuring basal metabolic rate

STANLEY REITMAN

COLLINS (BENEDICT-ROTH) APPARATUS

Description of the apparatus

This apparatus makes use of a water-sealed spirometer. One-way circulation, directing all exhaled air through the soda lime, is maintained by low resistance flutter valves. A large kymograph drum permits duplicate or even triplicate tests to be recorded on the same graph. It is also possible to extend the test period to as long as 15 min. if desired. The drum is driven by a precision spring-driven timing movement; a synchronous electric motor is optional.

Operating instructions

Put a chart around the kymograph drum, attach a sterile mouthpiece to the breathing tube, and fill the pen with ink.

Turn the 2-way valve handle so that the mouthpiece is in communication with room air and not with the contents of the spirometer.

Admit oxygen into the apparatus until the pen comes within 2 in. of the bottom of the paper, on the first vertical time line.

Admit the patient and allow him to relax on a comfortable couch or table for at least 30 min. before beginning the test.

Adjust the flexible arm of the apparatus so that the rubber mouthpiece comes near the patient's mouth and explain that the mouthpiece should be inserted so that the flange is between the gums and the lips and the 2 tabs are between the upper and lower teeth.

Apply the noseclip so that the sponge-rubber pads are well down on the nostrils, press them together firmly but gently, and adjust the thumbscrew to hold the noseclip in this position. Ask the patient to try to exhale slightly through the nose. If he can do this, the noseclip is not fitted properly and must be readjusted.

Turn the valve handle in its other position, which connects the patient to the breathing circuit of the machine. The oxygen bell and pen will now move up and down with each exhalation and inhalation.

At any convenient time set the clock in motion by moving its starting lever.

Note the thermometer and barometer readings.

Allow the test to run about 3 min., and as the pen crosses the third time line, place the leak tester weight on top of the bell and allow it to remain there until the pen crosses the next time line; then remove it and allow the test to continue another 3 or 4 min. If a leak is present, the test weight on top of the bell will cause the oxygen to escape, and the graph for the patient's respirations will assume a steeper angle. If there is evidence of leakage, stop the test and readjust the noseclip, mouthpiece, and tubing connections. Put more oxygen in the bell if necessary and proceed with the test, being certain to repeat the test for leakage again after 3 min.

After 7 or 8 min. end the test by turning the free-breathing valve back to the room air connection.

Shut off the clock and remove the mouthpiece and noseclip.

Note the thermometer and barometer readings. If there is a difference from those taken at the beginning of the test, take an average of the 2.

A duplicate test should always be performed, and it may be recorded on the same graph by starting the test 3 or 4 min. away from the beginning of the previous test.

If there is a leak of oxygen from the bell or any of the connections, the graph on the kymograph chart will rise rapidly.

If the patient is breathing outside air and not the oxygen in the tank, the line made by the pen will be almost horizontal.

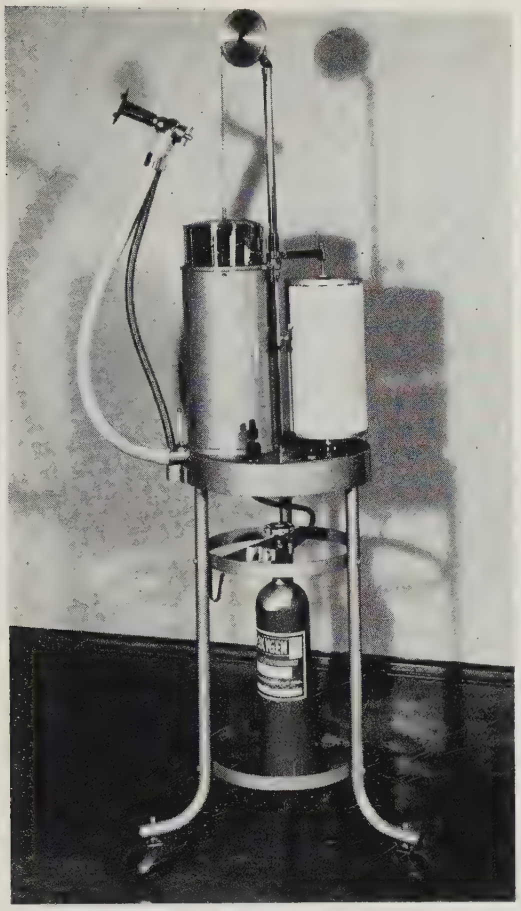

Fig. 697. Collins (Benedict-Roth) basal metabolism apparatus. (Courtesy Warren E. Collins, Inc., Boston, Mass.)

Obtain the patient's age, sex, weight without clothing, and height without shoes.

Calculation

Remove the chart from the drum and lay it flat on a desk. Using a ruler, draw a line through a majority, or an average, of the lower points. Note the rise in millimeters of this line in a 6 min. period on the chart. For example, if one end of the line cuts the vertical line at 47 mm. and 6 min. later it has risen to 121 mm., then the rise is 121 − 47 = 74.

To determine the normal*: Use Table "A" (Fig. 699). Rule a line to connect the "patient's height" found in column I with the "patient's weight" found in column II. The point at which this line intersects column III is the body surface area. Record this in the computation space allotted to it.

Now, using Table "B," find the calories/sq.M./hr., by using the patient's age (nearest birthday) and sex and record in space for computations. Multiply figure in column III by figure in Table "B" to obtain the total normal calories/hr., the exact normal for a person of this height, weight, age, and sex.

To determine the actual test: Record the difference in height of the 6 min. test period from the kymograph tracing in the space called "O_2 line."

Record the temperature of the oxygen bell from its thermometer and the prevailing barometric pressure in mm. Obtain the correction factor for pressure and temperature from Table "C" (the intersection of the 2 columns representing the temperature and pressure for this test). Record this in the proper computation space.

Multiply the figure recorded opposite "O_2 line" by the figure recorded opposite Table "C" to obtain the total actual test calories/hr.

To find the basal metabolic rate: Use the normal and the actual consumption of oxygen/hr.

Subtract the smaller from the larger figure.

Divide the difference by the normal. Move the decimal 2 places to the right to obtain basal metabolic rate in %.

If the actual test is greater than the normal, report as plus; if less than the normal, report as minus.

SANBORN METABULATOR*

Preparation of patient

The patient is prepared in the usual manner. He must be completely at rest mentally and physically, and 14 hr. must have elapsed since his last meal. He should lie down for 30 min. immediately preceding the test.

Preparation of apparatus

With the patient comfortable and resting, wheel the metabolism tester to a convenient position beside the bed and plug its power cord into the AC outlet.

Place the chromium-plated leak tester in a glass of cold water and allow it to remain there while the patient is being prepared. Place a sterilized rubber mouthpiece on the mouthpiece connector. Open the Plexiglas window over the writing stylus. Turn the breathing valve to the "test" position, thus connecting the bellows with the outside air, and then collapse the bellows by pushing the bellows carriage toward the absorption chamber as far as it will go. With the bellows in this position, turn the patient valve back to "fill," thus closing off the bellows. Now admit oxygen by carefully turning the handwheel on the oxygen tank to the left. Continue filling until the writing stylus is about 1 in. from the top edge of the paper; then close the valve on the oxygen tank tightly by turning it to the right.

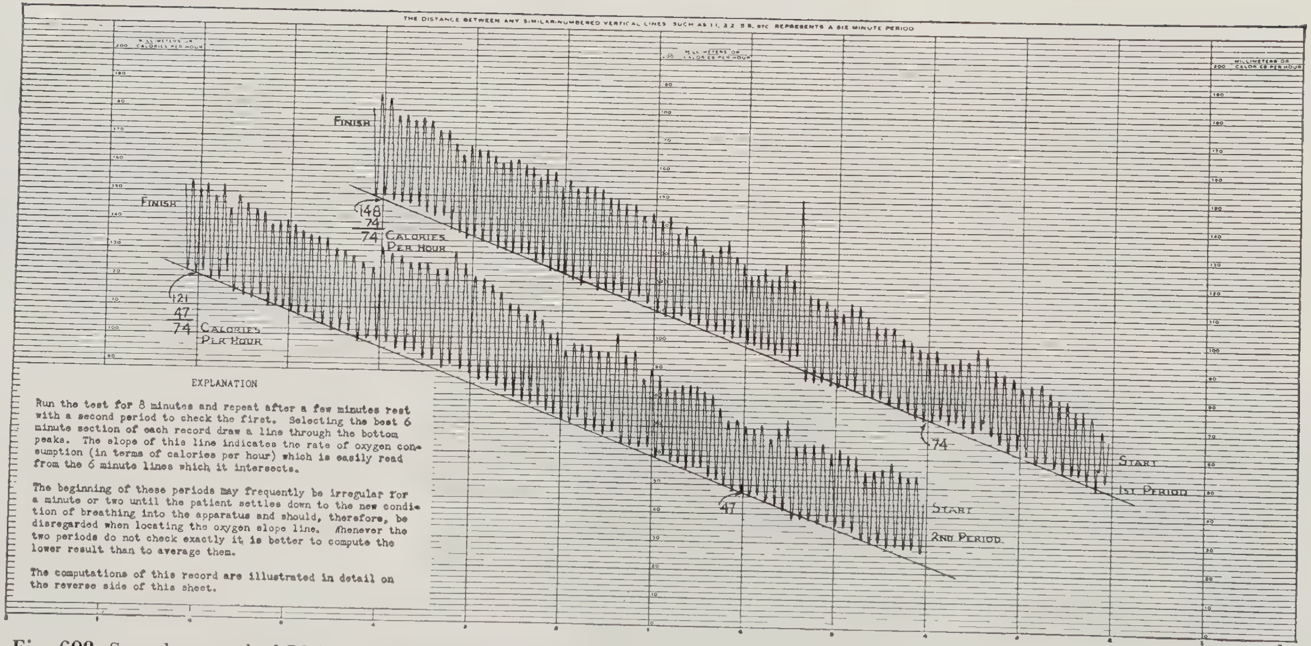
Adjusting noseclip

The instrument is now ready for the test. Adjust the noseclip before inserting the mouthpiece. The sponge-rubber pads are used to apply pressure

---

*These calculations are compiled from data furnished by Warren E. Collins, Inc., Boston, Mass.

*These data are compiled from facts furnished by the Sanborn Co., Cambridge, Mass. For further information refer to the brochure supplied with each Metabulator.



EXPLANATION

Run the test for 8 minutes and repeat after a few minutes rest with a second period to check the first. Selecting the best 6 minute section of each record draw a line through the bottom peaks. The slope of this line indicates the rate of oxygen consumption (in terms of calories per hour) which is easily read from the 6 minute lines which it intersects.

The beginning of these periods may frequently be irregular for a minute or two until the patient settles down to the new condition of breathing into the apparatus and should, therefore, be disregarded when locating the oxygen slope line. Whenever the two periods do not check exactly it is better to compute the lower result than to average them.

The computations of this record are illustrated in detail on the reverse side of this sheet.

TABLE "A"

DUBOIS BODY SURFACE CHART

[As prepared by Boothby and Sandiford of the Mayo Clinic]

DIRECTIONS

With the computation tables on this sheet it is possible to compute the Basal Metabolic Rate of any patient from 5 to 80 years of age according to the DuBois method, as modified by Boothby and Sandiford of the Mayo Clinic.

To determine the NORMAL use Table A and draw a line through the patient's height found in column I and through the weight in column II. Using a straight edge (ruler) draw a line between these two points and read the BODY SURFACE AREA where this line intersects column III. Transfer this body surface figure opposite "Column III" in the space for computations. Then refer to table B and using the patient's age (nearest birthday) and sex read the calories per square meter per hour. Transfer this figure beside "Table B" in space for computations. Multiply III x B which will give the total NORMAL CALORIES PER HOUR—the exact normal for a person of this height, weight, age and sex.

To determine the ACTUAL TEST transfer the difference in height of the 6 minute test period (from kymograph tracing on the reverse side) to the space provided for it opposite O line. Next record the temperature of the oxygen bell (from the thermometer) and the prevailing barometric pressure in millimeters. Using table C draw a circle around both the temperature and the barometer readings and at the intersection of these two columns you will find the correction factor. Transfer this figure opposite "Table C" in space for computations. Multiply O line by table C which will give the total ACTUAL TEST CALORIES PER HOUR.

Now you have the NORMAL oxygen consumption determined from the tables and the ACTUAL oxygen consumption as found by the TEST both in terms of calories per hour.

To find the BASAL METABOLIC RATE from these two figures (i.e. the relation of one to the other in terms of per cent) simply subtract the smaller figure from the larger then divide the difference ALWAYS by the normal. This will give you a decimal fraction which when multiplied by 100 or by moving the decimal point two figures to the right, gives the Basal Metabolic Rate in per cent. To determine whether this per cent is plus or minus, simply note whether the ACTUAL TEST is greater or less than the NORMAL. If greater than the Normal the result is plus and if less than the Normal the result is minus.

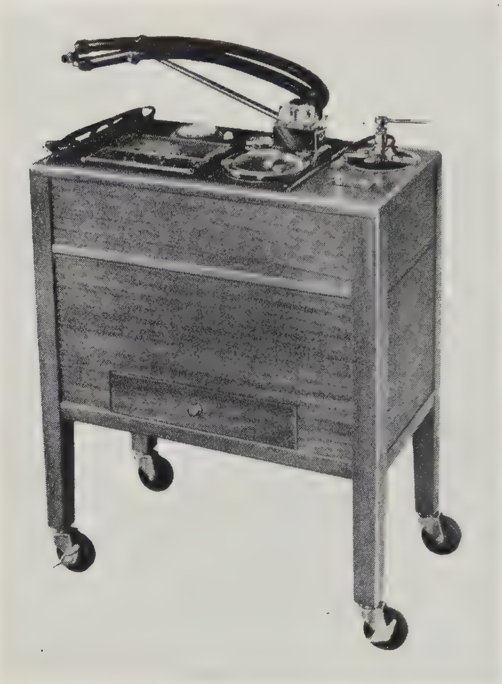

Fig. 700. Sanborn basal metabolism apparatus. (Courtesy Sanborn Co., Cambridge, Mass.)

against the soft sides of the nostrils. Loosen the thumbscrew so that the clip will fit loosely when first applied and then take the noseclip between the thumb and finger of both hands and, placing it over the nose near the bridge, slide it downward parallel to the patient's face until the pads are at the right level. Now tighten the thumbscrew until the patient finds he can no longer breathe out through his nose. Make sure of this by asking him to close his mouth and try. The noseclip must not be uncomfortably tight.

Placing mouthpiece

Adjust the position of the tester and of its flexible arm until the rubber mouthpiece is just in front of the patient's mouth, with its long axis pointing across the face. Insert the mouthpiece so that the 2 small projections lie between the upper and lower teeth while the flange of the mouthpiece lies between the lips and the teeth. See that the lips are not folded under, for this may permit leakage.

Dentures: Dentures will not cause trouble, especially if they fit well. Since there may be an air passage over the plate, however, it is doubly important with patients wearing artificial teeth to see that the lips make a good seal over the outside of the rubber mouthpiece. It is a mistake to remove the dentures for this may allow the mouthpiece to fall inward, away from the lips.

With patients with few or no front teeth, the problem is likely to become more difficult. This problem is solved, however, by having a good seal made by the lips. It may be necessary to draw the lips over the flange of the mouthpiece and hold them in place with adhesive tape.

Ruptured eardrums: If the patient has a ruptured eardrum and a patent auditory (eustachian) tube, air is likely to escape through the ear. If this occurs, the external ear canal is sealed with a cotton swab impregnated with petrolatum. The operator may have to hold the plug in place while the patient is being tested for leaks at the nose, for otherwise the plug may be blown out.

Making test

With the patient ready and breathing room air comfortably, start the record by turning on the motor switch. The stylus should now be tracing a horizontal line near the top of the record. The actual test is started by flipping the breathing valve to the "test" position, preferably at the end of an expiration. As soon as it is clear that the test is proceeding normally, check the seals at the patient's nose and mouth (and ears also, if necessary) with the leak tester. To do this, take it out of its glass of water, wipe it dry, and then hold it under the nose and at the corners of the mouth while watching for any condensation on the polished surface of the metal. The test should not be allowed to proceed unless all leaks have been eliminated, for a leak will spoil the accuracy of the oxygen-consumption measurement.

Run the test 10 min. or more unless the bellows become collapsed earlier. If a duplicate test is desired, turn the breathing valve to the "fill" position at the end of the first test, readmit oxygen from the tank as before, and when the bellows has been adequately filled, close the valve on the tank and return the breathing valve to the "test" position. If the patient shows any signs of discomfort or reluctance at the end of the first test, however, remove the mouthpiece and noseclip and allow him to rest before making a second run.

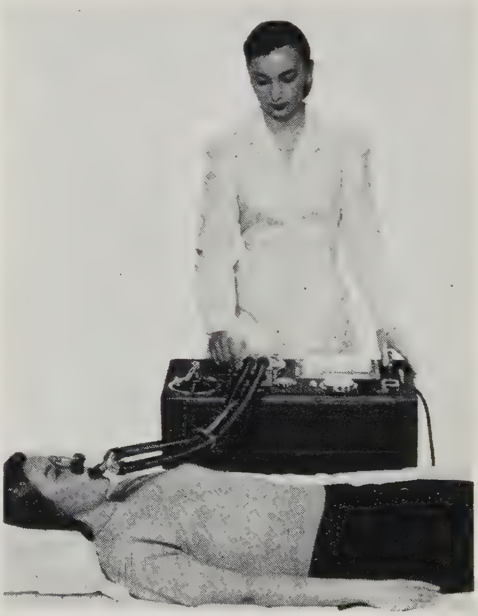

Fig. 701. Basal metabolism test using the Sanborn instrument. (Courtesy Sanborn Co., Cambridge, Mass.)

At the beginning of each test record the **temperature,** as read from the instrument's dial thermometer, and the **barometric pressure,** directly on the record. Tap the barometer gently before making the reading.

With the test completed, throw the breathing valve to the "fill" position again and remove the mouthpiece and noseclip from the patient. Pull carefully on the protruding paper in order to bring the remainder of the record out of the machine; then bend the paper sharply back over the barometer dial and move the free end a little to one side, whereupon a quick pull will tear off the protruding portion of the paper.

Be sure the motor switch is turned off. Write the date and the patient's name, height, weight, age, and sex on the record and also the temperature and barometer readings if this has not already been done.

Measurement

Since the volume occupied by a given amount of gas depends on the temperature and pressure, the statement that a patient's oxygen consumption is so many ml./min. means little unless the conditions under which the volume measurement was made are specified. However, temperature and pressure are likely to be different in each test, so that it has become accepted practice to refer all gas-volume measurements to "standard temperature and pressure," or "STP" for short. Standard temperature is 0° C. or 32° F., standard pressure is 1 atmosphere or 760 mm. of mercury. The actual volume measurement is made under the conditions prevailing during the experiment, and then the operator calculates, using the gas laws, the volume that **would have been found** if the measurement had been made under STP conditions. This is what is meant by an oxygen-consumption rate as "x ml. per minute, STP."

A measuring scale has been provided that eliminates the STP calculation.

The purpose of this test is to determine the patient's rate of oxygen consumption expressed in ml./min. at standard temperature and pressure. This is done by estimating the **average downward trend** of the patient's respiratory tracing. To do this draw a "slope line" through the top peaks of the record. The top peaks are chosen because they represent the expiratory position of the patient's lungs, which is usually a little more regular than the inspiratory position. The slope line can be drawn through the top, bottom, or the middle of the record as long as it represents the average downward trend. If the record is regular, the slope line can easily be drawn through the top peaks. If the record is jagged, the operator must exercise some judgment in deciding what represents the average slope. If the respiratory tracing is very irregular, it is useless to attempt to place a slope line, and the test must be repeated.

Lay the record on a flat surface and with a long ruler and a dry pen, pencil, or other scratching device draw a straight slope line to represent the average downward trend of the tracing. Extend this slope line to the edges of the record.

L-scale: A measuring device has been designed to enable the operator to read the oxygen consumption in ml. at STP/min. directly from the record. The L-scale will be found among the accessories in the case with the "slide-rule calculator." Hold the long arm of the "L" horizontal, with the lettering right-side up, and slide the shorter arm (pointing upward) over the left-hand end of the long one. The small slider will already be in place at the right-hand end of the arm. The scale now consists of a horizontal bar carrying 2 sliders, each with a vertical hairline lying over a correction scale (Fig. 702). One of these scales is for temperature and the other for barometric pressure. Adjust the sliders so that the hairlines mark the temperature and barometer readings taken during the test. Note that each slider also carries a **horizontal** hairline, lying a little above the upper edge of the long arm of the "L." The line on the right-hand slider has a vertical hairline crossing it, and the L-scale is to be applied to the respiratory tracing in such manner that the intersection of these 2 hairlines on the slider lies exactly over the intersection of the previously drawn slope line and one or other of the horizontal lines printed on the record (Fig. 702). When this has been done, adjust the "levelling" of the "L" until the horizontal hairline on the **left-hand** slider also coincides with the horizontal line that has been chosen. Check the position of the intersection on the right-hand slider again, to be sure that it has not moved, and then read the oxygen consumption directly at the point where the slope line strikes the right-hand margin of the vertical arm of the "L." The reading on this latter scale is the patient's oxygen consumption in ml./min., reduced to standard temperature and pressure.

T-scale: While the L-scale represents a considerable improvement over the T-scale that has been supplied with the Sanborn waterless metabolism tester, it is perfectly permissible for any operator who wishes to do so to use the T-scale on the records produced by the present machine. It is applied to the tracing exactly as in the case of the waterless testers, using a vertical line for the alignment and reading the oxygen consumption along the horizontal arm. Corrections for the temperature and pressure are made, of course, by adjustment of the sliders before the scale is applied.

Conversely, the L-scale may be used to measure a slope line produced on one of the older waterless machines. Since alignment of the L-scale depends on a **horizontal** line, it will be necessary to draw in a base line on the waterless chart, which can be done most conveniently before the chart is removed from the machine. Simply inflate the bellows to the point where the writing stylus will cross the respiratory record near its end and then, maintaining the bellows at this volume, give the drum one full turn by hand. This will provide a horizontal base line for the L-scale. If it has been placed correctly, as suggested above, the base line and the slope line will cross near the right-hand edge of the record. If the base line is too high or too low, it can easily be drawn in a more appropriately placed line parallel to the original.

Basal metabolic rate

The Metabulator will provide the operator with a measurement of the patient's oxygen consumption in STP ml./min. The BMR goes a step further—it is a measure of how nearly normal the de-

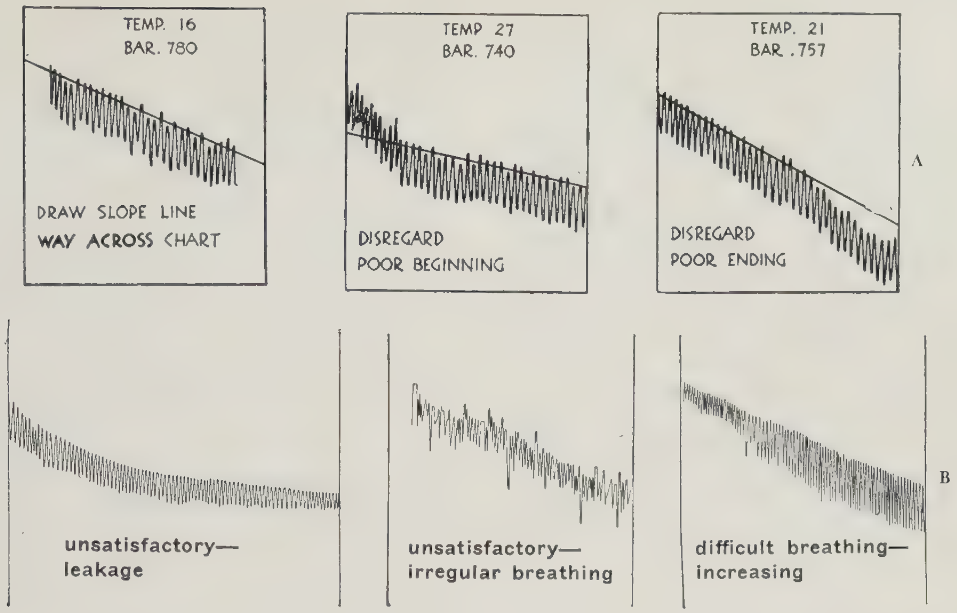

Fig. 703. A, How to draw slope lines, Sanborn basal metabolism test. **B,** Types of slopes that are to be discarded in making Sanborn basal metabolism tests. (Courtesy Sanborn Co., Cambridge, Mass.)

termined oxygen consumption is for the particular patient concerned, taking his height, weight, age, and sex into account. The BMR is expressed as a figure (with a prefixed plus or minus sign) showing the **percentage** by which the patient's oxygen consumption is above or below normal. Thus a BMR of +42 indicates an oxygen consumption 42% too high; while −17 indicates one 17% below normal, etc. The problem now is how to convert the figure found for oxygen consumption into a BMR for the patient concerned, thus telling by how many percentage points the oxygen consumption differs from the normal.

This conversion may be accomplished either by the "Slide-Rule Calculator" supplied with the accessories or by using metabolism tables.

Slide rule calculator

Adjust the hairline to oxygen consumption (corrected to standard temperature and pressure).

Shift the slides to bring the height under the hairline.

Reset the hairline to actual present age, male or female.

Move the slider to bring the weight under the hairline.

Read basal metabolic rate over the BMR arrow.

Metabolic tables

The tables formerly used with Sanborn metabolism testers are perfectly adequate to convert oxygen consumption to BMR. The new set of tables will greatly facilitate the calculation involved. The printing on the recording paper is designed so that the whole computation can be carried out on the original record.

The quantities concerned in the calculations are (1) the patient's height, (2) his weight, (3) his rate of oxygen consumption (L-scale reading), and (4) his age and sex.

The newer tables give a factor for each of these 4 measurements, and a column is provided on the chart for the factors found, so that they can be put down one above the other. They are then added together, and the sum is converted directly to a BMR through the use of a final conversion table.

English or metric units: The principle involved in this method of calculation makes it possible to use the same tables whether the heights and weights are in pounds and inches on the one hand or in kilograms and centimeters on the other. The difference is taken care of by the addition of a "metric conversion factor" if the metric units are used. Examine the printed box on one of the charts. The tabulations are set up so that if the bodily measurements are taken in English units the left-hand section is used, with no conversion factor; whereas if the measurements are in centimeters and kilograms the right-hand column is used and the metric conversion factor is printed at the bottom of the factor column so that it will be added in along with the other factors. The sum in line 6, obtained by the addition of all the figures in the factor column, will be the same whether the left-hand section with English units is used, with no conversion factor to add in, or whether the right-hand section with metric units is used and the conversion factor "0295" added in. Since the sum in line 6 is the same for either system of units, the BMR in line 7 will also be the same, as it should be.

Height factor: Measure the patient's height to the nearest inch or centimeter. In the column at the left-hand side of Table 1 on the recording paper will be found the heights arranged in steps of 10. Suppose the patient's height is 67 in. Since 67 = 60 + 7, follow the left-hand column down to "60," then follow that horizontal line across to the column headed "+7." This factor, 0750, is the correct one for a height of 67 in. Other values will be treated in exactly similar fashion. If the height is 182 cm., follow the height column down to "180" and then follow the horizontal line across to the column headed "+2," where the factor 0121 will be found, etc.

Weight factor: Measure the patient's weight without clothing in pounds or kilograms.* Find the weight factor in Table 2 on the recording paper. For example, if the patient's weight is 145 lb., follow the weight column down to "140" and then trace that horizontal line over to the "+5" column, where the factor 0765 will be found.

Oxygen-consumption factor: Use Table 3 on the recording paper to find the factor for oxygen consumption. The procedure is the same as for the other 2. The figure to start with is the number of STP ml. of oxygen/min. as determined from measurements of the patient's record. For a consumption rate of 217 ml./min., for example, find "210" in the left-hand column and then follow that line across to the column headed "+7." The factor is 1275.

Normal standard factor: Since the basal metabolic rate depends on a comparison of what the patient actually does with what a normal person of his age and sex ought to be doing, a factor must be found representing "normal" behavior. Table 4, showing the factors for the normal standard, will be found on the back of the tables card. The column for the age is in the middle, and the factors for male patients are found at the left, whereas those for females are to the right. Some of the factors are the same for a number of different ages. This is all right, for that is the way normal people behave. The groupings also differ between males and females.

Find the patient's "normal standard" factor and pull it down in line 4; e.g., for a female patient 29 years of age it would be 1208. For a male of the same age it would be 1114.

Conversion to BMR: When all the factors have been added (including the metric conversion factor if the height and weight were in centimeters and kilograms) the total is converted directly to BMR through the use of Table 5 on the recording paper. Reduce the sum to 3 figures by discarding the fourth, increasing the third figure by 1 if the fourth is 5 or more. Thus, if the total is 4316, call it "432"; whereas if it is 4312, it becomes "431." Using the conversion table just as the others were used, it will be seen that "431" gives a BMR of +43. Insert the result in line 7 on the chart.

JONES METHOD

This method was devised by Dr. Horry Jones of Chicago. The machine is a portable instrument, consisting of a bellows mounted on a strong metallic stand with a standard liter measuring device that automatically corrects its oxygen volume for atmospheric pressure and temperature.

The metabolism test is a quantitative determination and therefore requires more than ordinary precision in technic. Results should be within 1-5% of the patient's true metabolic rate; otherwise the technic is being very crudely performed.

Set up the apparatus as illustrated. Carry out each step in the exact sequence as given.

Connect the oxygen tank in place using a wheel wrench to tighten it against the leather gasket. Place the tracing sheet on the clock plate with the lettered end of the clock plate up.

Adjust clock plate so that its geared bar fits in the slot of clock housing and then slide the plate down into the slot until it comes to rest against the geared wheel inside of housing. If the clock starts, stop it by snapping the switch to OFF position. If it does not start with the switch in ON position, lift the clock plate about ½ in. and bring it down with slight downward jerk. Then see if the clock can now be started by turning on the switch. If this has succeeded in getting the geared bar and geared wheel to mesh, stop the clock until it is to be started as directed later.

Keep the pen tip free of dried ink or lint by drawing a pinpoint through it so that the pen will write with a fine, sharp line. Fasten the pen to its bar and rotate the clock in its seat until the pen traces evenly across the entire width of the clock plate. Now attach the mouthpiece (disinfected, not by boiling but by briefly immersing into wide-mouthed jar of 50% alcohol, and then rinsed with water) to the breathing tubes and rotate so that

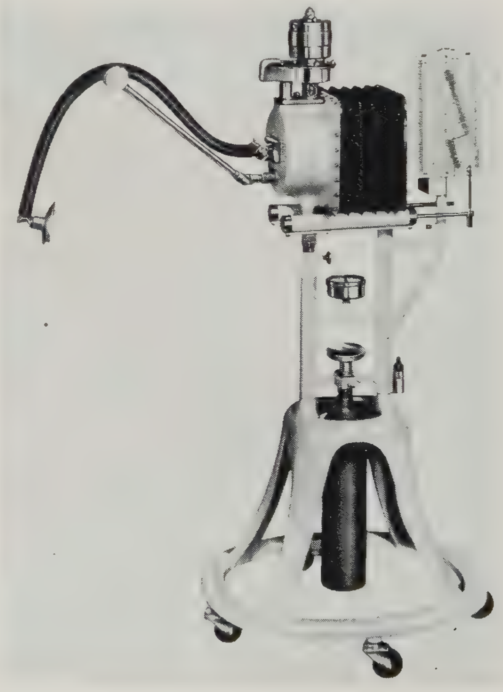

Fig. 704. Jones basal metabolism apparatus. (Courtesy Jones Metabolism Equipment Co., Chicago, Ill.)

---

*Needless to say, heights and weights must be either **both** English or **both** metric; do not try to mix a metric height with an English weight or vice versa.

it faces the patient's mouth squarely without twisting the tubes.

Stand the apparatus at exactly the correct distance (move apparatus to patient, not the patient to the apparatus) so that the mouthpiece will just reach the patient's mouth without bending the breathing tube.

Turn the 3-way valve so that its pin is parallel to the floor. Pull on the bellows until the point of the pen is at the air position on the graph. Holding the bellows in that position, turn the 3-way valve perpendicular to the floor, thereby holding the pen point at the air position.

Close the needle valve. This retains the oxygen in the measuring chamber.

Using the wheel wrench, admit oxygen into the measuring chamber until the black indicator is ½ to ¾ of the distance to the red indicator. Shut the oxygen tank valve.

Open the needle valve and admit enough of this oxygen into the bellows to push the pen point to S, M, or L on the paper (small, medium, or large, depending on the size of the patient).

Admit an exact liter of oxygen into the measureing chamber by turning the wheel wrench on the oxygen tank until the black needle is superimposed on the red needle of the gauge.

Take the patient's pulse and record.

Apply the nosepiece to the patient. Connect the mouthpiece to the apparatus. Instruct the patient how to use the mouthpiece and insert it into the patient's mouth.

To get the patient to relax at the beginning of the test and to overcome the tendency to erratic breathing, have the patient take one deep, forced full inspiration, then exhale slowly, and relax the arms and shoulder muscles for normal, even breathing.

Start the motor of the apparatus.

At the end of the patient's expiration turn the 3-way valve parallel to the floor, thus connecting the patient to the bellows.

After a few respirations start the clock and make the pen write on the graph.

When the tracing has crossed the base line at A (receded within the black line on the paper), open the needle valve and admit the known liter of oxygen from the measuring chamber into the bellows. This will push the pen out beyond the black line. When the pen recedes within the black line again at B, the test is ended.

Take the patient's pulse and record.

Repeat the test; the preliminary test alone is never sufficient.

Testing for nose leak

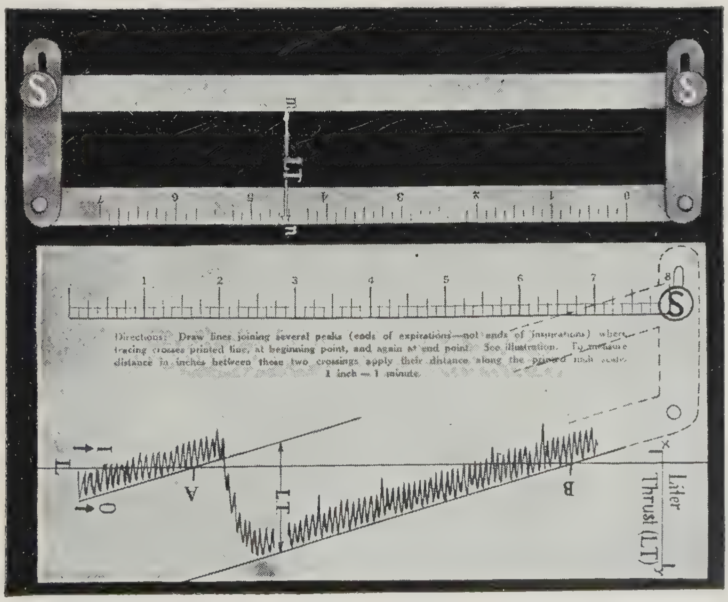
After the noseclip has been placed in position instruct the patient to try to breathe through his nose. If he is able to breathe through his nose while the clip is in place, adjust it to make it airtight. If there is a nose leak, the tracing will be concave instead of a straight line slope.

Testing for mouth leaks

If there is a mouth leak due to improper adjustment of the mouthpiece, the tracing will be a back-and-forth movement of the pen instead of a slope.

Calculation of basal metabolic rate

Use the protractor to determine the time required to consume 1 L. oxygen, as follows: Apply the top edge of the top ruler of the adjusted protractor along the long or "liter" slope of the tracing on the paper to line up with the highest peaks. Do not allow more than 1 or 2 peaks to project above the ruler edge. Holding the upper rule in this



Directions: Draw lines joining several peaks (ends of expirations—not ends of inspirations) where tracing crosses printed line, at beginning point, and again at end point. See illustration. To measure distance in inches between these two crossings apply their distance along the printed inch scale.
1 inch = 1 minute.

Fig. 705. Jones basal metabolism protractor and sample test chart. (Courtesy Jones Metabolism Equipment Co., Chicago, Ill.)

position, swing the connecting arms to such position that either edge of the connecting arm lies PARALLEL to the edge of either end of the tracing sheet. The shorter slope peaks should now line up with the upper edge of the lower ruler. If they do not, it indicates (1) that a full liter was not admitted to the breathing chamber, (2) that part of it was lost through a nose leak or mouth leak, (3) that soda lime has been used for more than 100 tests, or (4) that the patient was not made to relax for even breathing by taking a full, deep inspiration.

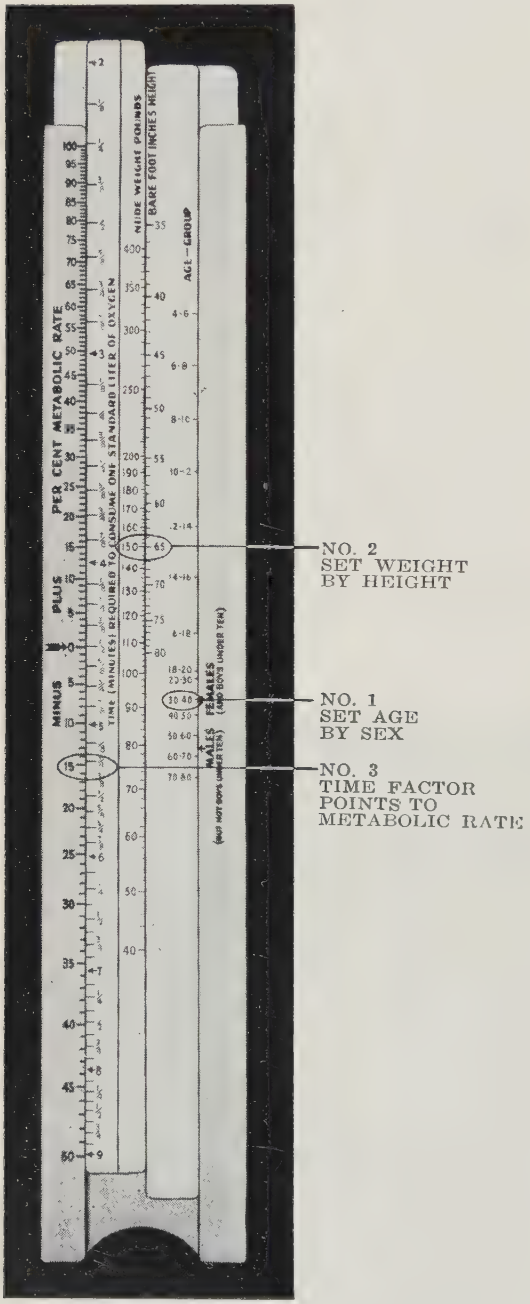


Fig. 706. Jones basal metabolism calculator. (Courtesy Jones Metabolism Equipment Co., Chicago, Ill.)

Draw a line along the top of the 2 edges of the protractor. A is the point at which the shorter or first slope crosses the printed line; B is the crossing of the longer slope. The distance between them, in inches, is the time in minutes required by the patient to consume the standard liter of oxygen.

Obtain the age of the patient, his weight without clothing, height without shoes, and sex.

Read off the basal metabolism rate on the automatic calculator (Fig. 706).

Determination of liter thrust of pen

When a liter of oxygen is discharged into the bellows, the pen moves outward by the amount of the expansion of the bellows. This is called the liter thrust of the pen. Measure a liter of oxygen in the usual way. Do not have the apparatus connected to a patient for this part of the procedure.

Next open the 3-way valve and pull the bellows carried by the hand to a point such that the pen tip is about ¾ in. inside the printed line of the tracing sheet; then close 3-way valve to hold the bellows at that point. Let the clock plate run to trace a short line (X) to show this position of the pen tip. Stop the clock plate.

Discharge the liter of oxygen now in the measuring chamber, making sure the indicator swings from the room temperature point on the gauge scale backward all the way to within ⅛ in. of the self-verifying zero of the gauge. The self-verifying zero is a short, black calibration mark somewhere near and slightly above the word "caution" at the edge of the gauge dial. If the indicator does not make this full swing, a liter of oxygen was not delivered to the bellows.

After all of the oxygen has gone into the bellows, i.e., after the pen has been thrust out as far as this liter pushes it, again let the clock run to trace another short line (Y) to show its new position. The distance between (X) and (Y) is the "liter thrust."

This part of the procedure should be done independently of the test, i.e., any time after or before the test. It is done only for the purpose of adjusting the rulers of the protractors and occasionally as a checkup to see if the protractor rulers are still adjusted to equal the distance of the liter thrust.

To adjust the rulers of the protractor to fit this liter thrust, release the knurled nuts of the short arms of the protractor; then move the rulers closer in or farther apart until the upper edge of one ruler coincides with (X) and the upper edge of the other ruler coincides with (Y). Adjust both ends of the protractor so that the upper edges of rulers equal the distance from (X) to (Y) throughout the entire length of the protractor; then tighten the knurled nuts to hold the rulers to that adjustment. At sea level and 25° C. this liter thrust of the pen is approximately $1\frac{7}{16}$ in., and for each 1000 ft. elevation above sea level this liter thrust is increased about $\frac{1}{16}$ in. For example: At about 6000 ft. above sea level the liter thrust would be $1\frac{7}{16}$ in. plus $\frac{6}{16}$, or $1\frac{13}{16}$ in. This serves as a means of determining whether or not the standard liter is actually delivered regardless of the barometric pressure changes caused by changes in elevation above sea level.

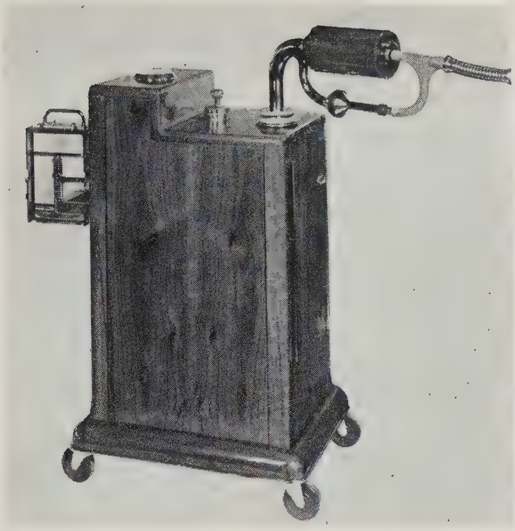

Fig. 707. Jones air basal metabolism instrument. (Courtesy Jones Metabolism Equipment Co., Chicago, Ill.)

Having determined the liter thrust for the sea-level elevation of the locality, this thrust is approximately constant, and thereafter it is unnecessary to adjust the rules of the protractor to equal the liter thrust, except as an occasional checkup.

JONES DOUBLE BELLOWS MOTOR-BASAL

This apparatus differs from the Jones motor-basal in that there are 2 bellows instead of 1 (one inside the other). The larger of the 2 bellows has exactly twice the cross-section area of the smaller bellows.

By means of a conversion valve a single turn converts the apparatus to either a small bellows or a large bellows hookup.

The smaller bellows hookup is used on a small-sized patient, who would be connected to the apparatus for an unnecessarily long period if a large capacity bellows were used. The large bellows hookup is used on a large-sized patient, who would be connected to the apparatus a relatively short time if a small bellows were used. Thus the capacity of the apparatus is adjustable to the size of the patient.

JONES AIR BASAL METABOLISM INSTRUMENT

The Jones air basal metabolism instrument utilizes air instead of oxygen in determining the BMR. Different volumes (800-2285 ml.) are obtainable, permitting the examiner to chose the volume best suited for the particular patient. Two timer speeds are also available.

Operating instructions

Take the patient's pulse and temperature and record.

Sweep out the used air of the previous test by taking hold of the sweep-out stopper and lifting the air-sweep up and down with about 2 or 3 full strokes of moderate speed, each up and each down stroke taking about 2 sec.

Adjust the elevator assembly to the correct height so that the mouthpiece is in the proper position for insertion.

Select the volume connection to be used in the preliminary test by referring to the table "For Preliminary Test" on the reverse of the slide rule calculator. Insert the volume pin in the hole in the T-bar corresponding to the volume selected. The push button on the side of the recording instrument should be at the IN position (1 in./min.) for this preliminary test.

Rest the sweep-out stopper on the rim of the sweep-out opening (in center of cabinet top).

Apply the nosepiece, making certain that there is no leak.

Insert the mouthpiece. The patient has access to free breathing through the sweep-out opening. To get patient to relax at the beginning of the test and to overcome the tendency to erratic breathing, have the patient take one deep, forced, full inspiration and then exhale and relax the arms and shoulder muscles for normal, even breathing.

Take hold of the knob at the top edge of the bellows panel and pull the panel out as far as it will come. While holding the bellows panel out with one hand, insert the sweep-out stopper in position with the other hand; then release the bellows panel. (In high altitudes, 4000 ft. or more, it may prove desirable to insert the sweep-out stopper at the beginning of expiration.)

Push the sweep-out stopper in a slightly slanted position to permit slow leakage of air past the stopper, while the outermost swing of the rocker stylus slowly recedes to the desired beginning point of the tracing sheet, which is about 3-4 lines farther out than the lines corresponding to the line or space pointed at by the VoluMeter indicator; then straighten the sweep-out stopper to gas-tight position, pressing down slightly.

Wait about 1 min.; then bring the rocker stylus and the T-bar stylus against the paper by turning the knurled knob for each stylus so as to bring the tip of each in contact with the paper.

Start the timer by operating the switch on top of it. Observe that the timer plate is actually descending. Continue the test until the graph completely crosses the midline.

Stop the timer, release each stylus, and remove the test chart. Remove the mouthpiece; then remove the nosepiece after checking to make certain a leak did not develop during the test.

To use the graph

Refer to the reverse side of the slide rule calculator for directions for determining "minutes per liter."

Using the table "For Repeat Tests"' decide whether a better volume connection could be used for a repeat test.

If examination of the graph reveals irregular breathing, a repeat test should be performed in which the volume is doubled, and the timer speed is halved (by pulling out the button on the timer).

At least one repeat test must always be made; the preliminary test alone is never sufficient.

Take and record the patient's pulse.

To prepare for the next test, take hold of the sweep-out stopper and lift the air-sweep up and down with about 2 or 3 full strokes of moderate speed, with each stroke taking about 2 sec.

If the apparatus is to be used again immediately, rest the sweep-out stopper on the rim of the sweep-out opening and proceed again as above. If the apparatus is not to be used immediately, leave the sweep-out stopper resting on the rim of the sweep-out opening as a means of hanging the sweep-out rod. This permits the air chamber to be ventilated.

Calculations

After determining the "minutes per liter," determine the BMR by reference to the opposite face of the slide rule calculator.

Section Two

ELECTROCARDIOGRAPHY

JULIUS ELSON

The frequency with which disorders of the cardiovascular system are encountered in the practice of medicine and the importance of the electrocardiograph in the diagnosis, treatment, and prognosis of these disturbances have made it desirable to include a discussion of the important subject of electrocardiography in this book.

It is not within the scope of this section to undertake an explanation of the theories underlying electrocardiographic interpretation and all the patterns that present themselves in clinical practice. These subjects are covered thoroughly in standard texts devoted solely to the subject of electrocardiography. This section will present the principle and the use of the electrocardiograph and will point out the more important patterns, clinical applications, and pitfalls of electrocardiography.

USE OF ELECTROCARDIOGRAPH

Because the terms **electrocardiograph** and **electrocardiogram** are so often confused, it is well to point out that **electrocardiograph** refers to the recording instrument, whereas **electrocardiogram** refers to the record itself. The electrocardiograph is an instrument by means of which a visible record is made of the many minute electrical or electrochemical changes occurring in the **heart muscle** associated with its contraction. It is important to stress the point that the electrocardiogram is a reflection merely of electrical activity of heart **muscle** and not dynamic activity so that one will recognize the limitations of the clinical application of this means of diagnosis.

For instance, in valvular disease or in certain congenital malformations in which the heart muscle is not primarily involved, the electrocardiogram cannot be expected to be of help except in those cases in which secondary heart muscle changes occur, usually in the form of hypertrophy of the atrial or ventricular musculature. These secondary effects on the musculature give a clue to the primary valvular disease; but until these effects do occur the electrocardiogram is often normal in the presence of valvular disease.

The electrocardiogram may be normal even in the presence of myocardial involvement if the site of the lesion is not in the proper axis with regard to the electrocardiographic "leads."

All laboratory tests must be interpreted in the light of the clinical picture. Laboratory tests alone should rarely if ever be relied upon for making a diagnosis or determining treatment and prognosis. This is an extremely important point and must constantly be borne in mind. In the experience of many electrocardiographers, patients are often referred for electrocardiographic tracings in the belief that such tracings may give the answer to the whole question of diagnosis. Actually, so many factors can affect electrical action currents in the heart that even experienced electrocardiographers may not be able to make proper electrocardiographic diagnoses without ample clinical data. Even with this information it may be impossible to make a decision in borderline electrocardiograms because of the many variations of the normal electrocardiogram.

Whereas a normal electrocardiogram does not necessarily exclude the presence of cardiac disease, an abnormal tracing surely indicates some disorder. This disorder may be organic in nature or it may involve disturbances in the cardiac mechanism; or it may merely reflect an abnormal psychosomatic effect on the heart. Many extracardiac influences can alter the electrocardiogram. Toxic substances, either bacterial or nonbacterial, and disturbances in other organs which might affect the position of the heart in the thoracic cavity are among the factors that sometimes alter the tracing. For example, drinking cold water, emotional disturbances, and smoking may change the normal electrocardiographic pattern.

VALUE OF THE ELECTROCARDIOGRAPH

The greatest value of the electrocardiograph lies in the field of coronary artery disease in which the myocardium is involved acutely or by progressive degenerative changes. The electrocardiograph in these conditions is of great value since in many instances there are no other objective positive clinical findings.

Often in acute myocardial infarction the electrocardiogram will present a pathognomonic picture, especially if serial electrocardiograms are taken. These electrocardiograms are found to undergo characteristic changing patterns. Although acute myocardial infarction without significant electrocardiographic abnormality does occur, such a diagnosis should be made with reservation.* The diagnosis can often be made clinically, but it is a great comfort to the clinician to have the added assurance of the electrocardiographic diagnosis. This may be of vital importance to the patient also, since on occasion the symptoms may be confusing and may simulate other conditions such as an acute surgical abdomen or dissecting aneurysm. Patients have been operated upon for perforated peptic ulcer when in reality they were suffering from myocardial infarction; others have been spared needless surgery by making an electrocardiogram that disclosed the cardiac nature of the patient's symptoms.

In addition to its value in coronary artery heart disease, electrocardiography is very useful in the positive recognition of certain cardiac arrhythmias and disturbances of conduction, the exact nature of which could not be ascertained without recourse to cumbersome methods of recording venous pressures, arterial pulses, and the apex impulse. The electrocardiograph has made the certain identification of these abnormal mechanisms a simple matter.

This instrument can sometimes be of aid as a guide to treatment. Recognition of characteristic alterations of certain segments of the tracings or of clinically obscure disturbances in rhythm and conduction that have occurred in the course of treatment with certain drugs, most commonly digitalis, is often the signal for discontinuation or more cautious administration of such drugs.

Recognition of the effects of electrolyte disturbances on the electrocardiogram, chiefly those of increases or decreases of potassium, has enabled the electrocardiograph to be a useful tool in the recognition and management of such disorders.

From a prognostic standpoint, conclusions from an electrocardiogram alone are most precarious. Prognosis should be made from an evaluation of the clinical aspects of the case. For instance, the presence or absence of heart failure, which is not indicated by the electrocardiogram, is very important. A patient with myocardial infarction may show an electrocardiogram approaching a normal pattern, yet he may die of cardiac rupture, embolism, ventricular fibrillation, or heart failure.

The characteristic alterations of the electrocardiogram caused by digitalis have led to another field of usefulness for the electrocardiograph, i.e., in the standardization of digitalis glycosides, using human subjects.

PRINCIPLE OF ELECTROCARDIOGRAPHY

The science of electrocardiography was first made possible in the middle of the nineteenth century, when it was discovered that the contraction of the frog's heart was accompanied by an electric current. By connecting the outside surface of the human subject by means of electrodes to a capillary electrometer, Ludwig and Waller in 1887 demonstrated that the electrical currents in the heart could be recorded. Because of the nature of the instrument, records at that time were inaccurate, and the method was not practicable. It was not until 1903, when Einthoven applied his string galvanometer to the study of the human heart, that electrocardiography was put on a firm, clinically reliable basis. Only with an understanding of the electrocardiogram in electrical terms can one appreciate the magnitude of Einthoven's contribution to medicine.

---

*Elevation of serum glutamic oxalacetic transaminase activity is frequently important corroborative evidence in such instances (p. 129).

The electrocardiogram, as recorded by electrodes placed upon the body surface, consists of a series of impulses, each of which is of relatively short duration. The baseline above and below which these impulses fluctuate is known as the **isoelectric level.** Some of these impulses may rise from the isoelectric level to their peak in a time interval as short as 0.02 sec. while the amplitude may represent as little as 1 mv.

Furthermore, the resistance of the circuit within the patient, the **patient circuit** as measured between a pair of electrodes, averages under good conditions about 2000 ohms. On the basis of 1 mv. amplitude and 2000 ohms resistance offered by the patient, the peak power that the body generating the electrical impulses can deliver to the recording instrument would be only one-eighth of one-thousandth of one-millionth of a watt.

String galvanometer: The string galvanometer is based upon the fundamental principle that a conductor that carries an electric current and is suspended in a magnetic field will tend to be deflected from its original position by a force acting on that conductor. This force is produced by the reaction between the current and the magnetic field.

String shadow: Until a few years ago the type of electrocardiograph solely used was the "string" type, in which the current-carrying conductor is a quartz "string" about $\frac{1}{5000}$ in. in diameter (5μ), covered with a metal such as platinum. This string is suspended between the north and south poles of an electromagnet. Without stretching this platinum-coated quartz string very tightly one may time this light fiber to a sufficiently high natural frequency of vibration to produce a moving system capable of following the details of the human electrocardiogram with a satisfactory degree of accuracy.

The actual motion of the "string" through which the current from the patient passes is so small that it must be magnified 500-1000 times. This is accomplished by means of a microscope through which light is thrown by an electrical source and condenser. The magnified shadow of the "string," with all its movements, is thus projected on a camera. The recording medium, usually bromide paper, is pulled through the camera at a constant speed. A timing device is provided by a spoked wheel rotating in the path of light and periodically interrupting the light to produce timing coordinates, thus allowing measurement of the various events of the cardiac cycle.

With most timers using a rotating wheel, the fifth spoke is wider, so that every fifth vertical time line is broader than the other 4. The distance between each fine line represents 0.04 sec.; that between each wide line, therefore, represents 0.2 sec.

A piece of glass with parallel lines ruled on it is mounted just in front of the paper so that it casts fine horizontal shadows on the sensitized paper at 1 mm. intervals. The resulting horizontal lines are the coordinates by means of which the amplitude of the electrical deviations is measured.

This combination of the string shadow, the light interruptions produced by the timer, and the ruled scale for the amplitude coordinates results in a completed record in which the string movements and the time and amplitude coordinates appear as white lines on a dark background.

Leads: There are 3 main types of leads in general use today: (1) the bipolar or conventional leads, (2) the unipolar leads, and (3) the augmented unipolar leads. These leads are applicable no matter what type of electrocardiograph is used.

Bipolar leads: These are obtained by placing metal electrodes on 2 different points of the body. By convention, and because experience has justified it, these leads are recorded from the right arm, left arm, and left leg, as well as from various positions on the chest.

The lead taken from the right and the left arm is known as **Lead I;** that from the right arm and the left leg is called **Lead II;** and that from the left arm and left leg is called **Lead III.** These are the conventional bipolar leads universally used.

The chest leads are designated in a variety of ways, depending on the position of the chest electrode or **exploring electrode** and the limb electrode or **indifferent electrode.** For further clarification of certain complexes of the electrocardiogram even esophageal leads have been used; in these a specially designed electrode is passed down into the esophagus and electrocardiograms are taken with this electrode held at various levels.

In recent years the method of unipolar lead electrocardiography has been widely adopted. These leads more nearly record the absolute potential at each of the extremities as well as at the exploring electrode on the chest wall.

Unipolar leads: There are 2 types of unipolar leads: (1) the Wilson type and (2) the generally adopted augmented unipolar limb leads. Unipolar leads are described on p. 1993.

The use of "unipolar" limb and chest leads has become general. The connections are made as for the "central terminal" (V) leads of Wilson, described on p. 1996. Three records are then made, with the precordial electrode placed on the right arm, on the left arm, and on the left leg, respectively. A discussion of the theoretical considerations and clinical applications of the unipolar leads can be found in *Unipolar lead electrocardiography* by Emanuel Goldberger[1] and many other publications devoted to this subject.

The choice of the lead or electrode pair to be recorded is made by a **lead selector** switch on the panel of the instrument.

Standard records: Records made at different times or by different instruments, in order to be comparable, must record the same electrical quantity according to the same scale. The unit of measurement is the millivolt, and the scale of recording is 1 cm., which corresponds to 1 mv. developed at the electrodes.

To standardize an electrocardiograph the sensitivity of the recording device is so adjusted that it responds to a 1 mv. current by deviating 1 cm. from the base line or zero level. The 1 mv. standardizing current is introduced from a source built into the instrument.

Before standardizing a string galvanometer type of electrocardiograph it is necessary that the patient, the galvanometer, and the standardizing circuit all be connected. Resistance in the patient circuit varies from time to time and from lead to lead; for this reason it is necessary to restandardize the instrument for each lead while the string and patient circuit are connected and the string is responding to cardiac action currents. This is not necessary in the modern direct writing electrocardiograph.

Skin resistance: The patient circuit resistance derived from the skin must be kept low, 2000 ohms or less.

Skin resistance is lowered by the application of some form of electrode paste or jelly to the skin at the site of the electrode. This paste contains an electrolyte; when rubbed into the skin with a little excess on the electrode, it reduces the resistance between the electrode and the tissues beneath the skin from a value of many thousands of ohms to about 1000 ohms.

Electron tube amplifier: Another type of electrocardiograph was later developed and is now in common use. It employs the electron tube amplifier principle. This type of instrument makes use of an amplifying circuit which greatly magnifies the tiny cardiac currents and includes a very large resistance to prevent overshooting. One such type instrument employs a very small mirror attached to the movable element or coil in the magnetic field. This mirror is so arranged that by its motion it swings either a spot of light or a field of light with a shadow in it across the face of the recording camera.

An advantage of this type of apparatus is that it is not necessary to standardize the instrument with the patient switched in. This enables the operator to make the tracing without any disturbance to the recording beam other than that caused by its response to the standardizing pulse. Still another advantage is that standardization need not be repeated after the patient is switched in, nor for each of the leads, as in the case with the string electrocardiograph. These advantages are possible because of the relatively high resistance and current in the amplifying circuit as compared with the slight resistance caused by the skin or by polarization. All of these electrocardiographs require the use of photographic paper or film for recording the electrocardiogram.

Direct writing electrocardiographs: Direct writing electrocardiographs have in most places supplanted the photographic types of instruments. These apparatus, by use of high-power radio tube amplifiers, have made possible direct, immediately visible recordings of the electrocardiogram. In addition to this very real advantage, the need for photographic materials and a dark room is obviated.

VECTORCARDIOGRAPHY

This method of electrocardiographic study is not new, but in the past few years it has been studied with greatly renewed interest and emphasis. There are 2 ways of analyzing electrocardiograms. One is the conventional or "pattern" method, with which we are largely concerned in this chapter, and the other is the "vector" method of analysis. In the former we learn by experience and correlation with pathologic specimens the various electrocardiographic patterns associated with disease entities, whereas in the latter the many electrical forces developing and receding in the cardiac cells are represented by an arrow, the length of which measures their resultant magnitude and the tip, their direction at any given instant. These arrows, representing the magnitude, direction, and sense of this force at a given instant, will vary from moment to moment as the impulses travel through the heart fibers in the various directions. These "instantaneous vectors" can be constructed from the conventional electrocardiogram taken to include the 3 bipolar limb leads, the 3 unipolar limb leads, and the 6 unipolar chest leads. By connecting the tip of each arrow representing the vector of electrical potential from moment to moment, a "loop" is formed, graphically depicting the direction of the vectors throughout the cardiac cycle. These vector loops can be much more accurately depicted by means of an oscillograph connected with the body by means of specially placed electrodes.

This method of interpretation has the advantage of not requiring memorizing of the numerous patterns with their wide range of normality; one merely visualizes abnormalities in direction and magnitude in the electrical potentials.

The **spatial vectorcardiogram** has shed light on a number of electrocardiographic problems in which the information derived from the electrocardiogram was obscure.

It has helped in the diagnosis of left ventricular hypertrophy in which the spatial vectorcardiogram usually has a typical appearance. The electrocardiogram in many cases of left ventricular hypertrophy may be normal or have alterations of doubtful significance.

In the detection of myocardial infarction in the presence of left bundle branch block, the spatial vectorcardiogram is quite useful since the electrocardiographic diagnosis of myocardial infarction is usually impossible in this situation.

In some cases of left ventricular hypertrophy, the QRS complex may be unusually prolonged to 0.12 sec. or more, creating confusion as to whether left bundle branch block may be present. The spatial vectorcardiogram will help in the differential diagnosis.

In many cases of left ventricular hypertrophy, diffuse myocardial damage may be present without evidence from the electrocardiogram. The spatial vectorcardiogram may give such a clue.

In myocardial infarction that is old or healed or in cases in which the electrocardiographic tracing is atypical, the diagnosis may be very difficult. The vectorcardiogram may be useful in such cases.

There are serious disadvantages to the routine adoption of spatial vectorcardiography as a routine method of study in clinical practice. The chief of these perhaps is the difficulty at this date of determining time relationships of the various phases of the cardiac cycle and the inability to identify arrhythmias accurately. Vectorcardiography should still be regarded as an experimental method, and until the objections mentioned above are obviated and until some standard method of lead placement is generally agreed upon, it perhaps should not be adopted as a routine method in clinical practice.

Chapter 110

Use of the electrocardiograph

JULIUS ELSON

Detailed descriptions of all the electrocardiographs on the market and their step-by-step operation will not be given since they vary in certain respects from each other. Complete information can be found in the brochures that each manufacturer supplies with the instrument. Because direct writing instruments have largely supplanted electrocardiographs that employ photographic methods, only the operation of a typical commonly used direct writing electrocardiograph will be described.

All electrocardiographs are delivered in proper working condition and are accompanied by a pamphlet giving complete detailed instructions for operating the instrument. Since maintenance and care of the instrument vary with the type of apparatus used, it is best to refer to these pamphlets for such information. In choosing an electrocardiograph it is advisable to bear in mind the availability of service for it.

VISO-CARDIETTE, MODEL 100*

One of the most commonly used types of direct writing instrument is the Viso-Cardiette. The Viso-Cardiette produces an electrocardiogram or graphic record of the electrical waves (action potentials) generated by the beating of a patient's heart. The record reads from left to right to represent the passage of time, the standard speed being 25 mm./sec. The paper is ruled in 1 mm. squares. The light vertical lines on the graph mark off 1/25 sec., or 0.04 sec., per square, and the heavy lines 1/5 sec. (0.2 sec.).

The vertical deflections of the recorded tracing show the electrical changes taking place in the heart. Each mm. square between the lighter horizontal lines represents 1/10 mv.; each square within the heavier horizontal lines represents ½ mv. The short lines above the graph printing indicate 3 sec. intervals.

Complete operating instructions, including checking the shipment and the instrument, accompany the instrument on purchase.

Operation of the Viso-Cardiette, Model 100

The Viso-Cardiette must not be operated on direct current or on alternating current having a frequency different from that marked on the serial name plate. Although 50-cycle current will not damage a 60-cycle instrument, it will make the recording paper run at a speed equal to 5/6 of the rated value. Direct current will blow the fuse in the instrument.

Remove all watches from the patients and the operator unless they are of the nonmagnetic variety. Watches may be easily demagnetized by gradual withdrawal from the center of an aircore coil carrying alternating current.

Zero temperatures will cause no damage if the Viso is warmed before operation by turning the power switch to ON for ½ hr. or more. Avoid high temperatures, such as are caused by direct sunlight. Avoid knocks and jars when carrying.

Preparation of instrument: The Viso-Cardiette should be placed on a table or other firm flat support, with the 2 cover latches facing the operator. Pull down on the top of both latches to release and swing back the cover. See that the power switch Off-On-Run is turned to OFF. Open the transparent cover and read the power requirements (volts and cycles) stamped on the name plate, visible below the hinge at the right. See that the electric power matches these requirements. Do not use any Viso on a direct current power line or on a 25-cycle power line.

Be sure that there is sufficient Permapaper in the Viso; then close the transparent cover.

---

*This section is abstracted from a pamphlet furnished by the Sanborn Co., Waltham, Mass., and is published with their permission.

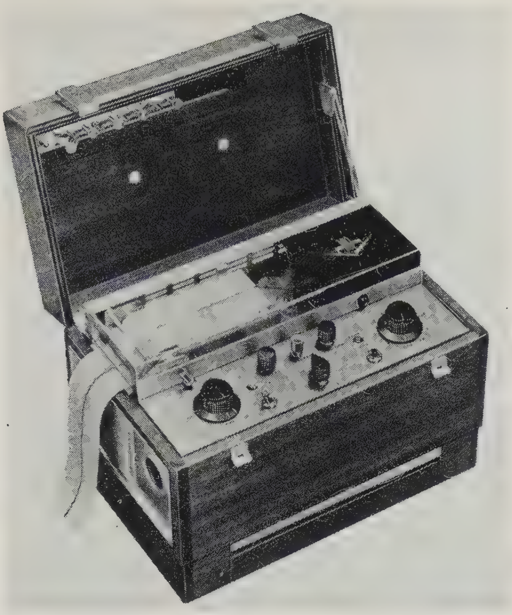

Fig. 708. Sanborn Viso-Cardiette, model 100. (Courtesy Sanborn Co., Waltham, Mass.)

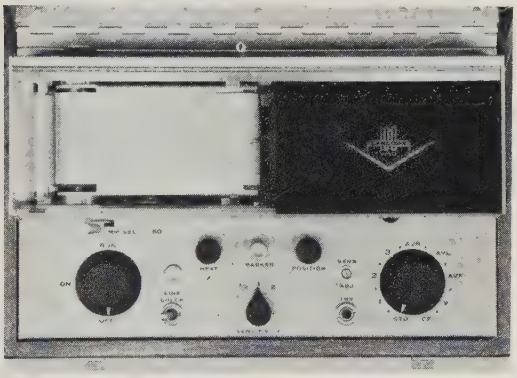

Fig. 709. Top view, Sanborn Viso-Cardiette, model 100. (Courtesy Sanborn Co., Waltham, Mass.)

Remove the power cord from the pocket in the case cover and plug the female end of the cord into the Viso power receptacle on the left side of the cabinet; plug the other end of the cord into a wall socket or other power outlet.

Turn the lead selector switch, at the extreme right side of the panel, to the small dot between STD and 1.

Turn the power switch Off-On-Run, at the extreme left side of the panel, to ON. The red indicator will light.

Let the apparatus warm for at least 2 min.

Turn the position control back and forth and watch the writing arm. It will be near the top of the Permapaper when the control is to the right (clockwise) and near the bottom of the paper when the control is to the left (counterclockwise).

Move the writing arm by means of the position control to the center of the paper and leave it in this position.

Turn the lead selector switch to STD.

With one hand clear of the apparatus, use one finger to touch the top of the Line Check button, which is directly above the Line Check switch, to see if touching this button will make the writing arm vibrate. Then throw the Line Check switch to the other position and touch the top of the Line Check button again to see if the writing arm will vibrate. Leave the Line Check switch in the position where the writing arm will **not** vibrate when the Line Check button is touched.

To test the paper drive, turn the power switch Off-On-Run back and forth between ON and RUN a few times. The paper will feed out of the apparatus while the switch is at RUN.

With the switch at RUN, move the speed shift lever 25 mm./sec.–50 mm./sec., between 25 and 50 a few times. The paper speed will be 25 mm./sec. while the lever is at 25 and 50 mm./sec. while the lever is at 50.

Turn the power switch back to ON. Leave the speed shift lever at 25.

To test the stylus heat, turn the power switch to RUN. Turn the stylus heat control clockwise until the stylus is a dull red and then turn fully counterclockwise. Watch the base line (black trace) formed by the hot stylus at the end of the writing arm. The base line will flood when the knob is to the right (clockwise) and the stylus is red hot. The base line will be less black and not flooded when the knob is to the left (counterclockwise) and the stylus has less heat.

Adjust the stylus heat controls for a firm, dense, black base line, with clear, well-defined edges. Once set, this setting is usually good for the 50 mm./sec. speed, but a slight adjustment may be necessary.

Turn the power switch back to ON.

To test the marker button, turn the power switch to RUN.

Press the marker button a few times, looking for the series of marks that appear in the margin of the Permapaper. Turn the power switch back to ON.

1 MV button:

Turn the Sensitivity switch to 1. Turn the power switch to RUN. Turn the lead selector switch to STD.

Press the 1 MV button and then release it. Repeat a few times. The base line will deflect each time, to form a standardization pulse on the paper. Turn the power switch back to ON.

Standardization:

Turn the power switch to RUN.

Turn the Sens Adj control back and forth with a screwdriver, furnished with the apparatus, while recording a series of standardization pulses with the 1 MV button. Notice the height of these pulses. The standardization pulses are largest when the Sens Adj control is to the right (clockwise) and are smallest when the Sens Adj control is to the left (counterclockwise).

Set the Sens Adj control for standardization pulses which are exactly 10 small divisions or 2 large divisions high.

Turn the Sensitivity switch to ½. Press the 1 MV button a few times. The standardization pulses will be 5 small divisions high.

Now turn the Sensitivity switch to 2. Press the

1 MV button a few times; the standardization pulses will be 20 small divisions high. Return the Sensitivity switch to 1.

Turn the power switch back to ON.

To turn off Viso:

Turn the Lead Selector switch to the small dot between STD and 1. Turn the power switch to OFF.

Unplug the power cord from the power outlet, unplug the other end from the Viso, coil it up, and replace in pocket of the case cover.

Check to see that the power cord and the patient cable are in the case cover pockets and that the accessories are neatly packed away in the Viso drawer and slide on the inside of the top cover; then close the case. Do not force the cover.

To prepare Viso for operation:

Combine all the preceding steps into one sequence, and practice this sequence until the preparation can be made without referring to the directions.

Open the Viso. Check the power required against the power available.

Set the power switch to OFF and connect the Viso to the power with the power cord.

Turn the lead selector switch to the dot between STD and 1. Turn the power switch to ON. Warm for 2 min. See that there is Permapaper in the Viso.

Turn the lead selector switch to STD. Perform the line check (writing arm does not vibrate) with the Line Check button and switch.

Center the writing arm on the paper with the position control.

Turn the power switch to RUN with the speed shift lever at 25. Adjust the base line density with the heat control.

Set the Sensitivity switch to 1. Record a standardization pulse, 1 MV switch, and a marking indication, marker button. Inspect the recording for base line quality, for a definite marking indication at the margin of the Permapaper, and for a standardization pulse which is exactly 10 small divisions high. The Sens Adj control should not have to be reset if it was properly set at the beginning.

Turn the lead selector switch to the dot between STD and 1.

Preparation of patient

Have the patient lie on an examining table or preferably a large comfortable cot or bed.

See that the patient is warm, relaxed, and not apprehensive. A few words of reassurance will be helpful.

Expose the patient's forearms and the calves of both legs.

It is most important that there be good contact between the skin and the electrode. This is obtained with Redux.* Press ½ in. of Redux from the tube onto a spot on the inner side of the patient's forearms, halfway between the wrist and the elbow. Do the same on the inner side of each calf.

Using a gauze pad or the corner of a cloth towel, or a tongue depressor, rub the Redux into the skin, covering an area of about 2 sq.in. Rub until a slight reddening of the skin is noticeable; 10 strokes usually suffice.

Connecting patient to apparatus

After rubbing, leave a slight moist residue of Redux.

Fasten the electrodes over this residue with the rubber straps. The strap hooks over the pin. Draw the strap tight enough for firm contact but not so tight as to cause discomfort.

Remove the patient cable from the pockets of the case cover.

Connect the ends of the patient cable leads to their corresponding electrodes, screwing them in place tightly with the thumbscrew.

RA lead (white)—fastens to the right arm electrode.

LA lead (black)—fastens to the left arm electrode.

RL lead (green) fastens to the right leg electrode.

LL lead (red)—fastens to the left leg electrode.

C lead (brown) is ignored for the present; coil it up, out of the way.

Turn the lead selector switch to the dot between STD and 1.

Plug the free end of the patient cable into the blue socket at the right end of the apparatus. The slot at the end of the patient cable plug mates with the projection inside the patient cable socket.

Disconnecting patient

See that the lead selector switch is set to the dot between STD and 1. Disconnect the patient cable from the socket.

Disconnect the ends of the patient cable leads from the electrodes.

Release the rubber straps and remove the electrodes.

With a damp towel sponge the Redux from the patient's arms and legs.

Wash the electrodes with soap and hot water. Rinse well. Do not use steel wool or any other abrasive.

Wipe any Redux from the rubber straps and the patient cable tips with a damp towel.

After drying, place the patient cable, rubber straps, and electrodes in their proper storage place and close the cover.

Taking the various leads

Lead I:

Prepare the apparatus and the patient.

Turn the lead selector switch to 1. The writing arm will flicker part way across the paper about once each second.

Turn the power switch to RUN. Press the marker button once briefly. Run a few inches of Permapaper through the Viso.

The recording should show a dense, black base line with clear, well-defined edges, a steady recording, which does not wander up and down on the paper, and a definite, unmistakable lead marking. If the record does not fulfill these requirements, more practice is needed before taking the electrocardiogram of a patient.

While recording the lead, insert a standardization pulse into the flat section of the electrocardiogram.

---

*Redux is a special jelly made by the Sanborn Co., Waltham, Mass.

Leads II, III, aV_R, aV_L, aV_F: These are taken as Lead I, except that the lead selector switch is turned to the proper lead. Lead II is marked with 2 short lead marks, Lead III with 3 short lead marks, Lead aV_R with 1 long lead mark, Lead aV_L with 2 long lead marks, and Lead aV_F with 3 long lead marks. All leads must show standardization, which is accomplished, as explained above, by inserting a standardization pulse.

The tracing should show a dense black base line with clear, well-defined edges; a prominent standardization pulse inserted just after the T wave so that the standardization will appear on a flat section of the recording; a definite, unmistakable lead marking for each lead of the recording; and a steady recording that does not wander up and down on the paper.

Chest lead:

Prepare the Viso-Cardiette for operation.

Prepare the patient, attaching the 2 arm electrodes and the 2 leg electrodes.

Prepare the locations on the chest wall as shown in Fig. 710.

Apply Redux and rub until the skin reddens. Important: Do not allow the Redux at one chest position to contact the Redux at another chest position, since this would interfere with and spoil the electrocardiogram. Prepare only enough area with Redux at any one location to match the area of the electrode.

Snap the chest electrode handle onto the electrode post and fasten the chest electrode to the C (brown) patient cable tip. If preferred, the Welsh vacuum cup electrode may be used in place of the standard electrode and handle.

Grasp the end of the chest electrode handle. Hold the chest electrode against one prepared location on the chest wall.

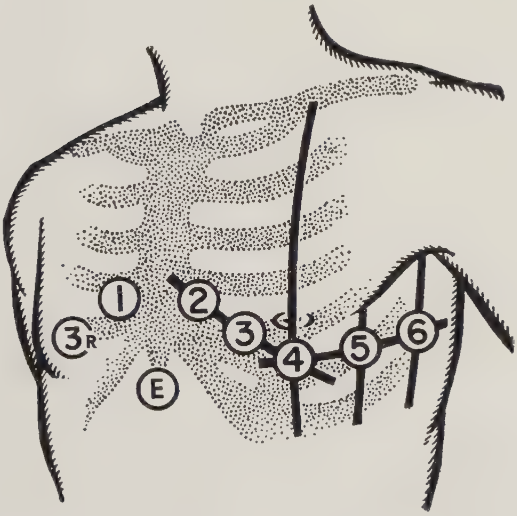

Fig. 710. Chest electrode standard positions for chest leads. **1,** Fourth intercostal space, at right border of sternum; **2,** same interspace, at left sternal border; **3,** midway between positions **2** and **4; 4,** fifth intercostal space, midclavicular line; **5,** same level as **4,** in anterior axillary line; **6,** same level as **4** and **5,** in midaxillary line. (Courtesy Sanborn Co., Waltham, Mass.)

Turn the lead selector to V, standardize, insert one extra-long lead mark, and record a few inches of the electrocardiogram.

To take the various chest leads, place the chest electrodes at the various sites as indicated in Fig. 710.

Replacement of Permapaper: Every roll of Permapaper has a star marked on it 30 ft. from the end as a warning that the paper is about to run out. Replace the paper as follows:

Turn the power switch to OFF. Lift the transparent cover at the rear of the Viso panel.

Press the lock lever to the right to unlock the writing table. This lever is located near the center of the transparent cover hinge.

Lift up the right end of the writing table and swing it back as far as it will go and then remove any unused paper. Clean any deposits from the writing plate at the end of the writing table with a damp cloth.

Mount the new roll of Permapaper on the spindle beneath the end of the writing table. The paper should unwind to the right, off the top of the roll, as the operator faces the apparatus.

Unroll about a foot of the paper and lay it back over the rubber brake roll.

Lift up the pressure roll at the left end of the writing table with the lift bar. Feed the end of the paper under the pressure roll and release the lift bar. Pull on the paper to take up the slack.

Be sure that the paper does not catch on the stylus while pressing the writing table back in place. Press the lock lever to the left.

Turn the power switch to RUN for a few moments to check for proper loading and to allow the paper to assume its proper tracking position.

Special electrocardiograms: Most electrocardiograms are recorded with the Sensitivity switch at 1. If the deflections of any recorded lead should be too large to fit conveniently on the Permapaper, set the Sensitivity switch to ½, press the 1 MV button, and then record the lead, which will then appear at ½ amplitude. If the recorded lead is too small for convenient viewing on the paper, set the Sensitivity switch to 2, press the 1 MV button, and then record the lead, which will then appear at twice the amplitude.

Bipolar chest leads: The CF bipolar chest lead is available by use of the lead selector switch.

The CR and CL bipolar chest leads are available by connecting the tip of the LL (left leg) lead wire to the chest electrode, located at its desired position on the chest. Then set the lead selector switch to lead 2 position for a CR recording, or set the lead selector switch to lead 3 position for a CL recording.

Maintenance, adjustments, and trouble shooting

Power fuse replacement: If the Viso will not operate at all, one or both of the power fuses may be blown. The 2 fuses are located behind the removable plate on the left-hand side of the Viso. To replace, remove the plate, turn the fuse knob ½ turn to the left, and pull out. Remove the blown fuse from the cap, replace with the new fuse, reinsert in place, and screw the fuse knob back in place; then replace the plate. The replacement is 0.6A slow blow fuse Sanborn No. 26 B-8.

Patient fuse replacement: If the Viso is inoperative at all lead positions (stylus goes off-scale, then drifts back on-scale 30 sec. later, with no EKG pulses, apparently normal on STD position), the patient fuse may need replacement. This fuse is located on the right-hand side of the Viso cabinet, next to the patient cable socket. To replace, turn the fuse knob ½ turn to the left and pull out. Remove the blown fuse, replace it with the new fuse, and screw the fuse knob back in place. The replacement fuse is 5 ma. fuse Sanborn No. 26A-1.

Indicator light replacement: If the Viso operates normally, but the red plastic lens will not light, the indicator lamp, visible upon lifting the transparent cover, will not light, this indicator will need replacing. To replace, lift the transparent cover, turn the lamp ½ turn to the left, insert the new lamp, press in firmly, and turn ½ turn to the right to fasten in place. The replacement lamp is Sanborn No. 30A-20.

Writing arm maintenance and replacement: The writing arm may need maintenance or replacement when a dense, sharply defined base line on both top and bottom of the tracing cannot be obtained at any position of the heat control. Turn off the apparatus, lift the transparent cover, and inspect the stylus ribbon to see if it is not broken or bent or tilted so that it is not flat against the paper. Check to see that the stylus writing surface is in contact with the paper.

If the stylus ribbon is not flat against the paper, loosen the writing arm clamping screw, tilt the writing arm to bring the stylus writing surface flat against the paper, and then tighten the clamping screw again.

If a satisfactory base line still cannot be obtained, loosen the writing arm clamping screw and lift out the writing arm. Inspect the writing surface of the stylus. If it is dirty, clean it by gently scraping it with a sharp instrument or by rubbing with No. 00 or finer sandpaper. Never use steel wool. Replace the writing arm and tighten the clamping screw.

Turn on the Viso and check again for a dense, sharply defined base line at some position of the heat control. If the base line is still not satisfactory, tighten the stylus pressure adjusting screw by turning clockwise until the stylus barely clears the Permapaper. Then slowly loosen the adjusting screw by turning counterclockwise for a satisfactory tracing, which should occur within the first full rotation of the screw.

If a satisfactory base line still cannot be obtained, return the stylus pressure adjusting screw to its original setting and loosen the clamping screw that holds the stylus in place. Remove the defective writing arm and tighten a new writing arm in its place.

Somatic tremor: Somatic tremor is identified by a fuzzy, totally irregular base line. It is usually caused by a tense or uncomfortable patient. Check the patient's comfort and reassure him. See that the electrode straps are not too tight.

Alternating current interference ("AC"): Alternating current interference is identified by regular sawtooth base line. The probable cause is poor electrode technic or poor patient location. Repeat the line check, tighten the thumbscrews, and move the patient to another part of the room.

Wandering base line: Wandering base line is identified by rhythmic up-and-down motion of the base line. It is probably caused by motion of the patient or the electrodes. Check the patient for comfort and relaxation. See that the cable does not pull on the electrodes.

Irregular base line: Irregular base line is identified by a rough, jagged, irregular base line. The probable cause is poor electrical contact or metallic particles under the electrode. Wash the patient's skin, tighten the thumbscrews, clean the electrodes, and avoid perspiration.

Lubrication: The Sanborn Model 100 Viso is lubricated for life at the time of manufacture. Do not lubricate except as directed by an authorized Sanborn Company representative.

Balance control adjustment: After adjusting the stylus pressure, press the 1 MV button intermittently and then inspect the upper left-hand corner of each pulse. This corner may have a spike (underdamped), may be rounded (overdamped), or may be square (adjusted). If spiked, turn the damping control R 68 on the bracket behind the galvanometer magnet, lift the Lucite cover, and adjust for a square corner.

Trouble shooting: In most cases of trouble the fault is located in the operating technic, or the trouble may be caused by some easily replaced item such as a fuse. The trouble-shooting procedure below will save time in curing the difficulty:

1. Does the Viso work at all? See that it is plugged into a live power socket of the right voltage and frequency. Try replacing the power fuse behind the shield at the left-hand end of the cabinet.

2. Does the Permapaper refuse to feed properly? Most paper feed problems can be cured by taking out the paper and reloading. See that the power switch is turned to RUN.

3. When switching to a lead position, does the stylus go off-scale and drift on-scale 30 sec. later, with no EKG pulses, Viso apparently normal on STD position? Try replacing the patient fuse next to the patient cable socket.

4. Do one or more controls fail to work properly? Repeat the entire process of preparing the apparatus preliminary to use.

5. Is the recording of the electrocardiogram unsatisfactory? Some suggested cures are listed above.

6. Does it seem impossible to adjust for a dense, black, sharply defined base line? See the information on writing arm maintenance and repair.

7. If these procedures still do not cure the difficulty, then it is best to consult with the Sanborn Company, describing the problem, stating whether it is intermittent or continuous, giving the serial number of the Viso, and sending a sample of the defective recordings.

Chapter 111

Unipolar lead electrocardiography

JULIUS ELSON

In the last 20 yr. there has been a steadily increasing interest in and awareness of the importance of unipolar lead electrocardiography so that at present this method has been universally adopted. These leads have been shown to be advantageous for a number of reasons. Among the most important is the light that they have thrown on the significance of abnormalities of the Q waves, particularly in Lead III in the diagnosis of posterior wall infarction, the differentiation of pulmonary artery obstruction from posterior myocardial infarction, the diagnosis of bundle branch block, right ventricular hypertrophy, and the detection of abnormalities when the standard lead electrocardiogram is normal or shows questionable changes. The effect of changes in position of the heart are particularly demonstrable with these leads.

METHOD OF TAKING UNIPOLAR LEADS*

A unipolar lead is one that represents the heart voltages present at **one** particular spot on the body with respect to a nonfluctuating reference point. This reference point is secured by connecting the limb electrodes together through 3 equal resistances of 5000 ohms or more; the junction is the reference point or central terminal, which is usually embodied in the lead selector of the electrocardiograph or in a special switching box.

The electrodes placed on the body are then paired, in turn, with this reference point or central terminal to secure the unipolar leads which represent the actual voltages present at these single points on the body.

With limb leads, however, these voltages may be rather small, so that special steps must be taken to secure a record with complexes of sufficient height or amplitude for easy and accurate measurement.

Leads V_R, V_L, V_F: Leads V_R, V_L, and V_F are unipolar limb leads in which the pairing is achieved by placing an additional "exploring" electrode (normally attached to the C wire of the patient cable) on the limb being measured, slightly removed from the electrode already in place. Do not allow electrode jelly to communicate between electrodes.

With the lead selector switch placed on V, a unipolar limb lead will be secured. Special steps must be taken to produce a record with complexes of "readable" amplitude. Therefore, in taking these leads it is customary to increase the sensitivity of the electrocardiograph by 50%, or from 1 to 1.5 cm./mv. Allowance must be made for this increase since the amplitude of the waves will show a voltage of 1.5 times that which is actually present at the location being recorded.

"R" designates the right arm, "L" the left arm, and "F" the left leg (or foot).

Leads aV_R, aV_L, aV_F: Leads aV_R, aV_L, and aV_F are also unipolar limb leads and now are the ones most widely used. They are referred to as "augmented" unipolar limb leads.

No special placement of electrodes is required, nor is it necessary to change the sensitivity of the electrocardiograph to secure the increased or augmented height of the complexes. All necessary functions are performed automatically within the instrument or within a special lead selector box interposed between the patient and the electrocardiograph.

Turn the switch to the desired position—aV_R, aV_L, aV_F—to obtain the augmented unipolar limb leads.

The terminal letters designate the extremity and are paired with the central terminal or reference point.

Allowance must be made in measurement and interpretation for the 1.5 cm./mv. increased sensitivity.

Leads V_1, V_2, etc.: Leads V_1, V_2, etc. are unipolar chest leads. They are achieved by pairing a point on the chest wall (Fig. 710) with a neutral or zero reference point.

The subordinate numerals—V_1, V_2—are used to designate the position of the exploring electrode on the chest.

---

*With permission of Sanborn Co., Waltham, Mass. From a bulletin entitled "Nomenclature and derivation of all presently-used leads" (1953).

Leads V_{3R}, V_{4R}, etc.: Leads V_{3R} and V_{4R} are unipolar chest leads, as described above, but are taken from positions on the chest wall to the right (R) of the sternum.

High V leads: High V leads are unipolar chest leads, taken with the chest or exploring electrode at positions on the chest wall one interspace above positions V_{1-6} and designated as high V_3, high V_4, etc.

V_E or V ensiform lead: V_E or V ensiform lead is a unipolar chest lead, taken with the exploring electrode placed on the chest wall at the ensiform (base of sternum) position.

Advantages of unipolar leads: Because of the method by which unipolar leads are obtained, their patterns can be explained in terms of easily understandable principles.

Since the indifferent electrode (of Wilson) is for practical purposes zero (though not absolutely so), the actual values of the potentials at each extremity can be determined with unipolar leads. This is in contrast to the conventional bipolar leads (the Leads I, II, III and the conventional chest leads), in which the potential recorded is the **difference** in the potential generated at each of the 2 electrodes in the bipolar leads.

In general, the relationships of the standard leads and the unipolar extremity leads are such that one type can be derived from the other as follows. The pattern of Lead I would be the potential values at the left arm (V_L) minus those at the right arm (V_R). The values of the potentials in Lead II would be the potentials recorded at the left leg (V_F) minus those at the right arm (V_R). The potentials recorded from Lead III would be the values derived from the left leg (V_F) minus those from the left arm (V_L). Thus it can be seen that the 3 standard bipolar leads consist of the algebraic summation of the unipolar leads.

Unipolar limb leads are useful to localize the altered electrical activity due to lesions of the various areas of heart muscle. Thus a unipolar lead from the left arm (V_L) records the altered potentials generated by a lesion in the left lateral wall of the heart; a unipolar lead from the left leg (V_F) records the effects of a lesion produced at the diaphragmatic (posterior) surface; the unipolar lead from the right arm reflects the potential variations of the heart muscle facing the atrial and ventricular cavities. Change in position of the heart with consequent altered relationships of the positions of these various regions of the heart with respect to the unipolar electrodes would alter the configurations of the electrocardiographic patterns in certain well-defined ways according to whether the heart is vertical, horizontal, or rotated either clockwise, counterclockwise, or backward or forward. It is beyond the scope of this section to describe and illustrate the different patterns of the unipolar leads according to the various positions of the heart and the modifications of these patterns produced by disease processes. This phase of electrocardiography has been thoroughly described in many books devoted to this subject.

Chapter 112

Interpretation of the electrocardiogram

JULIUS ELSON

THE NORMAL ELECTROCARDIOGRAM

The electrical activity in the heart muscle that precedes each contraction of the heart produces deviations in the electrocardiogram which are in general similar for all normal electrocardiograms. Nevertheless the electrocardiogram of every individual exhibits minor variations which are almost as characteristic for that individual as are his fingerprints. This is true only in so far as no alteration in the physiologic or anatomic state of the heart has occurred. The many variations of the normal electrocardiogram must be studied in order that proper interpretation of tracings may be made. Not infrequently erroneous conclusions with all their serious implications have been drawn by inexperienced persons who attributed minor deviations within the normal limits to organic heart diseases. Mistakes have also been made in the improper differentiation of abnormal tracings due to altered physiologic states from those due to actual organic disease.

Waves

The series of waves seen in electrocardiograms of normal heart cycles was arbitrarily named by Einthoven as the P, Q, R, S, T, and U waves. This is the conventional terminology that has been universally adopted.

The form, amplitude, and direction of the different waves vary in the different leads. The amplitude of the deflections in Lead II is equal to the sum of the amplitudes in Leads I and III. This knowledge is helpful in correcting errors that are sometimes made in labeling and mounting electrocardiograms of the conventional 3 leads.

The P wave is produced by electrical activity spread through the atria. It is a small, rounded deflection which varies in height from 0.5 to 3 mm., representing 0.05-0.3 mv. Duration or width of this deflection normally does not exceed 0.1 sec. At the end of this deflection, when the stylus has returned to the base line or isoelectric level, there is a period in which there is no deflection whatsoever from the isoelectric level until a group of sharper, taller waves, the QRS complex, appears.

The QRS deflections are due to the onset and spread of electrical activity throughout the ventricles. The interval between the onset of the P wave and the onset of the QRS complex is called the P-R or P-Q interval. The Q wave is often absent normally; under these circumstances the P-R interval is measured from the onset of the P wave to the onset of the R wave. If the Q wave is present, this interval is called the P-Q interval and is measured to the onset of the Q wave.

During this P-R interval the impulse is traveling through the atria to the ventricles along a set pathway known as the A-V node and the bundle of His. The P-R interval measures this time, which is normally from 0.12 to 0.2 sec. The QRS complex varies normally in certain respects—whether the initial deflection is directed upward or downward, whether the terminal deflection is downward (invert), or whether there are several upward or downward deflections. By convention the first deflection, if upright, is known as the R wave; if downward, the initial deflection is known as the Q wave.

The downward deflection that follows the R wave is known as the S wave. The S wave may often be absent. Not infrequently a second upward deflection occurs following the S wave. It is known as the R prime (R′) wave. If there is still another downward deflection following the R′ wave, it is called the S prime (S′) wave.

Since the QRS complex represents the spread of the action current throughout the ventricular musculature from start to finish, the time interval from the onset of QRS, whether it begins with a Q or with an R, to the end of its final deflection, either with an R or with an S, measures the speed of this electrical impulse through the ventricles. Normally this time interval does not exceed 0.1 sec.

The R wave normally varies in height from 5 to 15 mm. After the electrical disturbance represented by the QRS has subsided, there is a segment, known as the S-T segment, that is usually isoelectric and

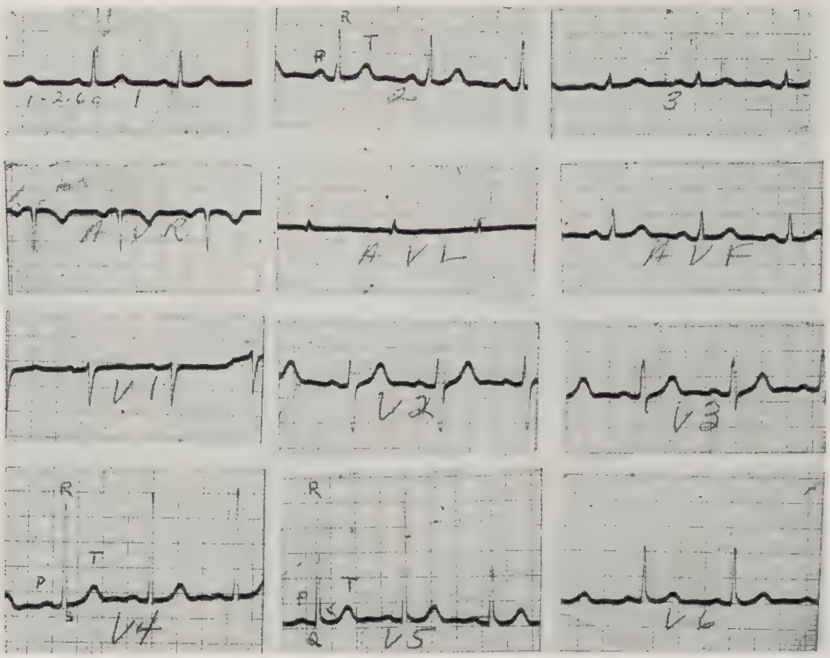

Fig. 711. Normal electrocardiogram. P, Q, R, S, and T waves appear in proper relationship and are of normal configuration and amplitude. Note that the amplitude of T in Lead II approximates the sum of the amplitudes of T in Leads I and III. Note also that Q and S may be absent normally.

of rather variable length; it ends in a rounded wider deflection known as the T wave. The ventricles are depolarized for the duration of the S-T segment and have not begun to recover their state of electrical excitement. This duration varies greatly, depending upon heart rate, age, and sex.

The interval from the beginning of the QRS complex to the end of the T wave is known as the Q-T interval. It represents the duration of the spread of the electrical excitation and then the recovery from this state of the ventricular musculature. This varies with heart rate, age, and sex, but for normal rates it is usually about 0.4 sec. The T wave, which is the final evidence of electrical imbalance in the ventricles, represents the phase of recovery from electrical excitation in the ventricles. During the period of the T wave the musculature approaches and reaches the completely polarized state. At the point of complete polarization the T wave has receded to the isoelectric level, and there are no deflections because the electrical potential is equal throughout the ventricles. The T wave in normal electrocardiograms is upright in Leads I and II, but in Lead III (called the "lead of exceptions" because of its variability under normal conditions) it may be upright or inverted. The amplitude of the T wave for the conventional leads varies from 1 to 6 mm.

A low upward wave often shortly follows the T wave. This is known as the U wave. Thus far the cause of this deflection has not been definitely ascertained. The U wave occasionally is inverted. When large or asymmetrical, it is sometimes associated with myocardial damage or certain electrolyte disturbances.

The chest or standard bipolar and most recently unipolar precordial leads have come into common clinical usage since 1932. They have been invaluable in the diagnosis of myocardial infarction. Two electrodes are used to take bipolar precordial leads. One, the exploring or chest electrode, is placed in various positions to be described. The other, the indifferent electrode, is placed over a point distant from the heart.

There are various types of bipolar chest leads, each designated according to the position of the chest (exploring) electrode and the indifferent electrode. These various positions of the electrodes are designated as follows: The Roman numeral IV is used to indicate a chest lead, and a letter follows the numeral IV to indicate the position of the indifferent electrode. If the indifferent electrode is on the left leg, the lead is called IV F; if on the right arm, it is IV R; if on the left arm, IV L; and if on the back, IV B. Another type of lead that is preferable is that advocated by Frank Wilson and his co-workers. It is a central terminal lead or V lead. In this lead the indifferent electrode is formed by connecting the right arm, left arm, and left leg electrodes together. This type of connection is advantageous in that the potential of this indifferent electrode is more nearly zero than when the indifferent electrodes are placed otherwise, where the current from the heart exerts some influence on the distant electrode though not nearly so much as on the exploring or chest electrode.

The chest lead may be recorded with the exploring electrode placed over different areas of the chest in relation to the heart. These positions on the chest are designated by numerals following the letters indicating the type of chest lead. They include the first letter C to indicate a chest lead, fol-

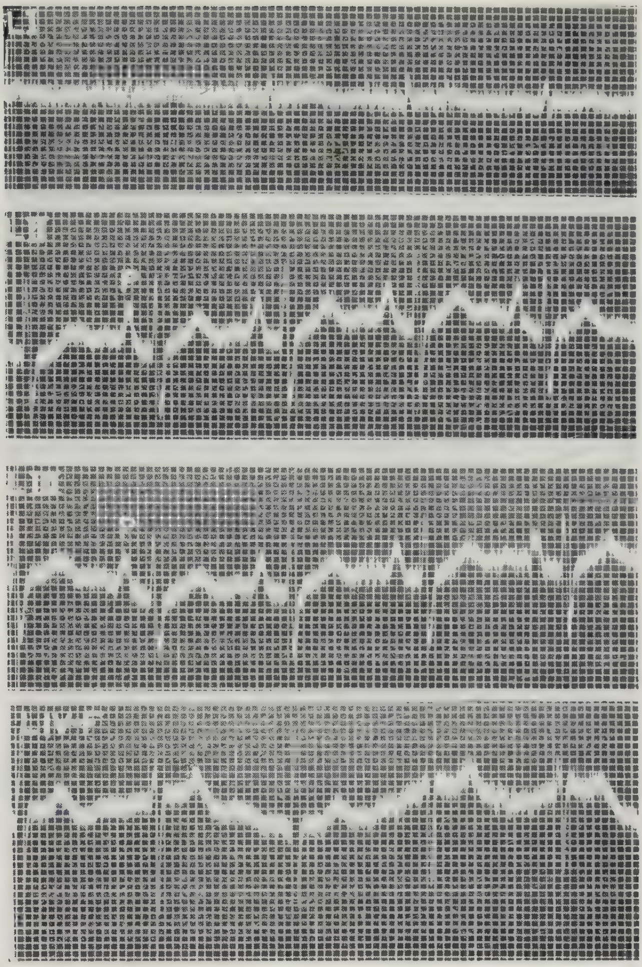

Fig. 712. Artifacts due to muscular tremors. In addition to the artifact characterized by fuzziness of the tracing due to muscular tremor, note the prominent sharply peaked P waves in Leads II and III characteristic of the so-called P-pulmonale. (Taken with a Cambridge galvanometer, using photographic equipment.)

lowed by the letters F, R, L, B, or V to indicate the position of the indifferent electrode as described above. In the case of the unipolar chest leads only the letter V is used as a prefix to the Roman numerals, signifying the position of the exploring electrode on the chest wall as described below.

If the chest electrode is placed in the fourth intercostal space just to the right of the sternum, the numeral 1 then follows. If the position is the fourth interspace just to the left of the sternum, the numeral 2 is used. When the position of the chest electrode is midway between that of numeral 2 and the midclavicular line in the fifth interspace, it is designated as 3. Position 4 is the fifth interspace, midclavicular line; position 5 is at the same horizontal level in the left anterior axillary line; position 6, the same horizontal level as 5, left midaxillary line.

If, for example, in the case of bipolar chest leads, the indifferent electrode is placed on the left leg, the various chest lead positions are recorded as CF_1, CF_2, CF_3, CF_4, CF_5, and CF_6, respectively.

To clarify these designations, let us emphasize the distinction between the leads CF_4 and IV F. With the first designation, the chest electrode is always in the fifth interspace, left midclavicular line; with the latter the chest electrode is placed over the heart apex wherever it may happen to be.

Various positions on the chest are utilized because it has been found that some lesions of the myocardium are more likely to be detected when the chest lead is placed in one position than when placed in another. Positions for the chest lead other than those previously described may sometimes be advisable when attempting to localize the site of the lesion or to determine the type of bundle branch block, if present.

As stated above, esophageal leads are sometimes desirable. In these instances a specially designed exploring electrode is swallowed until it reaches the level of the heart. The P waves are prominent in esophageal leads; for this reason this lead may be decisive in determining the nature of an arrhythmia in which P waves cannot be definitely identified in the conventional leads. This lead may also be of value in identifying posterior myocardial in-

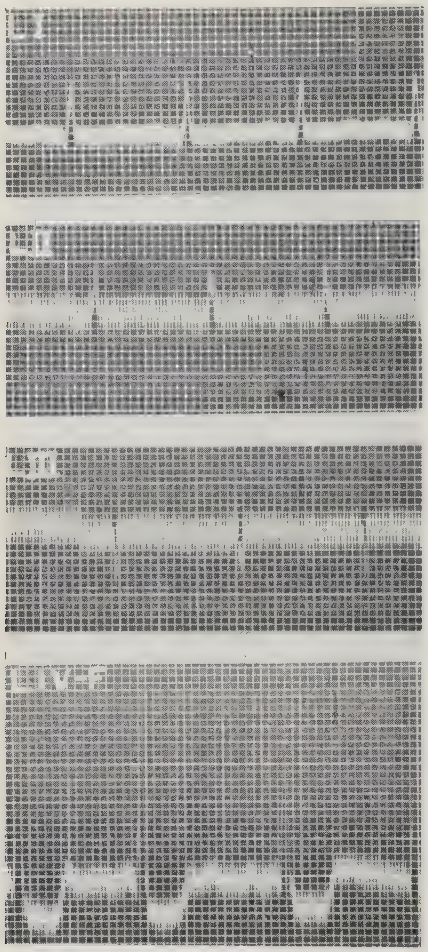

Fig. 713. Artifacts due to interfering alternating current. This is evident chiefly in Leads II, III, and IV F. (Taken with a Cambridge string galvanometer using photographic equipment.)

farction since the esophagus is more nearly in apposition to the posterior ventricular wall.

The appearance of the normal tracing taken with the chest leads varies in many details with the position of the electrodes. It is important, therefore, that the electrocardiographer familiarize himself with these normal variations. Since these variations are discussed in full in books devoted to electrocardiography, they are not presented in this chapter. The characteristics of Lead IV F are briefly described because Lead IV F is the one that has been used in taking many of the electrocardiograms reproduced in this chapter. In the last several years the unipolar chest leads (V leads) have generally replaced bipolar chest leads in common usage. What is said in describing the characteristics of the bipolar chest leads largely applies to the analogous unipolar chest leads (V_4).

Characteristics of waves in Leads IV F and V_4: The P wave is usually quite small and may be inverted, diphasic, or upright.

The P-R interval is as described for the conventional leads.

The QRS complex is usually of greater amplitude and tends to be slightly greater in duration than in the conventional leads. If R is less than 1 mm. in height, it is considered definitely pathologic. The S may be greater in amplitude than R, normally.

Q is usually absent, but when present, it is not greater than 2 mm. in depth. A Q wave deeper than this is usually significant of myocardial damage as a result of coronary artery involvement. If a Q wave is present in Lead I, there tends to be a Q in Lead V_4.

The S-T segment may be short or absent and normally is often elevated to a slight degree.

The T wave is characteristically larger than in the conventional leads, usually 5-7 mm., and is almost always upright in the adult. In young children the T wave is not infrequently inverted. Although it has been stated that the T wave is rarely notched or diphasic, it has been the author's experience on occasions to find notched and even slightly diphasic and inverted T waves in the absence of organic heart disease.

The U wave is often quite prominent, and at times its appearance shortly after the T wave gives a simulation of a terminal diphasic tendency to the T wave.

In V_1, T is normally often inverted, R is usually of low amplitude, and S is relatively deep. In V_4, which is taken with the electrode in the midclavicular line, fifth interspace, the appearance is the same as in IV F with the electrode over the apex, provided the apex is in its usual position in the midclavicular line, fifth interspace. Leads V_5 and V_6 give an appearance similar to that of Lead I except that the amplitudes of R, S, and T tend to be smaller. The rule is that with the exploring electrode to the right of the sternum the tendency is for R to be small, S to be deep, and T to be inverted; and as the electrode is moved to the left axillary line the R becomes relatively tall, the S relatively small, and the T upright.

Common technical difficulties

In order that a proper electrocardiogram be recorded it is necessary, when making the tracing, to understand some of the common technical difficulties that may cause artifacts or external deformities of the record, making proper interpretation difficult or impossible.

Deformities due to muscular movement of patient: The movement of an arm or leg may cause slipping of the electrode over the skin, with sudden marked or slight shifting of the stylus from the base line. Slighter muscular contractions such as muscular tremor produce smaller, very irregular vibrations in the stylus.

Deformities due to changes in skin resistance and polarization of electrodes: These are characterized by a more gradual undulating shifting of the base line.

Deformities due to improper grounding of electrocardiograph and interfering induction currents: These artifacts are characterized by regular vibrations due to 60-cycle alternating current at a rate of 60 times a second.

Deformities due to a loose string (applicable only

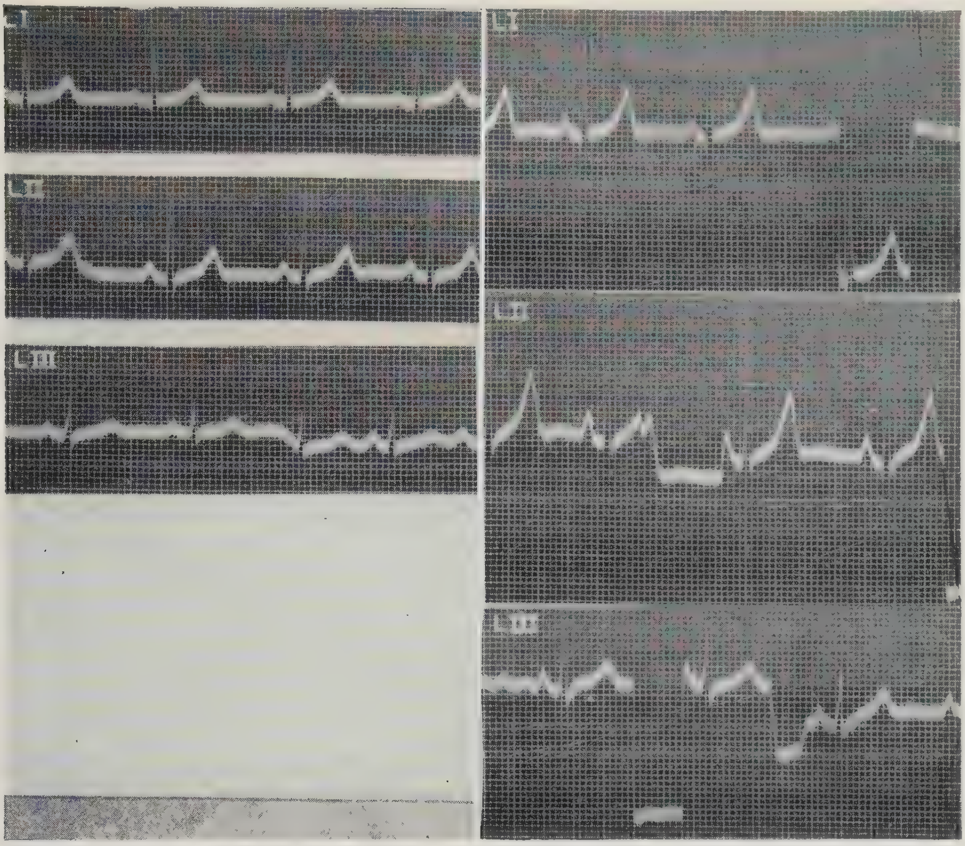

Fig. 714. Artifacts due to a loose string. In **A** the electrocardiogram has been properly standardized. In **B** the string has been overstandardized, the string being much too loose. Note that the P, QRS, and T waves are altered in size and form. (Taken with a Cambridge string type electrocardiograph using photographic equipment.)

to string type of electrocardiograph): If the resistance of the skin is too high, the string must be loosened to an unusual degree in order to standardize it. This prevents the string from stopping abruptly when a millivolt of current is added to the circuit so that the string "overshoots" or deviates above or below the proper amplitude. This would result in abnormally high amplitudes, slurring, and widening. When this occurs, the electrodes must be reapplied. The skin must be prepared more thoroughly, using electrode jelly to reduce skin resistance further. Overshooting must be watched for when taking each lead of the string galvanometer instrument.

Deformities due to loose contacts: Loose contacts at any place in the circuit may also cause sudden shifting of the base line.

Measurements of amplitude, heart rate, intervals, and duration of complexes

The duration of the P wave is measured from its convex surface at the instant it rises or falls from the base line to the moment it returns to this level. The duration of the QRS complex is measured from the beginning of the Q wave on its convex surface to the end of the R or S wave at its convex surface. The convex surface is used for making all other interval measurements such as P-R or P-Q, Q-T, and T.

The amplitudes of the upright deflections are measured from the upper surface of the base line to the upper surface of the topmost portion of that wave which is being measured. The inverted waves are measured from the lower surface of the isoelectric level to the apex at its lower surface. Duration and voltage of a complex are accepted as that measured in the lead in which they are the greatest.

Many ways of estimating the rates of the ventricles or atria have been described. A convenient method is to count the number of time lines lying in the space of 4 cycles, either atrial or ventricular. Then 6000 is divided by this figure; the result gives the rate of the atria or ventricles, according to which complexes were measured. Since the time lines are divided into groups of 5 by each heavy line (see above), it is convenient to begin measuring the 4 complexes where the first one falls on a heavy time line and then to count the heavy time lines, each representing a group of 5, until the fourth complex is reached, and figure accordingly.

1 - From the electrocardiogram determine the heart rate and the QT interval.
2 - Place this rule on paper. Mark rate with an arrow and interval with a dot.
3 - Using upper edge, place arrow to arrow and read the QTc under the dot. OR,
4 - Using lower edge, place arrow to arrow and read QT ratio over the dot.
The maximum of normal is 1.08.

The maximum of normal is 1.08.

Fig. 716. Procedure for obtaining the QTc and the Q-T ratio. **A,** Place the ruler on any piece of paper. Note that on the upper edge of the ruler there are 2 overlapping scales, one marked "Q-T Interval" and the other "Heart Rate." Mark an arrow on the paper above the determined heart rate and a dot above the determined Q-T interval. **B,** The QTc is obtained by placing the arrow on the upper edge of the ruler under the arrow on the paper and reading the QTc under the dot. The QTc in the example is 0.416. **C,** The Q-T ratio is obtained by placing the arrow on the lower edge of the ruler above the arrow on the paper and reading the Q-T ratio over the dot. The Q-T ratio in the example is 1.04. A marked elevation shows heart disease, just as does a prolonged P-R interval or QRS interval. (Courtesy Bowen & Co., Inc., Bethesda, Md.)

Procedure for determining the heart rate and Q-T interval*

Another commonly used simple method employs a calculating ruler designed by William Welch, M.D.* This ruler has the added advantage of affording a simple method of measuring Q-T intervals and Q-T ratios.

Q-T calculator: The Q-T calculator is a calculating ruler to correct the Q-T interval for the heart rate.

Q-T ratio: The Q-T ratio is the ratio between what the Q-T interval is and what it should be. What it should be is expressed by Bazett's formula:

$$\text{Q-T} = 0.4\sqrt{\text{R-R}}$$

The Q-T ratio is therefore:

$$\frac{\text{Actual Q-T}}{0.4\sqrt{\text{R-R}}}$$

To calculate R-R from the heart rate, as determined from the electrocardiogram, and then to calculate the Q-T ratio is a simple slide rule procedure. The calculating ruler is, in effect, a preset slide rule to solve this formula.

Corrected Q-T (QTc): The corrected Q-T is expressed according to the following formula:

$$\frac{\text{Actual Q-T}}{\sqrt{\text{R-R}}}$$

It is readily seen that this is equal to Q-T ratio × 0.4. The ruler will also solve this formula.

An increase in the Q-T ratio or the QTc has diagnostic significance. Either should be determined as a matter of routine.

Procedure for determining heart rate and Q-T interval from electrocardiogram: Determine the heart rate by placing the arrow at the beginning of the rate-measuring scale on the peak of an R wave and measuring off 3 R-R intervals. See Fig. 715, *A*, in which the ruler shows the heart rate to be 80.

Determine the Q-T interval by using the millimeter scale and measuring the distance from Q to the end of T. In the example this is 9 mm. Because the paper speed is 1 mm./0.04 sec., it is necessary that the measured distance be multiplied by 0.04. The Q-T interval is therefore 9 × 0.04 or 0.36 sec. (Fig. 715, *B*.)

Procedure for obtaining QTc and Q-T ratio: Place the ruler on any piece of paper. Note that on the upper edge of the ruler there are 2 overlapping scales, one marked "QT interval" and the other "heart rate." Mark an arrow on the paper above the determined heart rate and a dot above the determined Q-T interval. (Fig. 716, *A*.)

The **QTc** is obtained by placing the arrow on the upper edge of the ruler under the arrow on the paper and reading the QTc under the dot. The QTc in the example is 0.416. (Fig. 716, *B*.)

The **Q-T ratio** is obtained by placing the arrow on the lower edge of the ruler above the arrow on the paper and reading the Q-T ratio over the dot. The Q-T ratio in the example is 1.04. (Fig. 716, *C*.)

The maximum of normal is 1.08.

A marked elevation is indicative of heart disease, just as is a prolonged P-R interval or QRS interval.

ELECTROCARDIOGRAPHY IN DISEASE AND IN DISORDERED PHYSIOLOGIC STATES

The electrocardiogram can be altered in many respects both by disease processes localized to the heart itself and by general constitutional disorders. Although many of these disease states cause electrocardiographic alterations that are nonspecific for that disease, there are others that are pathognomonic or highly suggestive of disease. The picture of acute myocardial infarction, for example, is usually characteristic. The location of this lesion can often be ascertained with a high degree of accuracy from the electrocardiogram alone. On the other hand, degenerative changes involving the myocardium, general constitutional disease, toxic agents, and even psychogenic factors may produce alterations in the electrocardiogram that are indistinguishable from each other.

The most significant changes in the electrocardiogram are those involving the QRS and T waves; in other words, those involving ventricular contraction. The QRS and T both comprise what is referred to as the "ventricular complex." The size, shape, direction, and duration of these complexes depend on several factors. The relative thicknesses of the right and left ventricular muscles, for instance, determine whether the direction of the main deflection of QRS is up or down in Leads I or III. Certain diseases of the cardiovascular system alter the relative thickness of the right and left ventricles in characteristic fashion. The origin of the impulse which the muscle, atrial or ventricular, receives also determines the size, shape, and duration of the complexes. If, for instance, the impulse stimulating the atria to contraction arises in the atrium in a point other than the normal location, the P wave will be altered in direction, size, or shape, and in its time relationship to QRS as well, since the time necessary for the impulse to reach the ventricles will be altered. It is normal for the impulse stimulating ventricular contraction to arise from a point above the ventricular musculature proper. As long as this obtains, the QRS and T complexes maintain a form, size, duration, and direction that is usual for this patient. If, however, a stimulus should arise in the ventricular muscle itself, the shape, size, duration, and direction are altered in a bizarre fashion, depending on the location of the exciting impulse in the ventricles. The T waves alone may be altered by multitudinous causes ranging from drinking cold water, psychogenic influences, or drug effects to serious organic disease involving the ventricular muscle. Any condition involving the pathway of conduction from the atria to the ventricles may alter the duration of the P-R or P-Q interval.

---

*Manufactured by Bowen & Co., Inc., Bethesda, Md. Method by permission of the manufacturers.

In the same way, any disease or toxic process that impedes the conduction of the impulse as it spreads through the ventricles will cause increased duration of the QRS complex. The level and form of the S-T segments may be altered in certain characteristic respects by disease or toxic influences. Disordered rhythms of the heart, usually involving abnormal sites of impulse formation, and occurring as a result of a wide variety of organic and functional disturbances of the heart, give characteristic electrocardiographic patterns.

It is not our purpose here to give in detail the many patterns of electrocardiographic alterations that may occur. The electrocardiogram in the main types of cardiovascular diseases only will be discussed. An understanding of the pathologic physiology of disease is necessary in order to interpret abnormalities of the electrocardiogram.

Disturbances in depolarization and repolarization of heart muscle are caused by numerous factors both physiologic and pathologic; often these are manifested merely by lowering or inversion of the T wave. This change in T wave may not be specific for any type of lesion and may be caused by factors ranging from psychogenic influences to fibrosis resulting from long-standing and progressive coronary occlusion. In many cases it is possible to gain valuable clues to the nature of the disease by making serial electrocardiograms. With certain physiologic states, toxemias, and drugs, the T-wave changes are reversible; with organic disease, such as fibrosis of the myocardium, the changes usually are permanent. Often when serial electrocardiograms are taken, the electrocardiograms undergo characteristic pattern changes that are pathognomonic of acute myocardial infarction.

Clues to the types of disease may be obtained if one understands the effects of disease in causing strain on the various chambers of the heart. Strain on the left ventricle, on the right ventricle, and on the atria, with the consequent increase in muscle mass, produces characteristic evidence in the electrocardiogram. Some diseases or drugs are likely to exert their effects primarily on the conduction system, so that the presence of increased P-R conduction time will often give a clue to the disease or drug involved.

Axis deviation

Many cardiac diseases involve changes in relative size of the right and left ventricles, with consequent effect on the "electrical axis" of the heart. This electrical axis may also be altered by changes in the position assumed by the heart in the chest cavity. Thick-chested, sthenic individuals with diaphragms that tend to be high often have hearts that lie transversely in the thorax, whereas slender individuals with long chests often have hearts that assume a more nearly vertical position with consequently a different electrical axis with respect to the conventional leads. Since deep inspiration alters the position of the heart, it therefore affects the electrical axis. This applies to changes in position of the heart occasioned by extracardiac lesions such as pneumothorax, fluid in the chest, pulmonary collapse, fibrosis with pull on the mediastinal structures, etc.

It thus becomes important to determine alterations in the normal electrical axis of the heart. When the largest deflection of QRS is upright (R) in Lead I and invert (S) in Lead III, this indicates the presence of left axis deviation. See Fig. 717. When the largest deflection of QRS is upright (R) in Lead III and invert (S) in Lead I, right axis deviation is present. See Fig. 718. Left axis deviation is present in any condition that causes relative enlargement of the left ventricle over the right.

Right axis deviation occurs when there is relative enlargement of the right ventricle over the left. A transversely placed heart in which the apex lies more to the left produces the picture of left axis deviation. A vertically placed heart tends to produce a picture approaching right axis deviation. In young children, when the right ventricle is relatively thicker in relation to the left, the picture normally more nearly approaches right axis deviation, but, with age, as the left ventricle thickens, the picture of left axis deviation may finally be produced.

Deep inspiration will often cause a deeply inverted deflection (S) in Lead III to disappear and abolish the picture of left axis

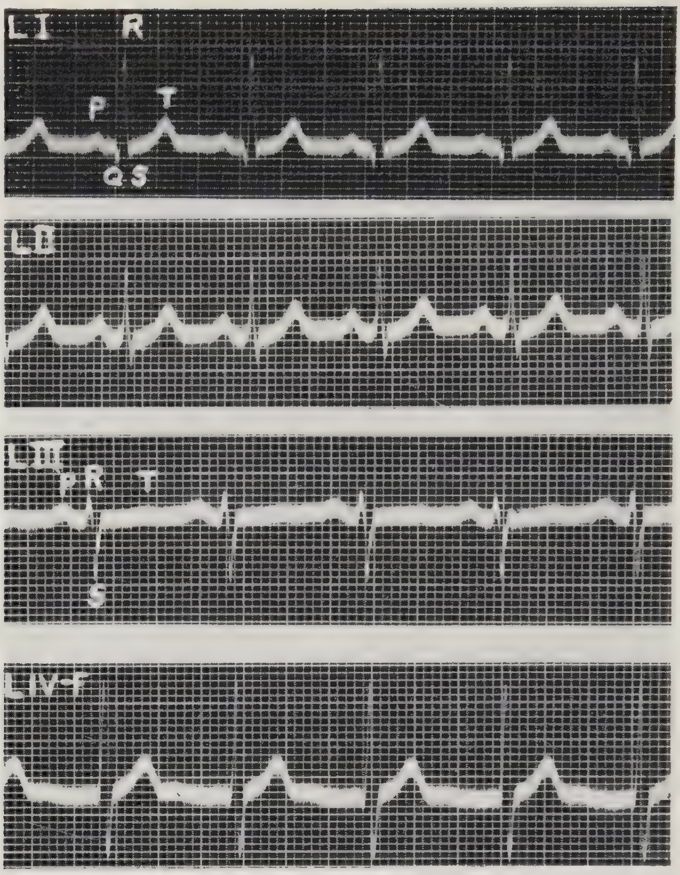

Fig. 717. Left axis deviation. Note that the chief deflection in Lead I (R) is upright and the chief deflection in Lead III (S) is inverted. A small R is present in Lead III. In more marked degrees of left axis deviation R in Lead III may be entirely absent. (Taken with a Cambridge string type of electrocardiograph using photographic equipment.)

deviation by producing a vertical position of the heart. If the right and left ventricles both enlarge and maintain their normal relationship with respect to size, then no change in electrical axis may occur. The occurrence of axis deviation can be helpful in determining the presence or absence and the type of valvular disease, since it is known that certain types of valvular disease tend to produce right axis deviation, whereas others tend to cause left axis deviation. The characteristic murmurs of these valvular deformities, or of congenital anomalies as well, may be absent or confusing; the finding of axis deviation suggestive of one or the other valvular condition may be decisive in the diagnosis. Changes in axis deviation associated with various types of cardiac pathology are mentioned in the discussion of electrocardiographic patterns found in the main classes of cardiac diseases. It is well to emphasize that left axis deviation may often be a normal occurrence. In these instances T_1 is upright, T_3 is inverted, and S_2 is absent or very small.

There are several methods for calculating the electrical axis of any electrocardiogram. The 3 most commonly used are (1) Einthoven's triangle, (2) the triaxial reference system, and (3) Dieuaide's chart. These methods are well described in monographs devoted to electrocardiography and its underlying theories.

Congenital heart disease

Although there is no absolutely specific electrocardiographic pattern for a congenital heart lesion with the exception of congenital dextrocardia, one can obtain from the electrocardiogram much information that together with other clinical data will establish the diagnosis.

The reason for this is that the electrocardiographic pattern reflects only what is going on in the heart muscle and is not produced by

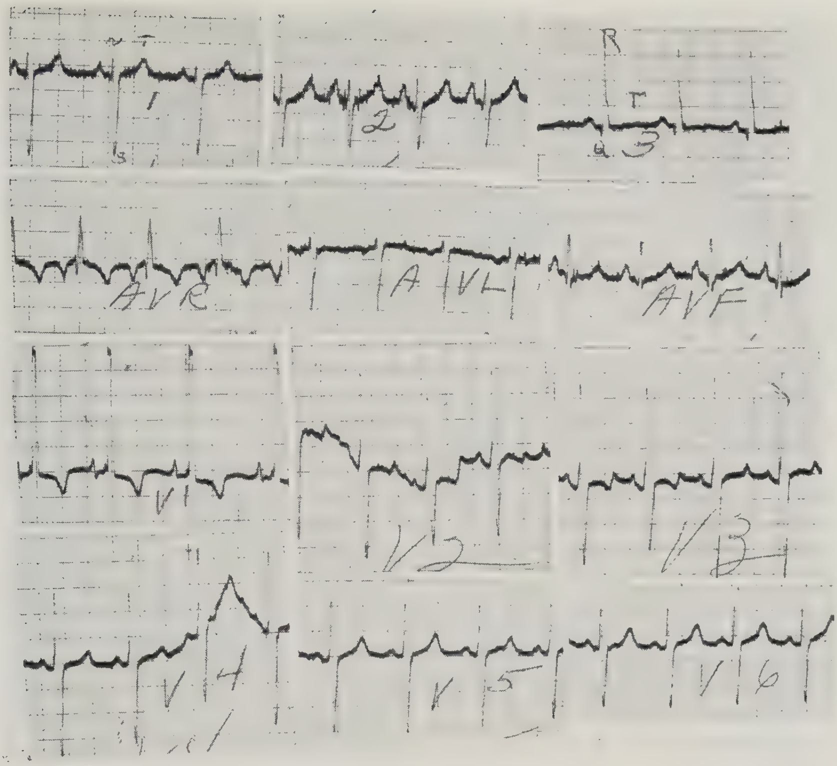

Fig. 718. Right ventricular hypertrophy and right axis deviation. Note the marked right axis deviation—low amplitude R (r) and deep S with upright T in Lead I; the small q and tall R in Lead III; the small q, prominent R, and small s in Lead aV_F; and especially the very tall R, depressed ST and inverted T in Lead V_1. Also note that R becomes progressively smaller and T less inverted and finally upright as the leads are taken over the left chest positions—V_2, V_3, V_4, V_5, and V_6. Taken from a patient with congenital cyanotic heart disease (tetralogy of Fallot).

the anatomic defect itself. Therefore, the type of abnormal electrocardiogram will depend on the character of the alterations in the hemodynamics with the resultant strain and enlargement of the various segments of heart muscle surrounding the individual chambers of the heart and a consequent change in position of the heart in relation to the electrocardiographic leads. The importance of the electrocardiogram in congenital heart disease has been particularly enhanced by the spectacular advances in surgical correction of certain defects. It is therefore of vital importance to be certain of the type of anatomic defect. This can be illustrated by citing its importance in helping to distinguish the ostium primum type of atrial septal defect from the ostium secundum type. In the latter there is usually right axis deviation and incomplete bundle branch block, whereas in the former there is usually a characteristic combination of left axis deviation in the extremity leads, and incomplete right bundle branch block together with right ventricular hypertrophy as shown in the chest leads. The prognosis is much more serious, and the surgical means of correcting the defect is more difficult in the ostium primum type.

The most striking and characteristic electrocardiographic changes occurring in congenital heart disease are those found in true congenital dextrocardia (right-sided heart). In this condition all the complexes in Lead I are inverted, Lead II resembles a normal Lead III, and Lead III resembles a normal Lead II.

Diagnosis of congenital dextrocardia may be made with absolute certainty from the electrocardiogram alone if the electrocardiographer can be sure that the technician who took the tracing did not reverse the arm leads, erroneously connecting the right arm lead wire to the left arm electrode and the left arm lead wire to the right arm electrode. Unfortunately this careless technical error is by no means a rare occurrence. It behooves all those who are responsible for making electrocardiograms to check carefully all lead wires several times to make sure that no such errors will be made.

Other congenital anomalies that commonly result in electrocardiographic changes are congenital pulmonary stenosis and defective interventricular septum. These conditions cause well-marked right axis deviation. The QRS complexes are of much greater amplitude than usual. Congenital heart block may occur in which the atrial complexes (P) have no constant relationship to the QRS complexes; in other words, the ventricles contract independently of the atria because the stimulus from the atria is blocked somewhere in the conduction pathway from the atria to the ventricles.

Rheumatic heart disease

Rheumatic fever may cause changes in the endocardium, chiefly the valves, the myocardium, or the pericardium, or changes may occur in all these structures at the same time. One of the most characteristic electrocardiographic effects of rheumatic fever in its acute stage is involvement by the acute inflammatory process of the atrioventricular conduction system. This results in delay in atrioventricular conduction with a subsequent increase in the P-R interval. This depression in conduction with consequent increase in P-R interval may be very slight, or it may become so marked that the ventricles do not receive any impulse at all from the atria. Thus they do not contract in response to atrial stimulation so that one may see P waves (atrial) without any regular relationship to their corresponding QRS complexes.

These varying degrees of increased P-R interval represent what is known as **heart block.** Heart block may be so marked as to be complete. If the block is complete, no ventricular complexes occur in response to the atrial wave. In complete heart block each of the ventricular complexes occurs independently of the atrial waves at a much slower rate than the latter. Milder degrees of heart block, in which each ventricular contraction responds to an atrial contraction, cannot be detected by ordinary clinical means. The electrocardiograph is invaluable in these conditions. It gives definite, objective, confirmatory evidence of the presence of acute rheumatic fever. Usually such P-R interval changes in acute rheumatic fever are transitory and disappear when the acute inflammation subsides. This must be distinguished from the P-R interval prolongation caused by digitalis, in which there are usually other tell-tale effects indicating digitalis action.

The inflammatory changes of rheumatic fever which involve the myocardium proper cause alterations in the electrocardiogram not

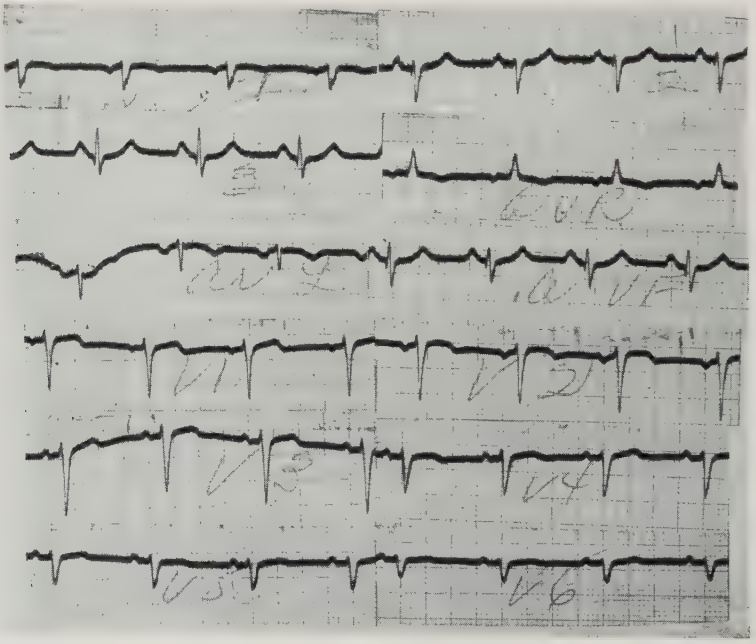

Fig. 719. Congenital dextrocardia. Note the pathognomonic inversion of all the complexes in Lead I. In the normal electrocardiogram Lead II would resemble Lead III, and Lead III would resemble Lead II.

so specifically associated with rheumatic fever as the P-R interval changes. Other types of pathologic processes may also cause these patterns. Such manifestations may be characterized by slurring or notching, lowering or widening of the QRS complex, lowering or inversion of the T waves, and changes in the Q-T intervals.

If the pericardium is involved by the rheumatic inflammatory process, there will likely be elevation of the S-T segments in Leads I and II and the chest leads. These changes are not specific for rheumatic fever since any process that alters depolarization by involving the pericardium in this way can cause such electrocardiographic patterns.

The electrocardiographic pattern that develops with chronic endocarditis and consequent valvular involvement depends upon the valve involved. Since the mitral valve is frequently stenosed, increased strain is placed on the chambers behind this valve, i.e., the left atrium, the right ventricle, and eventually the right atrium. The pattern of right axis deviation develops with increased right ventricular strain and increased muscle mass. Because the left atrial muscle so often becomes hypertrophied in mitral stenosis, the P wave is often altered, becoming prominent and notched. The atrial muscle is increased and a longer time is needed for the action current to traverse it; thus there is widening of the P wave. This type of P wave, characteristically present in Leads I and II, is quite suggestive of mitral stenosis.

A disorder of rhythm, known as atrial fibrillation, is very common in rheumatic heart disease with mitral stenosis because of the strain upon the left atrium. This is reflected in the electrocardiogram in a characteristic manner.

If the mitral valve involvement is such that regurgitation is prominent and the stenosis is relatively minor or absent, strain is put upon the left ventricle, and left axis deviation occurs. This is not so suggestive of rheumatic heart disease since many more pathologic heart conditions other than rheumatic heart disease may give left axis rather than right axis deviation. If the aortic valve is involved and causes regurgitation or stenosis of that valve, a frequent occurrence in rheumatic heart disease, strain is put primarily on the left ventricle. This ventricle hypertrophies and left axis deviation develops. If both mitral stenosis and aortic stenosis or aortic regurgitation are present, and if both right and left ventricles hypertrophy, then the electrical effects of right and left ventricular hypertrophy may counterbalance each other, and no axis deviation may result.

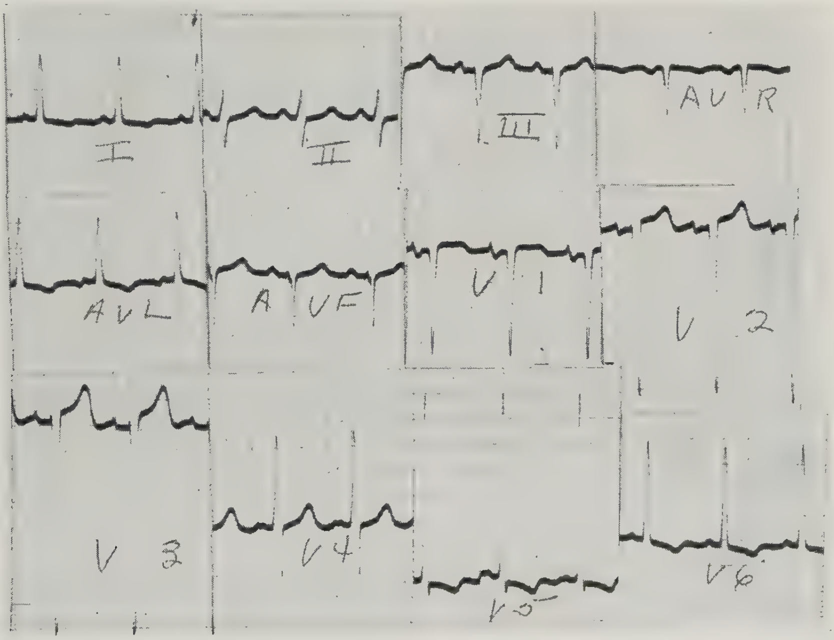

Fig. 720. Left ventricular strain and left ventricular enlargement. Note the prominent R and inverted T in Leads I and aV_L, the deep S and upright T in Leads III and aV_F, the very tall R, depressed ST, and inverted T in Lead V_5 and to a less extent in Lead V_6.

Hypertension

In hypertension, especially of a marked degree and of long standing, a rather typical electrocardiographic pattern of left ventricular strain develops. The R wave in Lead I is usually tall and the S-T segment becomes depressed and coved in Lead I and elevated in Lead III. The S wave is deep in Lead III, and the R wave is relatively small or absent in Lead III. The T waves in Leads I and III are in opposite direction from those of the main deflection of QRS in Leads I and III, i.e., inverted in Lead I and upright in Lead III. The QRS may be slightly widened in some instances due to the additional time required for the action current to traverse the thickened ventricular muscle. Fig. 720 is an example of left ventricular strain and enlargement.

Electrocardiography in coronary artery disease

General comments

The electrocardiogram does not record abnormalities in coronary arteries but only the electrical deviations caused by changes in the myocardium. In some instances, all too frequent, disease of the myocardium may be present but in such a location with respect to the electrocardiographic leads that the electrocardiogram remains normal.

Many electrocardiographic abnormalities seen in coronary artery disease are not specific and occur in other diseases. These may be alterations in rhythm, conduction, or the presence of left ventricular hypertrophy. Although T-wave inversion occurs quite uniformly as a result of myocardial ischemia, it is found not infrequently when ischemia is absent. Emotional factors, the drinking of cold water, indulgence in tobacco, hyperventilation, position of the patient, whether upright or recumbent, certain drugs, such as digitalis, quinidine, and morphine, and electrolyte disturbances all may alter the T wave. Thus, particularly when T-wave changes alone are observed, it becomes important to take into consideration all the above possible factors in trying to arrive at a conclusion concerning their clinical significance.

The diagnosis of myocardial infarction can be made on the basis of the electrocardiogram alone in the absence of other data only under certain circumstances. These are such that the QRS, S-T segment, and T-wave patterns go through certain characteristic evolutionary changes when serial electrocardiograms are taken. Indeed, the general extent and site of such infarction can be determined when such characteristic patterns are elicited. These characteristic serial evolutionary patterns are illustrated in Figs. 721-726.

Myocardial infarction

The electrocardiograph has been of great value in ascertaining definitely the presence of myocardial infarction. This condition is commonly referred to as **coronary thrombosis.** Since, however, the electrocardiographic patterns are caused directly by resulting actual necrosis of the heart muscle itself, that is, the infarction of the muscle, and not by the thrombus which obstructs the coronary artery, it is more correct to refer to these electrocardiographic changes as being due to myocardial infarction. This fact must be emphasized that, whereas most cases of myocardial infarction are due to coronary thrombosis, **occasionally myocardial infarction occurs in cases with extensive narrowing of the coronary arteries without thrombosis.**

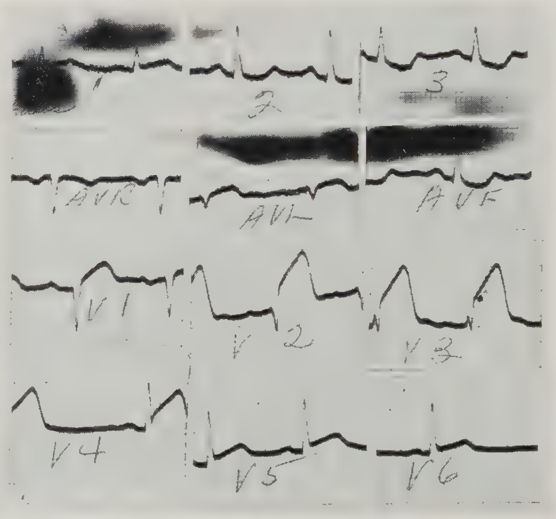

Fig. 721. Serial changes in acute anterior myocardial infarction. Electrocardiogram taken the day of the attack. The S-T segment is slightly elevated and has a suggestion of upward convexity in Lead I and depressed and sagging in Leads II and III. In Lead aV_L the R wave is almost absent, the S-T segment is upward bowed, and the T wave is somewhat elevated with slight terminal inversion. In Lead aV_F the S-T segment is reciprocally depressed and sagging as in Lead III. The most striking and diagnostic changes are in Leads V_2, V_3, and V_4 and to a small extent in V_5 and V_6. The R wave in Lead V_2 is almost nonexistent and very small in V_3; the S-T segment is almost absent with abrupt and markedly elevated take-off of the T wave in Leads V_2, V_3, and V_4 and to a relatively small extent in Leads V_5 and V_6.

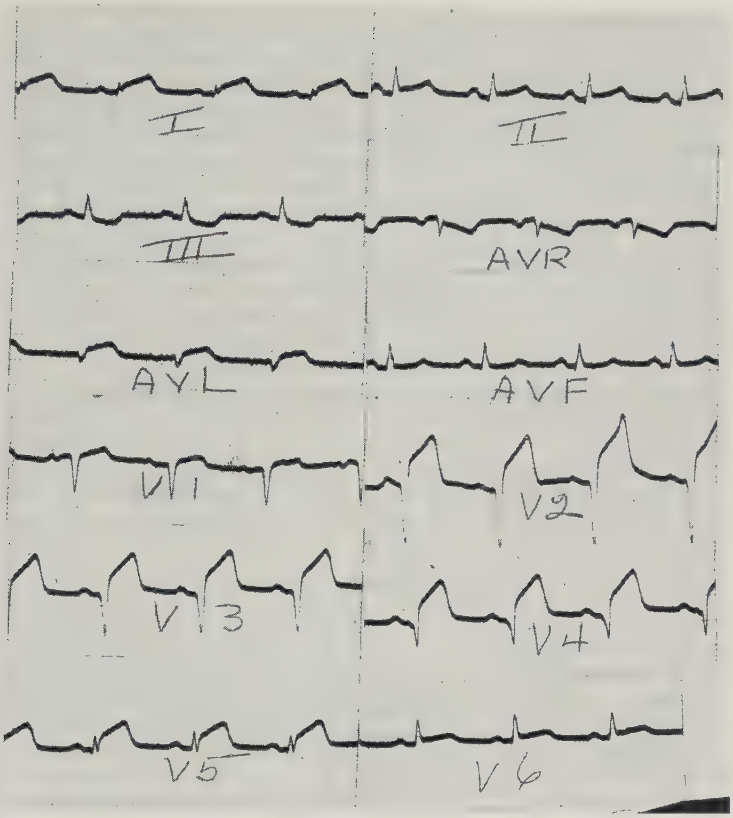

Fig. 722. Electrocardiogram of same patient as shown in Fig. 721 taken 7 days later.

The electrocardiographic picture of myocardial infarction varies according to the site and extent of the coronary artery obstruction. In general, there are 2 main varieties of coronary obstruction, anterior and posterior. These pictures may be modified by such factors as presence of previous infarctions, involvement of the conduction system, or involvement of the pericardium or endocardium. Posterior infarction is often referred to as "diaphragmatic" infarction since in these cases the area of ventricle involved faces the diaphragm.

Anterior myocardial infarction: Most commonly the left anterior coronary artery is obstructed, with resultant infarction of the anterior apical portion of the left ventricle. If serial electrocardiograms are taken, a characteristic series of changing electrocardiographic patterns will usually be noted. These changes are often referred to as "evolutionary" changes. The QRS complexes in Lead I are frequently small, slurred, and W shaped. The earliest (within the first 2 days) and most characteristic change is an elevation and upward convexity of the S-T segment in Lead I and aV_L, and a reciprocal depression of the same segment in Lead III. The T wave early has a high take-off from the S-T segment and may have merely a plateau type of configuration with perhaps a slight terminal dip. Later the S-T segment in Lead I drops steadily until it assumes a position at or slightly below the isoelectric level, maintaining a characteristically upward convexity.

The T wave in Lead I becomes completely inverted with a characteristic "coved" take-off from the S-T segment. The opposite changes occur in Lead III. The Q wave in Lead I, which has made its appearance early, will usually persist. The S-T segments and T waves occasionally may eventually resume a completely normal pattern. The characteristic residual patterns of an anterior myocardial infarction are the prominent Q and inverted and coved T waves in Lead I, with opposite configuration (normal) in Lead III. This is known as the $Q_I T_I$ pattern of anterior myocardial infarction.

Changes in the chest leads in anterior infarction are quite characteristic and frequently even more striking than in the other leads.

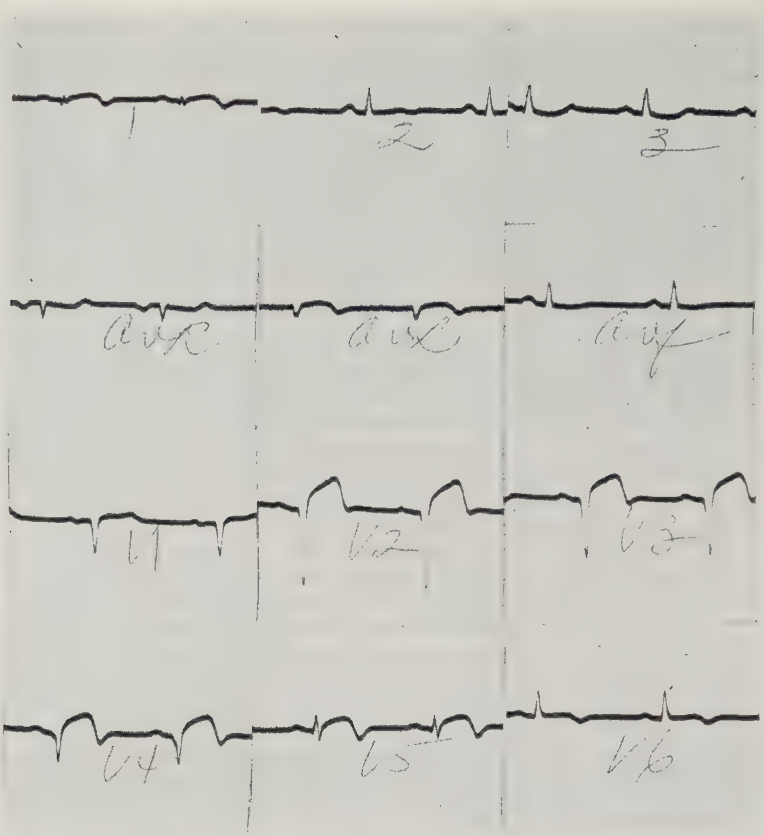

Fig. 723. Electrocardiogram of same patient as shown in Figs. 721 and 722 taken 12 days after the attack. A small Q is now present, R has become minute, the S-T segment has become almost isoelectric, and T has become inverted in Lead I; T has become inverted in Lead II and S-T sagging has become much less in Lead III. In Lead aV_L the changes resemble those in Lead I. The S-T deviations and high take-off of T have become much less in V_2, V_3, V_4, and V_5: T shows terminal inversion in V_2, V_3, and V_4 and is completely inverted in V_5 and V_6.

Occasionally, in this type of infarction, chest leads may be the only leads that reveal the changes characteristic of anterior infarction, thus emphasizing the value of these leads in this condition. In general, the changes in the left chest leads parallel those in Lead I except that they are often more marked. In the early stages the S-T segment is displaced upward and the initial deflection of QRS may be only very slightly upright or deeply inverted (deep Q). A deep Q in Lead V_4 is never normal and usually signifies myocardial infarction. The T in the early stages has an elevated take-off from the S-T segment that is short and abrupt and often exhibits a slight terminal dip. Gradually, the S-T segment becomes depressed until it reaches the isoelectric level or a point slightly below it.

The T wave becomes sharply and deeply inverted. The Q wave is characteristically prominent and is more definitely indicative of the presence of anterior infarction than an inverted T wave. Nevertheless a deep Q wave might never appear in Leads V_4, V_5, and V_6, and an inverted T wave in these left chest leads may be the only evidence of an anterior myocardial infarction.

If the initial deflection in Lead V_4 is upright but is only 2 mm. or less in amplitude, it is quite suggestive of the presence of myocardial infarction. If an inverted T wave as well is found, then the evidence of myocardial infarction is more nearly conclusive. Figs. 721-723 show the sequential changes, over a period of several weeks, in a case of acute anterior myocardial infarction.

Posterior or diaphragmatic myocardial infarction: Posterior or diaphragmatic myocardial infarction produces changes similar to those of anterior infarction in Leads I and III except that the patterns are reversed. The characteristic rise in the RS-T level takes place in Lead III and usually also in Leads II and aV_F, whereas reciprocal depression occurs in Lead I and often in the left chest leads. A prominent Q wave in Leads III and

aV_F, and often in Lead II becomes evident just as in anterior infarction a Q_I makes its appearance. There is the same upward rounding or convexity of the S-T segment, together with the elevation of this segment, the same stages of progressive lowering of S-T segment and inversion of T wave in Lead III resulting from acute posterior infarction as are found in Lead I in cases of anterior infarction. Variations from these classical patterns are seen. These depend upon the presence of the infarction in locations other than those described above, or they may be due to the fact that an old lesion has preceded the fresh lesion.

In the chest leads changes with posterior infarction are not striking. Occasionally a prominent R is present in V_I. The S-T segment may be depressed to varying degrees and may gradually rise to the isoelectric level. The T wave is normal or is occasionally unusually tall. Figs. 724-726 show the serial changes occurring in a case of acute posterior myocardial infarction.

More information relative to posterior infarction may be obtained by using esophageal leads since these leads are placed as near the posterior surface of the heart as it is possible to place a lead in a living subject.

Subendocardial myocardial infarction

In these cases the infarction is confined to the subendocardial region. Because there is no transmural (through and through) involvement, there is no Q wave, or at least the Q wave if present is not significantly abnormal. Characteristically, there are well-marked S-T depressions in the standard and chest leads. The RS-T segments may be elevated in Lead aV_R. Refer to Fig. 727.

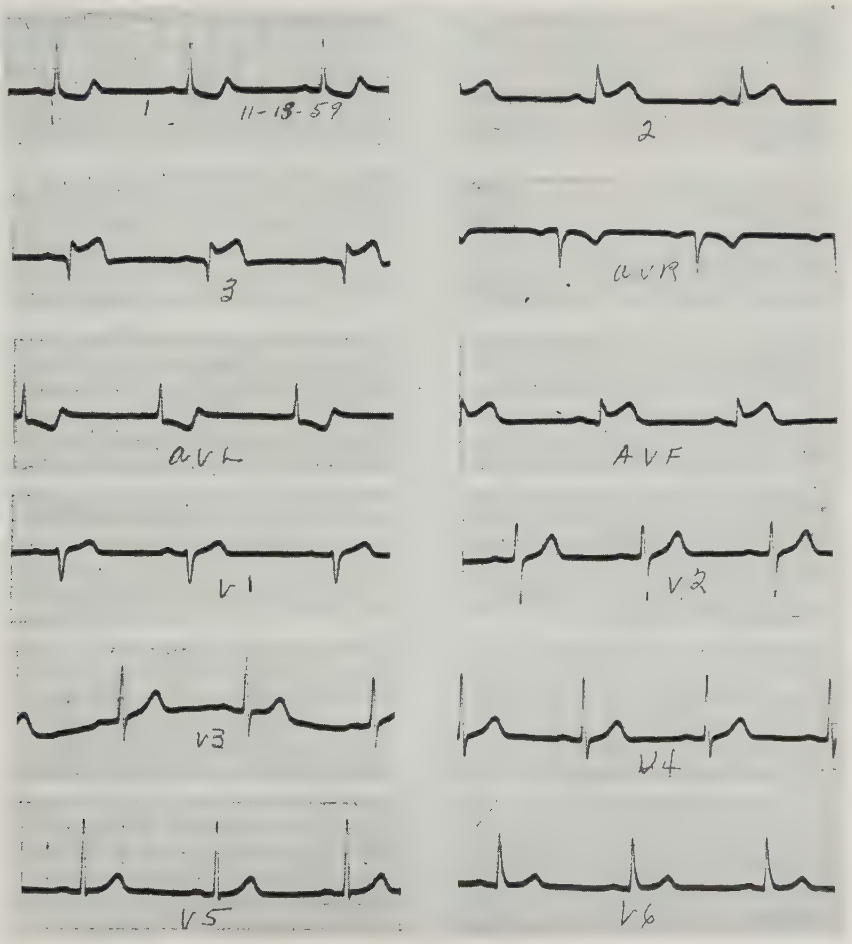

Fig. 724. Acute diaphragmatic (posterior) myocardial infarction. The characteristic changes occur in Leads II, III, and aV_F with reciprocal S-T deviations in Leads I and aV_L. This electrocardiogram was taken the day of the attack. Note that the S-T elevations are in Leads II, III, and aV_F. The Q wave is deep and the R wave small in Lead III.

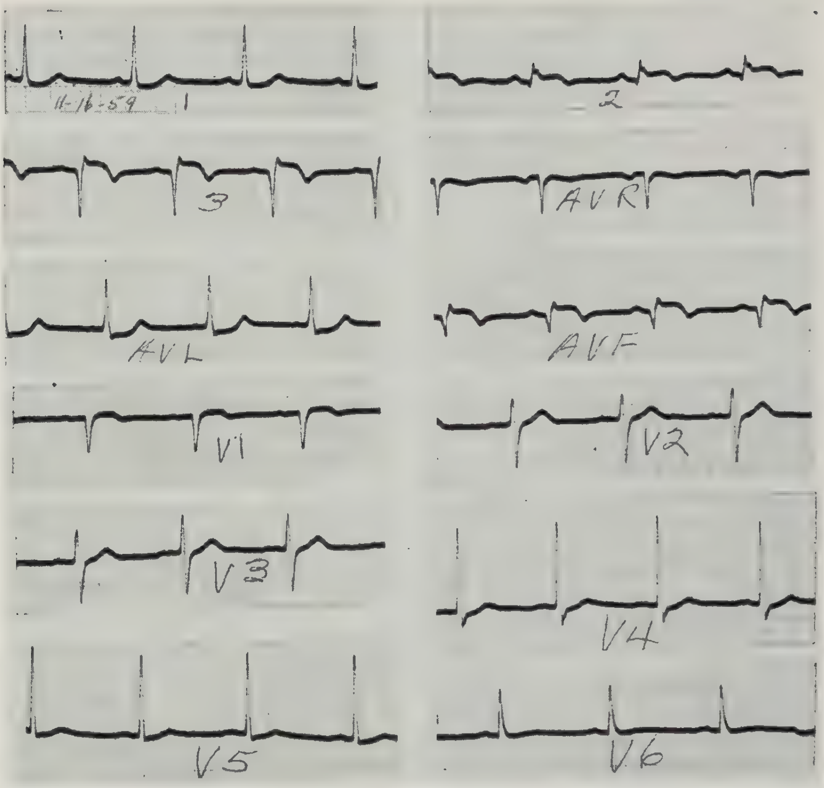

Fig. 725. Electrocardiogram of the same patient as shown in Fig. 724, 3 days after the attack. The Q wave in Lead II is somewhat more evident. T waves in Leads II and III are now inverted with less elevation of S-T. Changes in Lead aV_F resemble those in Lead III. The reciprocal sagging of S-T in Leads I and aV_L has almost completely disappeared.

Ventricular aneurysm

As has been described, the elevated S-T segment with high take-off of T and the subsequent evolutionary lowering of the S-T segment to the isoelectric level, together with subsequent complete inversion of T and the presence of a deep- or wide-notched Q, are highly characteristic of the serial patterns of acute myocardial infarction. Occasionally, the S-T segment elevation and high take-off of T will persist as a permanent pattern. When this happens, the diagnosis of ventricular aneurysm should suggest itself.

The Master 2-step test

In the great majority of instances, in the presence of myocardial infarction, the electrocardiogram will afford a clue, if not conclusive evidence, of the presence of this lesion. In fact, it is unusual for myocardial infarction to be present, particularly if it is recent, in the absence of electrocardiographic abnormalities. However, in the presence of myocardial ischemia,* whatever the cause (but usually on the basis of coronary artery disease), it all too often happens that patients will have symptoms, usually chest discomfort or pain, with normal electrocardiograms. When this occurs, the history, the symptoms, such as location of the discomfort, its radiation, the circumstances under which the symptoms occur and are relieved, are of utmost importance in determining the diagnosis. Indeed, the diagnosis of angina pectoris or coronary insufficiency is justifiable on the basis of the history alone in the absence of abnormal electrocardiograms if the history is entirely characteristic. However, it always is important when the physician can have the assurance of the electrocardiogram to lend support to such a serious diagnosis. In order to help clarify the diagnosis in those patients who have symptoms suggestive of coronary disease, but perhaps not entirely typical, and who have normal electrocardiograms, further electrocardiographic tests have been devised. The test most commonly accepted and used and the one in which the findings are considered to be most affirmative, provided they are properly interpreted, is the Master 2-step exercise test. This test has been the most widely employed and accepted of those used to determine impairment of coronary reserve and presence of coronary insufficiency, and consequently more data concerning normal controls over a wide range of patients have been accumulated than with other exercise tests. This test is not without some danger and should not be performed on patients in whom the diagnosis is evident. It should be performed in the presence of a physician. At times the Master 2-step test is performed to evaluate response to treatment.

Even after the Master 2-step test is performed, there may remain some patients who still will have a normal response to the test and yet will have been proved eventually to have had coronary artery disease. However, these incidences are relatively few. Certainly the Master test has helped to remove from the doubtful group a large number of diagnostic problems involving chest discomfort. On the other hand, a comment of caution should be made at this point. There is no doubt that some patients have been condemned to a life of psychologic invalidism and economic stress through misinterpretation of the results of the Master 2-step test.

As with other tests, there is some dispute concerning the criteria for a diagnosis of a positive test indicative of the presence of coronary artery disease. The most significant feature of a positive 2-step test is an S-T segment depression of more than 0.5 mm. from the isoelectric level. The development of characteristic chest pain during the test is considered to be of some significance as is the development of bundle branch block or conversion of an upright T wave to a diphasic or inverted T wave in Leads I or II or the chest leads.

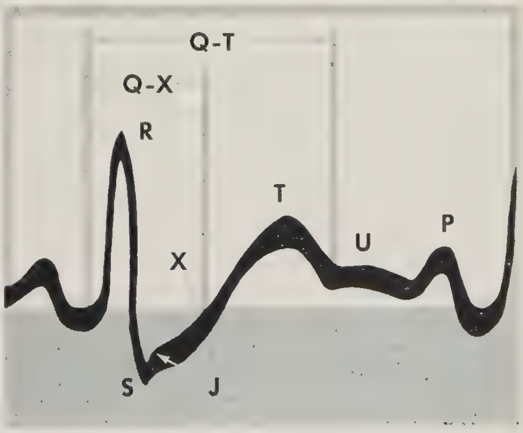

Fig. 728. Diagram by Master and Rosenfeld showing method of determining the QX/QT ratio; modification of a drawing by Lepeschkin and Surawicz: New England J. Med. 258:512, 1958. This expresses the configuration of RS-T in a quantitative manner, independently of heart rate. (From Roche Report on Medical Progress, Aug. 8, 1960.)

---

*Characterized by absence of death of heart muscle tissue but the presence of insufficient oxygenation.

Recently Master[2] proposed a more refined criterion for evaluating the results of his exercise test. This criterion involved the determination of the QX/QT ratio, in which Q is the interval from the onset of QRS to X, the point at which a depressed S-T segment returns to the isoelectric line and the QT is the interval from the onset of QRS to the termination of T.

Master concluded that ratios of more than 0.5 were significant of organic heart disease. This criterion was found to be 97% accurate in the male and 83% in the female.

Technic of performing the Master 2-step test*: "The patient is prepared essentially as for a basal metabolism test. After a good night's rest, he should either have no breakfast or only a dry piece of toast or cracker and a cup of weak tea. Smoking and medicines are prohibited that morning. In order for the patient to be at ease, a matter-of-fact, calm atmosphere should prevail. There should be a short rest period just before the test is started.

"The two steps are each 9 inches high, and the subject ascends the steps and walks down the other side (Fig. 729). This is counted as one trip. He then turns and retraces his steps. This is another trip. . . .

"The method of performing the 'two-step exercise test' should not be varied. Before any exercise is undertaken, the 12-lead resting electrocardiogram must be normal. It is usually taken with the patient in a recumbent position. If a photographic electrocardiograph is used, the tracing should be developed before the test is done.

"While the exercise is being performed, the electrodes should be kept in place. The number of trips varies with the age, sex, and weight of the patient (Table 368). To give the patient a sense of security, the steps are placed near a wall. Thus, should the patient so desire, he can support himself. As each trip is completed, the subject should turn in the same direction, i.e., either always toward the wall or always toward the person supervising the test. An occasionual firm grip on the patient's arm as he climbs the steps, without exerting any upward force, may increase his confidence. A large clock or a wristwatch with a sweep second hand should be used to regulate rate of ascent and descent of the patient. If the pace is too slow, he is urged to go faster; if he walks too rapidly, he is asked to slow his rate. This is done so that the specified number of trips may be completed at the end of the time allotted for the test: 1½ minutes (single test) or twice the number of trips in 3 minutes (double test). A variation of 1 to 3 seconds is of no importance.

"When the exercise has been completed, the patient immediately returns to the recumbent position. An electrocardiogram is taken at once, another is taken 2 minutes later, and a third 6 minutes after cessation of the exercise. Originally, we preferred to record the three standard leads and one precordial lead, usually V_4 or V_5, whichever had the better combination of a tall R and small S wave. The precordial leads have been found to be the most informative, however, and for several years now we have been taking only Lead II of the limb leads (frontal plane) and precordial leads V_3, V_4, and V_5, or V_4, V_5, and V_6 (horizontal plane). These 4 leads can easily be obtained within 40 seconds. On rare occasions electrocardiographic changes may be missed if more than a minute is required for the 'immediate' record, but 1 minute is actually ample time to obtain the first postexercise electrocardiogram.

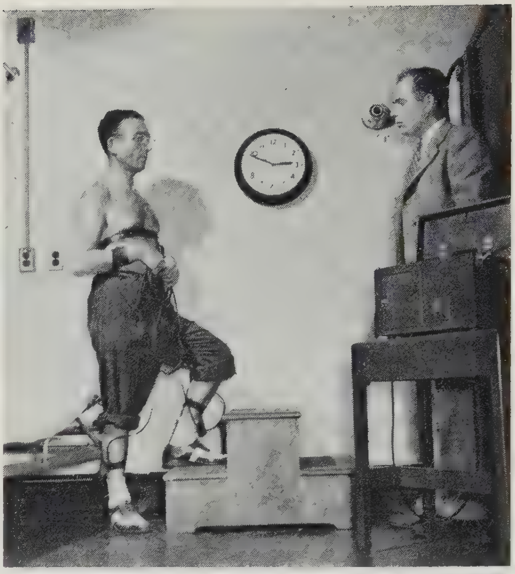

Fig. 729. Picture of steps used in Master 2-step test. (Courtesy Dr. Arthur M. Master, New York, N. Y.)

"When the base line (line of reference) of the electrocardiogram ascends, there is a tendency for the RS-T segment to be elevated artificially. It may be depressed when the base line descends. For this reason, it is wise to obtain a record of 3 or 4 beats on a horizontal level, so that the reading of the exercise electrocardiogram can be accurately made. . . ."

The proper base line (isoelectric level) from which to ascertain deviations of the S-T segment has been the subject of differences of opinion.

The T-P segment is often subject to artifactual alteration, or drifting, and when the heart rate is fast may even be absent. The P-R segment is relatively stable and its level is therefore easier to determine. It is thus the author's opinion that the level of the P-R segment should be used as the level of reference for the determination of deviations of the S-T segment. Master is likewise of the opinion that the P-R segment is the proper base line rather than the T-P segment.[4]

"Precautions: If the following simple precautions are heeded, the test is completely safe:

"1. The 'two-step test' should be performed only if the 12-lead resting electrocardiogram taken immediately prior to the test is normal.

"2. The exercise should be discontinued if the patient complains of chest pain.

*From Master, A. M., Field, L. E., and Donoso, E.: New York State J. Med. 57:1051, 1957.

"3. The test should not be done when the patient is sick.

"4. A single test should always first be performed on patients. Only when the single test is negative should the double test be undertaken. The latter is usually done an hour after the single test or on the following morning.

"With these precautions we have never had an accident during the performance of the 'two-step exercise test.' So-called modifications of the test may be dangerous since they usually require excessive physical exertion. They are, in addition, of little clinical diagnostic value since no criteria have been established to determine what constitutes a positive result in these various modifications.

"**Criterion of a positive test:** An RS-T depression of more than 0.5 mm. in any lead is our criterion of a positive test. T-wave alterations may often occur with the RS-T depressions. Minor T-wave changes alone are less significant, but definite T-wave inversion is probably abnormal. Transient arrhythmias or bundle branch block are of little diagnostic importance."

In addition to establishing the diagnosis of coronary artery disease, the Master 2-step test has been found useful in detecting the presence of a deficient coronary circulation in those persons who have no cardiac symptoms but are engaged in a type of work in which the occurrence of a heart attack would endanger not only themselves but also the people dependent upon them.

Other uses have been made of this test in the evaluation of the effects of various drugs on the coronary circulation.

Fig. 730 illustrates electrocardiographic changes in a positive Master 2-step test.

Pericarditis

The electrocardiogram is often of considerable aid in the diagnosis of pericarditis both with and without effusion. This is not to say,

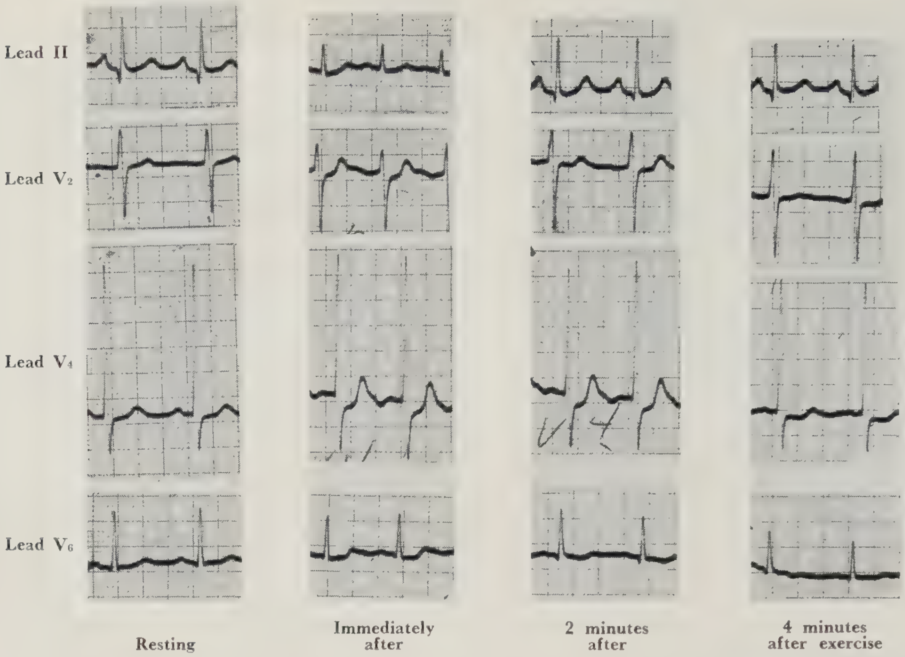

Fig. 730. Positive Master 2-step test. Note the decrease in amplitude of T_2 immediately after exercise, the depression of ST of 1 mm. in V_2 and particularly the depression of ST in V_4 of 2 mm. persisting until 4 min. after exercise, when the depression has decreased to 1 mm. These tracings are indicative of embarrassment of the coronary circulation.

however, that in this condition the electrocardiogram may not be normal. As in so many other clinical states, a normal electrocardiogram does not exclude the presence of pericarditis. Another confusing consideration is that underlying abnormalities other than pericarditis, such as myocardial ischemia, hypertension, electrolyte imbalance, etc., may obscure the electrocardiographic pattern usually associated with pericarditis.

In pericarditis there is inflammation of the pericardium and the superficial heart muscle adjacent to it. Death or necrosis of the heart muscle does not occur unless there is some other factor such as coronary thrombosis. Since significant Q waves are indicative of heart muscle death, abnormal Q waves will not be expected to occur as a result of pericarditis. This is an important difference that distinguishes the electrocardiogram of myocardial infarction from that of pericarditis. The changes most characteristic of pericarditis occur in the S-T segments and T waves. These are best elicited by taking serial electrocardiograms. The early sign is an elevation of the RS-T segment that usually occurs in all the standard leads and the chest leads. This may be a point of differentiation from myocardial infarction in which the elevation occurs in Lead I or Leads II and III with **reciprocal** depression in Leads III or II and I, depending on the site of the infarct.

The RS-T elevation progressively becomes less so that after several days the RS-T segment is at the isoelectric level, and if only one electrocardiogram were taken confined to this period, the resulting normal electrocardiogram would give no clue as to the presence of pericarditis. The T waves then progressively become lower in amplitude so that eventually they are isoelectric, diphasic, and finally inverted. Here again it is important to stress that the T-wave changes, just as is the case with the RS-T segment elevation, occur often in all the standard leads and are not reciprocal as would be the case in myocardial infarction. Subsequently, the T waves will often but not always return to normal, this period being variable but usually being several weeks. Another distinction from myocardial infarction is that the electrocardiographic changes are much more evanescent and less likely to be permanent in pericarditis.

Another striking type of electrocardiographic change is found when pericarditis has resulted in the formation of effusion. Under this circumstance there is likely to be low voltage in all the standard leads and often in the chest leads. This low voltage is caused by

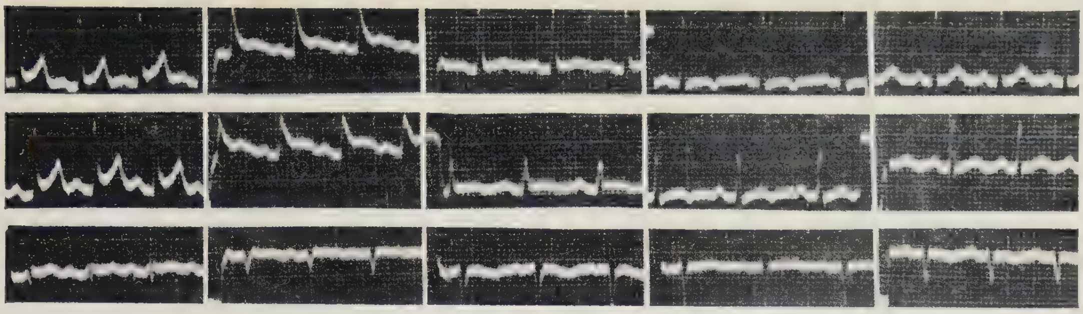

Fig. 731. A series of electrocardiograms of a patient with rheumatic pericarditis. (From Scherf, D., and Boyd, L. J.: Clinical electrocardiography, Philadelphia, 1946, J. B. Lippincott Co.)

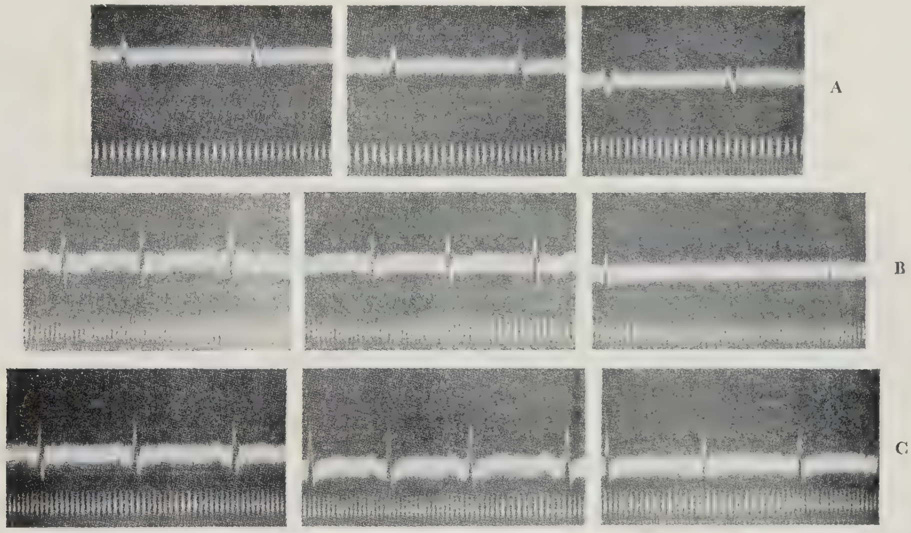

Fig. 732. A, Electrocardiograms in a pericardial effusion. **B,** After removal of 500 ml. fluid. **C,** After absorption of effusion. (From Scherf, D., and Boyd, L. J.: Clinical electrocardiography, Philadelphia, 1946, J. B. Lippincott Co.)

the short circuiting of the electrical potentials of the heart by the pericardial fluid. One must be cautious about interpreting low voltage since it may occur in normal persons (in whom the P and T waves are of normal amplitude), in myxedema, and in severe pulmonary emphysema.

If pericardial adhesions form as a result of pericarditis, the heart may be fixed in a relatively immobile position in the chest, and electrocardiograms taken with the patient in various positions will fail to show a shift in the electric axis of the electrocardiogram.

Syphilitic heart disease

The characteristic lesion of syphilitic heart disease is aortic regurgitation. Since changes in an electrocardiogram depend on muscular involvement and not on valvular defects, the effect of aortic regurgitation on the electrocardiogram will be caused by secondary results of this valve lesion, i.e., left ventricular enlargement. As stated above, increase in size of the left ventricular muscle causes left axis devitation. It is thus evident that the electrocardiographic pattern that one expects for the usual syphilitic involvement of the cardiovascular apparatus is not specific for that condition. It may occur as well in any other condition causing left ventricular enlargement. If the syphilitic aortic regurgitation is early or is only slight and no significant left ventricular enlargement has occurred, the electrocardiogram may then show a normal axis. Other changes (nonspecific) in the electrocardiogram may occur if the mouths of the coronary arteries are obstructed by a syphilitic lesion of the aorta with resultant fibrosis of the myocardium. The electrocardiographic effects will then be not unlike those of chronic coronary obstruction from other causes—inversions of T waves, alterations in conduction, spread and notching of QRS complexes, and increased P-R interval.

Acute pulmonary artery obstruction

Acute pulmonary artery obstruction is a condition that is often catastrophic and may cause death instantly or within a short period of time. The electrocardiogram often gives characteristic patterns that will fortify the physician in his decision to take heroic measures for treatment. It should be emphasized, however, that the electrocardiogram may be entirely normal in this condition.

In characteristic examples, the S wave in Lead I is prominent and wide, and leads rather abruptly and by a steplike configuration of the shortened S-T segment into the T waves. Q waves are often present in Leads II and III, and T_2 and T_3 are inverted. Note that the pattern of Q_3 and inverted T_3 is that described for posterior infarction. The prominent, wide S_1 and the characteristic S-T segment in Lead I, as well as the much more transitory nature of the picture in acute pulmonary artery obstruction, all help to differentiate it from posterior infarction in which the changes endure for months and are usually permanent. The electrocardiogram of acute pulmonary artery obstruction often though not necessarily reveals right axis deviation because of the strain on the right heart. Fig. 733 illustrates an electrocardiogram in acute massive pulmonary artery obstruction.

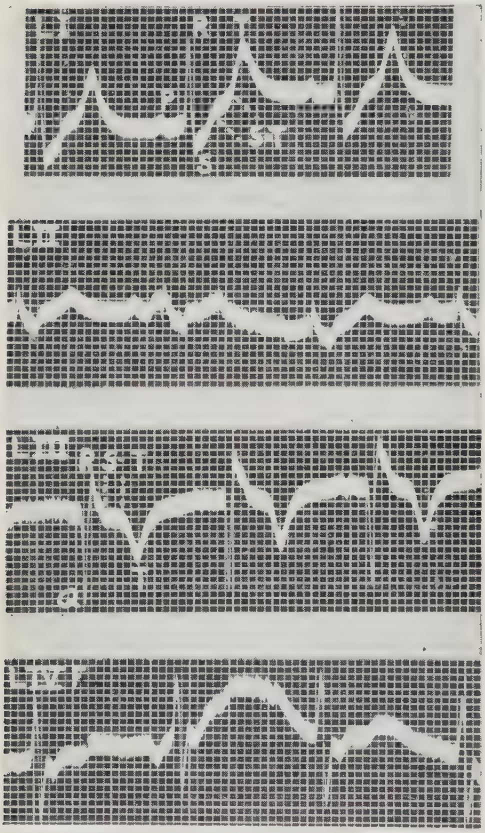

Fig. 733. Acute massive pulmonary artery obstruction. Note the prominent wide and slurred S wave and the short steplike S-T segment in Lead I. The deep Q wave and inverted T wave in Lead III resemble those of posterior wall myocardial infarction. (Cambridge spring instrument using photographic equipment.)

Pulmonary emphysema and pulmonary artery sclerosis

Pulmonary emphysema and pulmonary artery sclerosis may cause changes in the electrocardiogram by increasing the strain on the right ventricle and thus result in right axis deviation. The P wave is often characteristically altered in pulmonary emphysema. It becomes tall and sharply peaked in Leads II and III (the P pulmonale) in contrast to the P wave of mitral stenosis, which is broad, prominent, and notched in Leads I and II. The T waves not infrequently may be low or inverted. Fig. 712 shows an example of P pulmonale.

Any other conditions that affect oxygenation of the heart muscle, such as anemias, can be expected to cause lowering or inversion of T waves.

Electrolyte disturbances and the electrocardiogram

It has been well known that certain electrolyte disturbances have distinct and often recognizable effects on the electrocardiogram. The electrolytes of clinical significance that have been studied with relation to the electrocardiogram are chiefly potassium and, to a less extent, calcium. These electrolytes may cause electrocardiographic disturbance by being either increased or decreased in the blood.

Potassium is the most important of the electrolytes in this connection. It has been established that its passage in and out of the cardiac cell is vitally influenced by digitalis. In certain cardiac arrhythmias caused by digitalis intoxication, such as paroxysmal tachycardia with block, the administration of potassium is of therapeutic importance.

The changes in the electrocardiogram roughly correlate with the level of the serum potassium. In hyperpotassemia, with levels between 7 and 9 mEq./L. potassium (normal about 5 mEq./L.), there is increase in T-wave amplitude and decrease in its width (Fig. 734). As the level of potassium increases above this, the P wave disappears as a result of standstill of the atria (Fig. 735). When the potassium level reaches 10-10.5 mEq./L., progressive widening of QRS occurs until it finally fuses with the T wave (Fig. 736). At 12-14 mEq. complete cardiac cessation occurs.

In hypopotassemia there may be entirely normal electrocardiographic patterns, but in general the following changes occur:

1. S-T segment depression with lengthening of the Q-T interval.
2. Inversion of the T wave and lengthening of the Q-T interval.
3. Increase in amplitude of the T wave which remains upright with prolongation of Q-T interval.
4. Presence of a U wave with a small T wave.

The electrocardiographic patterns accompanying increased potassium levels in the blood have been used as a means of following the efficacy of therapy directed toward correcting this abnormality, although this may be difficult to evaluate since other factors such as digitalis therapy or myocardial disease may influence the T wave, S-T segments, and Q-T interval.

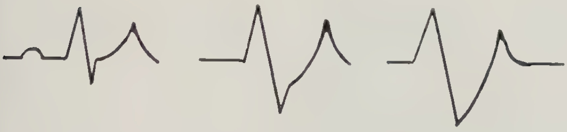

Fig. 734 Fig. 735 Fig. 736

Figs. 734-736. Effect of slight, moderate, and marked hyperkalemia on the electrocardiogram. (From Dimond, E. G.: Electrocardiography, St. Louis, 1954, The C. V. Mosby Co.)

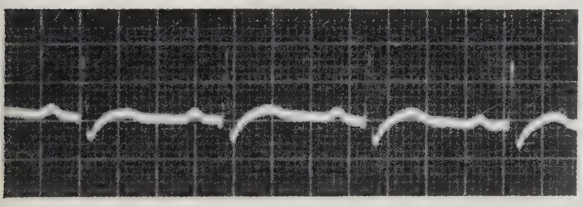

Fig. 737. Effect of increased serum calcium on electrocardiogram. Note shortened Q-T interval. (From Dimond, E. G.: Electrocardiography, St. Louis, 1954, The C. V. Mosby Co.)

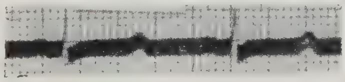

Fig. 738. Effect of decreased serum calcium on electrocardiogram. Note prolonged Q-T interval. (From Dimond, E. G.: Electrocardiography, St. Louis, 1954, The C. V. Mosby Co.)

Calcium is another electrolyte that is known to affect the electrocardiogram at times. Increased level of calcium (hypercalcemia) may cause a shortening of the Q-T interval. The T wave may be increased in amplitude (Fig. 737).

Decreased calcium levels (hypocalcemia) produce prolonged Q-T interval (Fig. 738).

Thyroid disturbances

Thyrotoxicosis is commonly associated with an electrocardiogram that shows merely normal complexes occurring at a faster than normal rate, i.e., sinus tachycardia. Occasionally the QRS and T waves may show greater voltage than usual. One common abnormality of rhythm that is manifested by hearts exhibiting the effects of the increased cardiovascular strain of thyrotoxicosis is atrial fibrillation, described below under "abnormal rhythms."

The opposite picture of thyrotoxicosis, myxedema, is often associated with electrocardiographic changes revealing low QRS and low or inverted T waves as well as slow rates (sinus bradycardia).

Deficiency diseases

Deficiency diseases, of which beriberi is an outstanding example, often show electrocardiographic evidences of myocardial involvement such as low ventricular complexes (QRS and T) and inversion of the T waves.

Malnutrition often causes prolonged Q-T interval and decrease in amplitude of all the complexes. In extreme starvation the heart rate is often decreased.

Pellagra and beriberi frequently cause the T wave to become inverted. In addition, in these states there are RS-T elevations and often low ventricular complexes as well as increased heart rate.

Toxic states

Acute toxic conditions such as diphtheria and scarlet fever may cause changes in T waves—flattening or inversion—and varying degrees of heart block—increase in P-R interval.

Chronic toxemias, such as uremia, often exhibit effects on the electrocardiogram. The QRS interval is often increased, the T waves are inverted, the S-T segment is depressed, and the Q-T interval is increased as well. Pericarditis, a complication of uremia, may superimpose its effect upon the electrocardiogram. P waves and Q-T alterations may occur in uremia secondary to the increase in serum potassium levels often seen in uremia.

Drug effects

Digitalis: It is important to consider the effects of certain drugs on the electrocardiogram. Digitalis, the most important drug used in the treatment of heart disease, exerts certain characteristic effects. The most characteristic effect is on the S-T segment which descends abruptly without any tendency toward upward convexity as in the coronary S-T segments. The T waves are also depressed and eventually may become inverted with full digitalis effect.

Digitalis also manifests an effect on atrioventricular conduction so that the P-R interval is increased to the extent that even marked degrees of heart block are produced. In toxic effects many different types of disturbances of rhythm, most often extrasystoles, are produced. Fig. 739 shows the effect of digitalis on the electrocardiogram.

Quinidine: Quinidine is a valuable drug in the treatment of certain serious cardiac

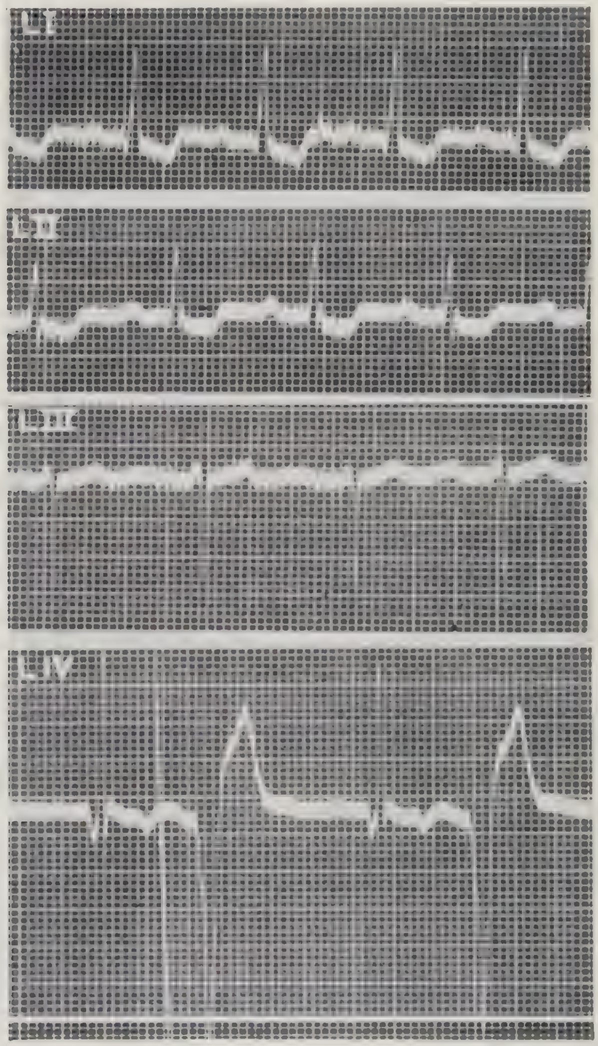

Fig. 739. Digitalis effect. The S-T segments are depressed with abruptly downward deviation and no convexity upward. The T waves have become inverted in Leads I, II, and IV. The characteristic changes are here most typically shown in Leads I and II. In Lead IV are seen ventricular premature beats occurring every second cycle (pulsus bigeminus), a toxic manifestation of digitalis. The P-R interval is increased to 0.23 sec., this being also a toxic effect of digitalis.

arrhythmias, such as paroxysmal ventricular tachycardia, paroxysmal superventricular tachycardia, and atrial flutter. However, in overdosage it can be dangerous. The use of the electrocardiograph is an important means of preventing overdosage with quinidine since quinidine causes well-defined effects on the electrocardiogram. Quinidine causes prolongation of the QRS complex, and for this reason it should not be used except with the greatest of caution in patients having intraventricular conduction defects (right and left bundle branch block and arborization block).

Furthermore, in a patient who is under intensive treatment with quinidine, electrocardiograms should be taken at frequent intervals, and if the QRS complex becomes significantly prolonged (perhaps 25% more than normal), further therapy with quinidine should be continued only after careful consideration of the calculated risks involved in continuing or stopping the administration. Quinidine, in addition to its effect on the QRS complex, causes slowing of the heart rate, prolongation of the Q-T interval, and lengthening of the P-R interval and P waves. Although it does not appear to be described in the literature, the author has seen markedly widened, large, and bizarre T waves with consequent prolonged Q-T interval often enough to consider this effect as characteristic of high quinidine dosage.

Neurocirculatory asthenia

The importance of distinguishing psychogenic effects on the electrocardiogram from those of organic diseases has been pointed out. These psychogenic effects are manifested by flattening, notching, or inversion of the T waves usually in Leads II and III or the chest leads and very occasionally in Lead I. They have often been mistaken for organic effects. The importance of distinguishing between the changes in the electrocardiogram occasionally associated with neurocirculatory asthenia and those caused by organic heart disease is obvious since it involves matters affecting the happiness of the patient—prognosis, insurability, physical activity, desirability of marriage, etc. That such distinction can often be made has been pointed out by Wendkos, who restored abnormal T waves to normal by the use of certain drugs that act upon the autonomic nervous system. This type of pattern usually occurring in the young has been referred to as the "juvenile pattern."

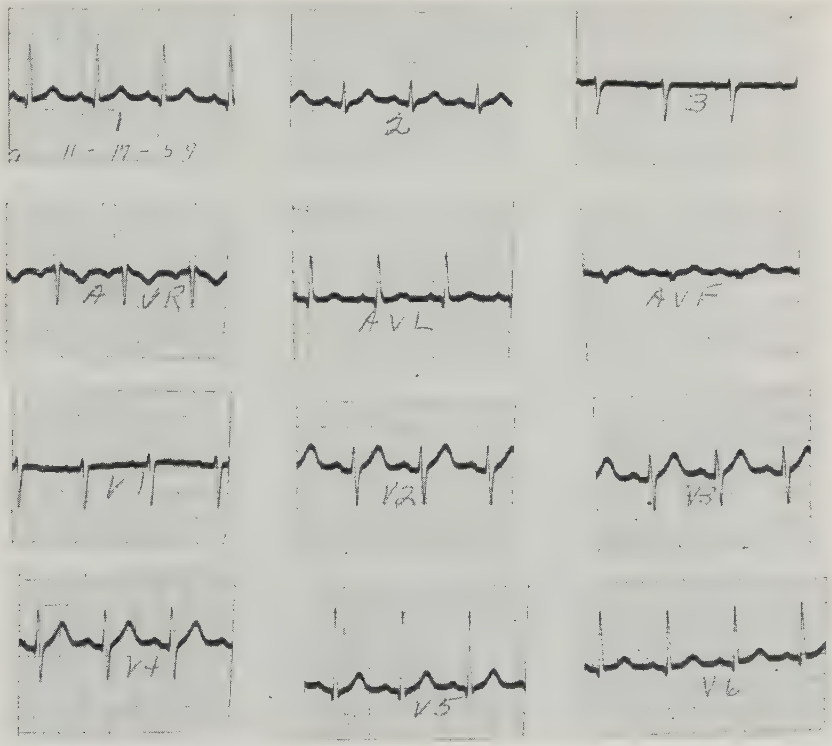

Fig. 740. Sinus tachycardia. The configuration, duration, and relationship of the complexes to each other are normal. The heart rate is 115/min.

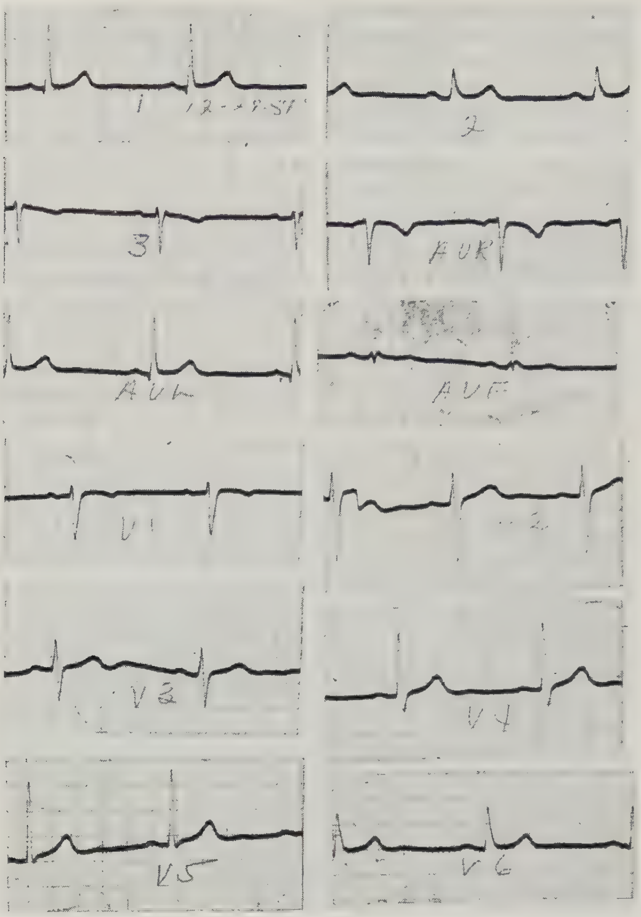

Fig. 741. Sinus bradycardia. The configuration, duration, and relationship of the complexes to each other are normal. The heart rate is 53/min.

In many patients either with or without organic heart disease, a great variety of disturbances in rate, rhythm, and conduction may occur. It is important to remember that these abnormalities in many instances do not necessarily indicate the presence of organic heart disease, but that, on the other hand, some are more likely to be associated with serious heart disease than others. It is not our purpose here to describe these clinical correlations but rather to describe briefly those disorders in mechanism that are more commonly seen.

NORMAL VARIATION IN RATE AND RHYTHM

In a normal electrocardiogram the normal sequence of complexes, P, QRS, and T occurring in their correct relationships with each other and at a rate of 60-100/min., is known as a normal sinus mechanism. The impulse starts in its normal place in the sinus node and passes through the atria down the A-V node, the bundle of His, the right and left bundle branches, and throughout the ventricles in a normal manner.

Sinus tachycardia: Impulses emanating from the sinus node occur at a rate exceeding 100/min. Because the impulse follows the normal conduction pathways, the complexes are situated normally with respect to each other. The increased rate results in varying degrees of shortening of the T-P interval. If the rate is fast enough, the T-P interval may be so shortened that P waves are superimposed upon the preceding T waves. Fig. 740 shows sinus tachycardia.

Sinus bradycardia: Here again the mechanism of conduction is normal, and consequently the relationships of the complexes are normal. The rate, however, is below 60/min. Fig. 741 shows sinus bradycardia.

Sinus arrhythmia: The impulse for cardiac contraction originates in the normal place in the sinus node. However, because of variations in vagus nerve tone affecting the speed of impulse formation in the sinus node, the rhythm varies, with regularly recurring faster and slower cycles. The configuration of the complexes and the relationships between the atrial and the ventricular complexes are normal; the only variation is a regularly recurring increase and decrease of the T-P intervals with the slower and faster cycles. This mechanism is considered a normal alteration in rhythm. It depends, as a rule, upon the phase of respiration, an increase in rate occurring with inspiration, and a decrease with expiration.

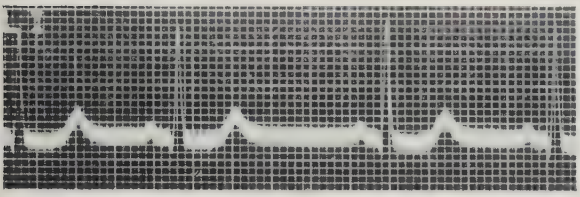

Fig. 742. Sinus arrhythmia. Note that the atrial and ventricular complexes are of normal configuration and have normal time relationships. The only alteration is the shortening and lengthening of the T-P intervals.

ABNORMAL VARIATIONS IN MECHANISM

Disturbances in pacemaker

Since the impulse that originates cardiac contraction normally starts in the sinus node, this node is known as the pacemaker. The site of origin may shift from its normal place and occur anywhere along the conduction system from the atria to the ventricles. This abnormal disturbance in site of the pacemaker may occur as a result of functional or nervous influences, of toxic effects such as those due to drugs, and of organic disease involving the conduction system.

Sinus arrest (sinoatrial block)

In this mechanism there is a dropping out of a complete atrial cycle together with its

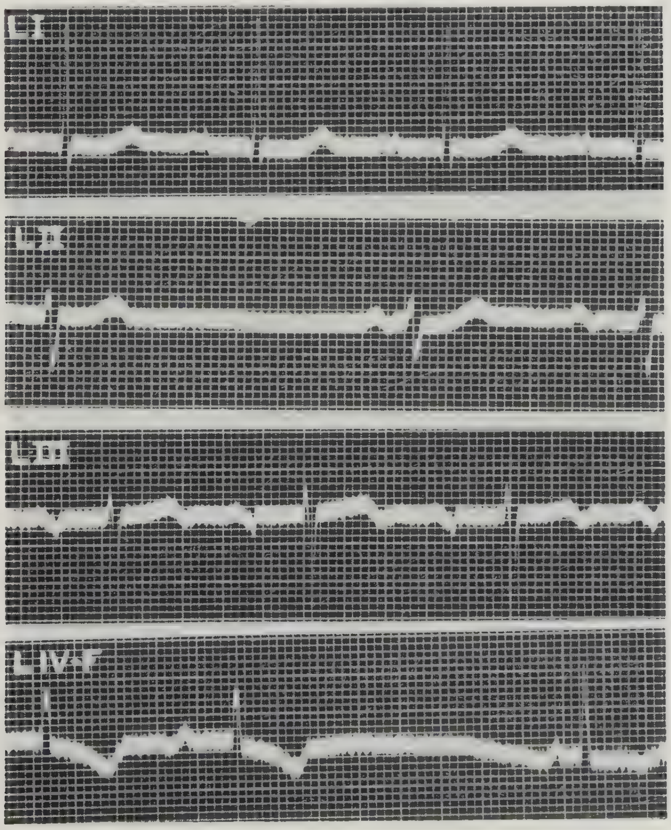

Fig. 743. Sinus arrest (sinoatrial block), also delayed A-V conduction. Note dropping out of a complete heart cycle including P and QRS and T waves in Lead II.

accompanying ventricular cycle, resulting in a pause usually almost the length of 2 normal cycles. The impulse at the sinus node has either not occurred at all or it has been blocked from reaching the atrial muscle. Fig. 743 shows sinoatrial block.

Ventricular escape

In ventricular escape the impulse emanates in the bundle of His or on rare occasions below the bifurcation of the bundle. This occasionally occurs in sinus arrest when there is depression of the higher centers of impulse formation with rising degree of irritability of the lower centers, to a point at which the lower center "escapes" from the control of the higher center (sinus node) and originates an impulse of its own. In this pattern a ventricular complex is seen after a long pause. This complex is normal because the impulse is supraventricular in origin, but no P wave precedes it. If, as rarely happens, the focus originates below the bifurcation of the bundle, the form of the ventricular complex becomes

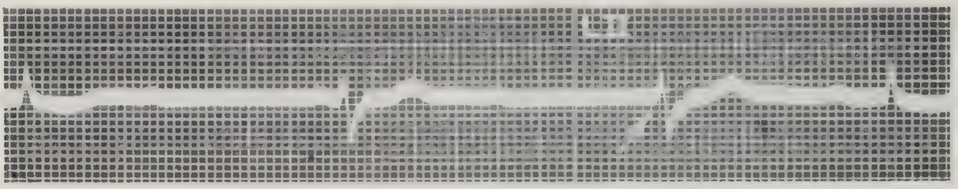

Fig. 744. Ventricular escape. Note that the "escaping" ventricular complex is not preceded by a P wave and is of similar configuration to the preceding one except for the slight distortion of the S limb due to a superimposed P wave. The electrocardiogram also shows 2:1 heart block.

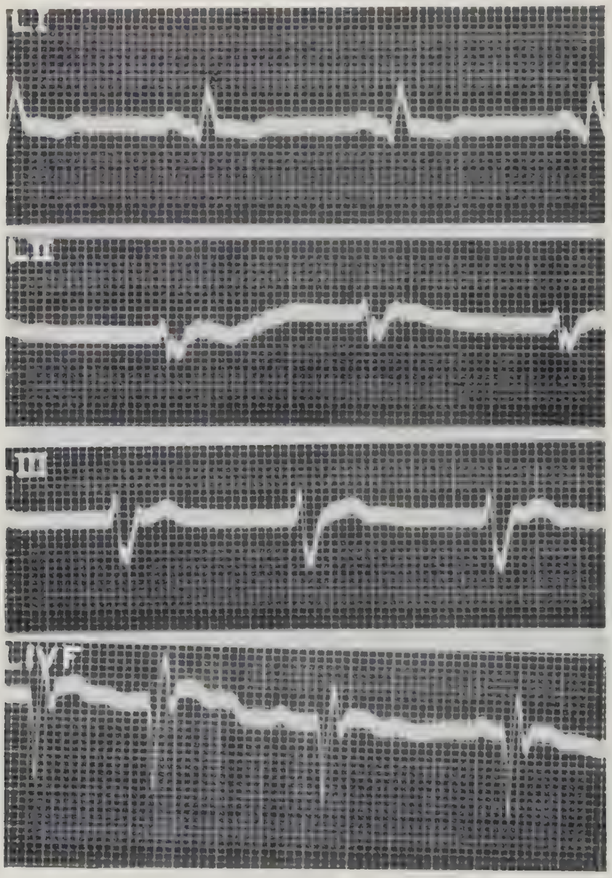

Fig. 745. Shifting pacemaker. In Leads I and IV F, the time relationship of P to QRS varies, with slight variation in form of P especially evident in Lead IV F.

distorted (aberrant). Fig. 744 shows ventricular escape.

Shifting pacemaker

In this mechanism the site of impulse formation may wander anywhere from the sinoatrial node to the atrioventricular node. The farther the impulse occurs from its normal origin in the sinoatrial node, the greater the alteration in the P wave. These alterations vary from only minor changes in the shape of the P wave to inversion of this wave. The relationship of P to QRS changes so that the P may precede the QRS by a much shortened P-R interval or the P may be buried in or may even follow the QRS. Contour of the QRS does not change since the site of impulse formation is supraventricular. There is sometimes slight arrhythmia, as may be expected. See Fig. 745.

Nodal rhythm

Here the site of pacemaking impulse formation is in the atrioventricular (A-V) node. Since this is a supraventricular site, the ventricular complexes are of normal contour. The rhythm is regular. The P wave may not be seen; it may be buried in the QRS or it may occur immediately before or after the QRS, depending on whether the impulse reaches the atria or the ventricles first. See Fig. 746.

Premature contractions (extrasystoles)

The existing rhythm may at times be interrupted by a contraction of the heart caused by an irritable focus that may arise elsewhere than in the sinus node—in the atria, in the A-V node, in the bundle of His, or in the right or left ventricle. These contractions occur early after the normal cycle, some time before the next normal contraction is ordinarily expected to appear. The site of origin of these contractions can be detected by the characteristic alterations of the electrocardiographic complexes and their time relationships. Premature contractions are usually followed by a pause which, in the case of atrial extrasystoles, is longer than the normal pause between 2 cycles but is not equal to the sum of 2 cycles. The pause following extrasystoles arising in the ventricles, is **compensatory;** that is, the length of the 2 cycles is equal to 2 normal cycles. There is an exception to this. Occasionally a ventricular extrasystole occurs without interrupting the regularity of the rhythm. No compensatory pause occurs, and in this case the extrasystolic beat may be followed by a pause shorter than the normal interval. Such ventricular extrasystoles are termed **interpolated.**

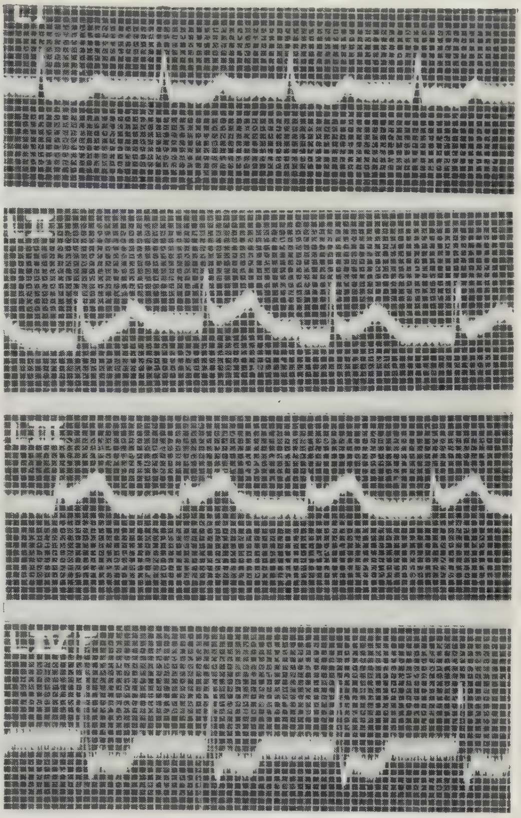

Fig. 746. Nodal rhythm. The rhythm is regular and the rate is 100. The P waves cannot be seen and are buried in the QRS complexes. The ventricular complexes are supraventricular in form. The impulse has probably originated in the middle of the A-V node. If it had originated in the lower portion of the node, P waves would be visible following the QRS and would be of abnormal contour; if it had originated in the upper portion of the A-V node, the P would have preceded QRS with a very short P-R interval. In all these types, P waves may be absent. Note that the ventricular complexes in this electrocardiogram indicate that posterior wall myocardial infarction is present.

The greater the distance from the normal site that the premature focus arises, the greater is the change in appearance of the extrasystolic complex from that of the usual one for the patient.

Premature systoles may occur with varying frequency. The rhythm is termed **bigeminy** when they occur every second cycle, **trigeminy** if they occur every third cycle, and **quadrigeminy** if they occur every fourth cycle. It is possible to see numerous extrasystoles of variable origin in the same electrocardiogram.

Premature atrial systole (atrial extrasystole): When an irritable focus in the atrium other than the sinoatrial node gives rise to an

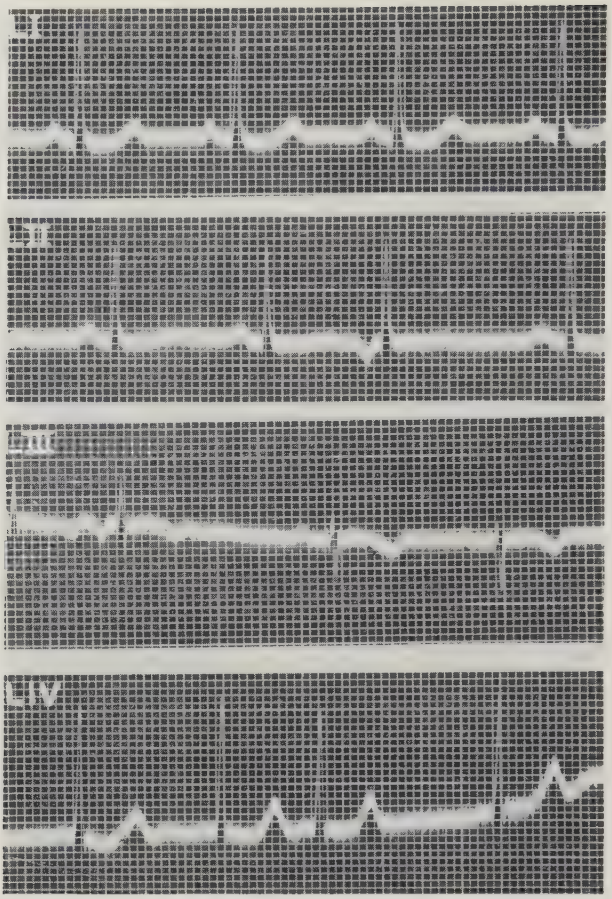

Fig. 747. Premature atrial contraction. The premature beat comes earlier than anticipated. The P waves of the premature cycles in Leads II, III, and IV are inverted and are followed by ventricular complexes of normal configuration except in Lead III where the QRS and T are slightly altered (aberrant). The P-R interval of the regular cycle in Lead II is 0.15 sec.; that of the extrasystole is 0.11 sec. Note that the pause following the premature atrial contraction is not compensatory.

atrial contraction, a premature atrial systole results. It is characterized by a P wave that occurs before it is expected, sometimes superimposed upon the preceding T wave, but differing in form from the usual P waves for that particular record. This alteration in form may vary from only a slight degree to a marked degree characterized by a completely inverted P wave, depending upon the distance between the point of origin of the premature focus and the sinoatrial node. The P-R interval is increased or decreased and the QRS and T waves are unaltered in form, although these may occasionally be changed (aberrant). At times an extrasystolic P may occur without a corresponding QRS; that is, the ventricles may be refractory and do not respond to the extrasystolic impulse from the atrium, or the extrasystolic impulse from the atrium may be entirely blocked from reaching the ventricles. The pause that follows an atrial extrasystole is greater than the interval between 2 normal cycles, but the total time between the cycle preceding the premature systole and the one following it is less than the total of 2 normal cycles. In other words, the pause following a premature atrial systole is not usually compensatory.

Premature nodal contractions (nodal extrasystoles): The impulse for this type of premature contraction arises in the atrioventricular node or the bundle of His. This impulse travels downward to the ventricle and backward to the atrium and produces both an atrial and a ventricular contraction. If the backward-traveling impulse reaches the atrium at the time of the ventricular contraction, the P wave is concealed in the QRS complex. The P waves, when visible, are inverted and may occur before or after the QRS, depending on when the impulse has reached the atria in relation to the time that the opposite traveling impulse has reached the ventricle. Since the impulse has reached the ventricles from above (supraventricular), the form of the ventricular complexes will not be altered, or it will be altered only to a slight degree (slightly aberrant). The pause following this type of premature contraction may or may not be compensatory.

In rare instances the retrograde impulse does not reach the atria, or the atria are unresponsive (refractory) to the backward traveling impulse. The atria in such cases continue to respond to the normally traveling impulses from the sinoatrial node, and the P waves are normal in shape and direction. See Fig. 748 illustrating premature nodal systole.

Premature ventricular contraction (ventricular extrasystole): In this type of premature contraction the focus arises either in the right or in the left ventricle below the bifurcation of the bundle of His. The ventricular complexes occur before the next regular complex. The QRS complex is characterized by increased width, notching, and slurring and usually increased amplitude. The accompanying T is usually in a direction opposite to the main deflection of the QRS; it is of greater amplitude and width than the other T waves.

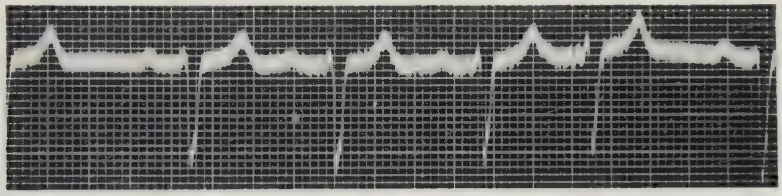

Fig. 748. Premature nodal contraction (Lead III). The premature contraction occurs early. The ventricular waves of the nodal contraction are normal in configuration (supraventricular). The P wave is not visible.

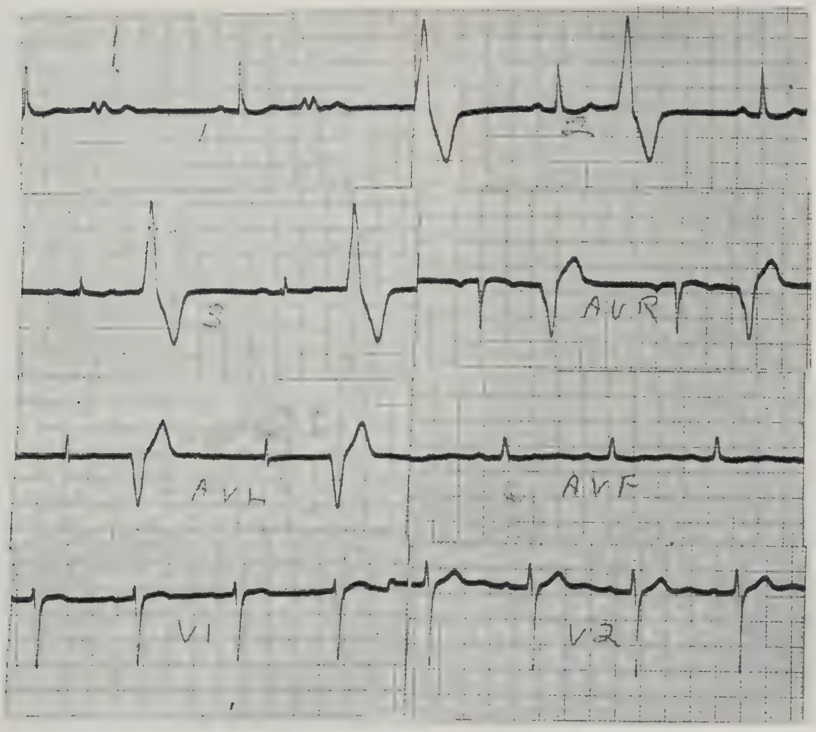

Fig. 749. Ventricular premature contraction (extrasystole). The QRS complexes are widened and slurred, and the T waves are large and in opposite direction from the main deflection of QRS. The premature ventricular complexes occur every second cycle in Leads I, II, III, $\mathrm{aV_R}$, and $\mathrm{aV_L}$ (pulsus bigeminus).

The pause that follows the ventricular extrasystole is compensatory; that is, the sum of the duration of the preceding cycle and of the cycle following the extrasystole is equal to the duration of 2 normal cycles.

Atrial rhythm is not influenced, but the P waves are often lost in the premature ventricular complexes. The ventricles are refractory shortly after the extrasystolic contraction; thus they do not respond to atrial stimulus during this phase. Sometimes the refractory phase has passed before it is time for the next regular contraction. In such cases no dropping out of the regular cycle is evident, and the extrasystole is followed by a pause that is less than the interval between 2 successive normal cycles of the record. The extrasystole is then termed **interpolated.**

If the premature focus arises in the left ventricle, the main deflection of QRS is down in Lead I (Fig. 749); if it arises in the right ventricle, the main deflection is up in Lead I. The main deflections of QRS in Leads II and III may be up or down in either left or right ventricular extrasystoles, although usually an upward main deflection of QRS in these leads indicates a left ventricular extrasystole and a downward main deflection indicates a right ventricular extrasystole.

Paroxysmal tachycardia

Paroxysmal tachycardia is a term applied to a series of rapidly recurring heart cycles that have their origin in an abnormal focus in the atria, in the atrioventricular node or bundle, or in the ventricles. These episodes are characterized by the suddenness with which they start and stop; hence the term

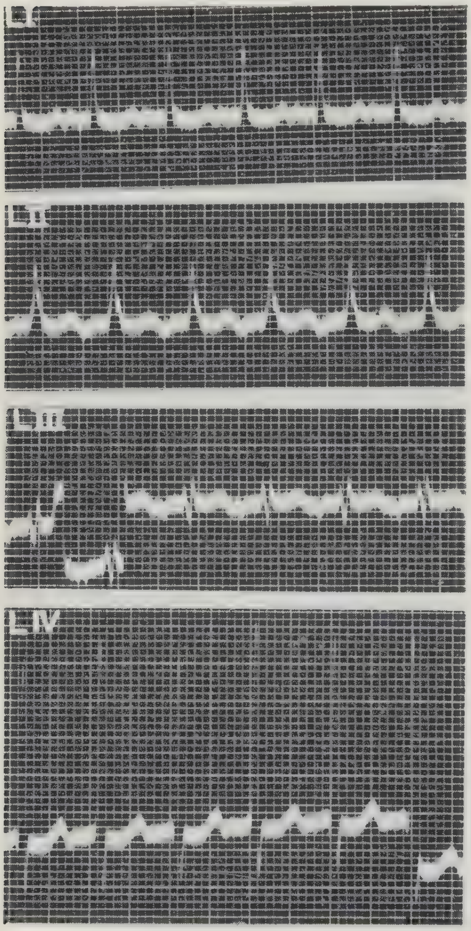

Fig. 750. Paroxysmal atrial tachycardia. The rate is 157 and the rhythm is regular. The P waves in Lead I are tiny and follow immediately the preceding T waves. In Leads II and III the P waves are inverted. The P-R interval is 0.12 sec. The QRS is of normal duration and of normal configuration.

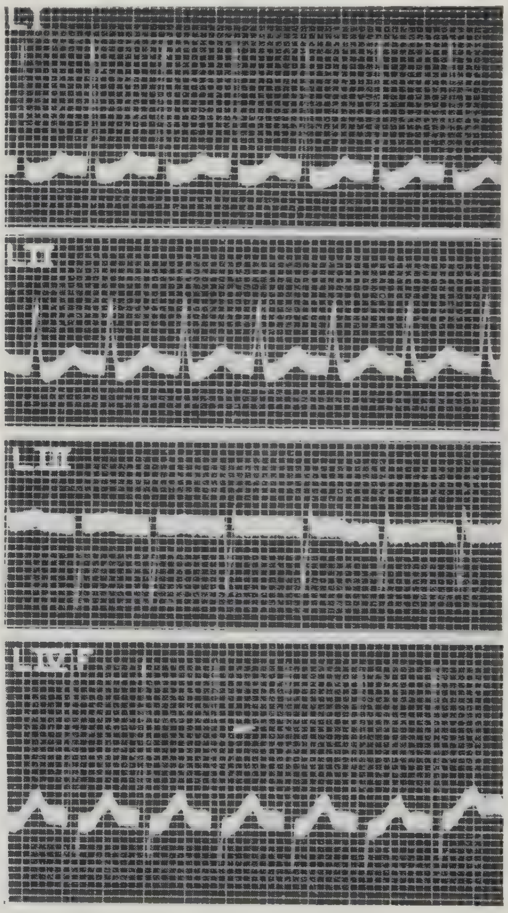

Fig. 751. Paroxysmal nodal tachycardia. The appearance of the ventricular complexes is supraventricular and like that in nodal rhythm. However, the rate is much faster—171/min. The rhythm is perfectly regular. The P waves, as in the example of nodal rhythm, cannot be identified.

"paroxysmal." They may last from a minute or more to several days. The rate usually is quite constant, depending upon the origin of the impulse formation. The rate may be between 150 and 250/min. Because they originate in some abnormal irritable focus, these tachycardias may be regarded as a series of rapidly recurring premature systoles. These tachycardias are termed paroxysmal atrial, nodal, or ventricular tachycardia, deriving their names from the site of the abnormal focus.

Paroxysmal atrial tachycardia: This type of mechanism is thought of as a series of rapidly recurring atrial extrasystoles. The P waves are different in form or in direction from P waves of a normal mechanism. The preceding T wave is often superimposed on the P wave so that identification of the P wave may be difficult or even impossible. In such instances differentiation of paroxysmal atrial tachycardia from paroxysmal nodal tachycardia cannot always be made. The QRS complexes are not usually altered in form, but they may be aberrant to varying degrees. Rate and rhythm are characteristically constant. Fig. 750 shows an example of paroxysmal atrial tachycardia.

Paroxysmal nodal tachycardia: Here, too, rate and rhythm are absolutely constant. The P waves are usually hidden in the QRS complex, but occasionally they occur before or after the QRS. Configuration of the QRS and T waves is not disturbed. The picture is one of nodal rhythm except for the rates which are much higher in paroxysmal nodal tachycardia. Fig. 751 shows an example of paroxysmal nodal tachycardia.

Paroxysmal ventricular tachycardia: The rate in paroxysmal ventricular tachycardia, as in the other tachycardias, may be from 150 to 250/min. The appearance is that of a series of rapidly recurring ventricular extrasystoles. The P waves are usually not identifiable, but, if seen, their rhythm is not altered. The rhythm is usually regular, although this type of tachycardia differs from nodal and atrial tachycardia in that the rhythm is often slightly irregular. This slight irregularity may at times offer a means of distinguishing atrial from ventricular tachycardia without the aid of the electrocardiograph. Fig. 752 is an example of paroxysmal ventricular tachycardia. This type of mechanism imposes a more serious prognosis, and its recognition is an urgent signal to the physician for prompt measures to terminate it.

Atrial flutter

This mechanism may be persistent or transitory. The sinoatrial node loses control of the dominant rhythm of the heart. The impulse travels a pathway about a ring of atrial musculature in a continuous cycle. This has been described as **circus movement.**

The electrocardiogram shows the atrial ac-

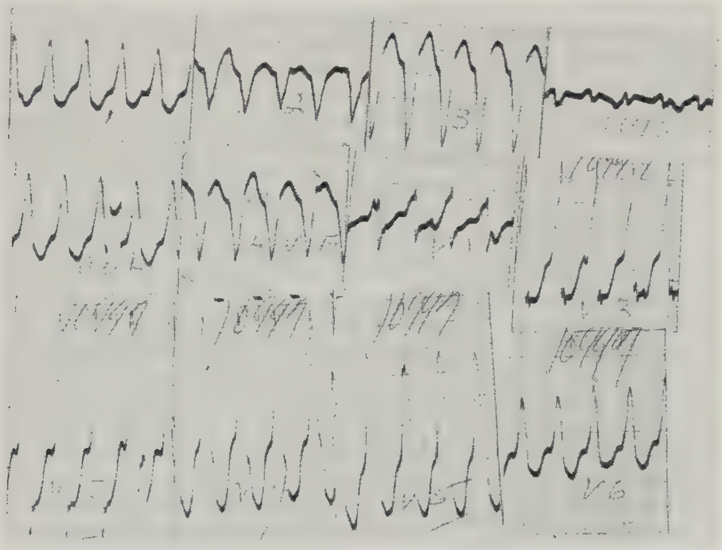

Fig. 752. Paroxysmal ventricular tachycardia. The ventricular rate is 200. The QRS complexes are widened, 0.12 sec. in duration, slurred, and notched, with T waves in opposite direction from the main deflection of QRS. The rhythm is regular.

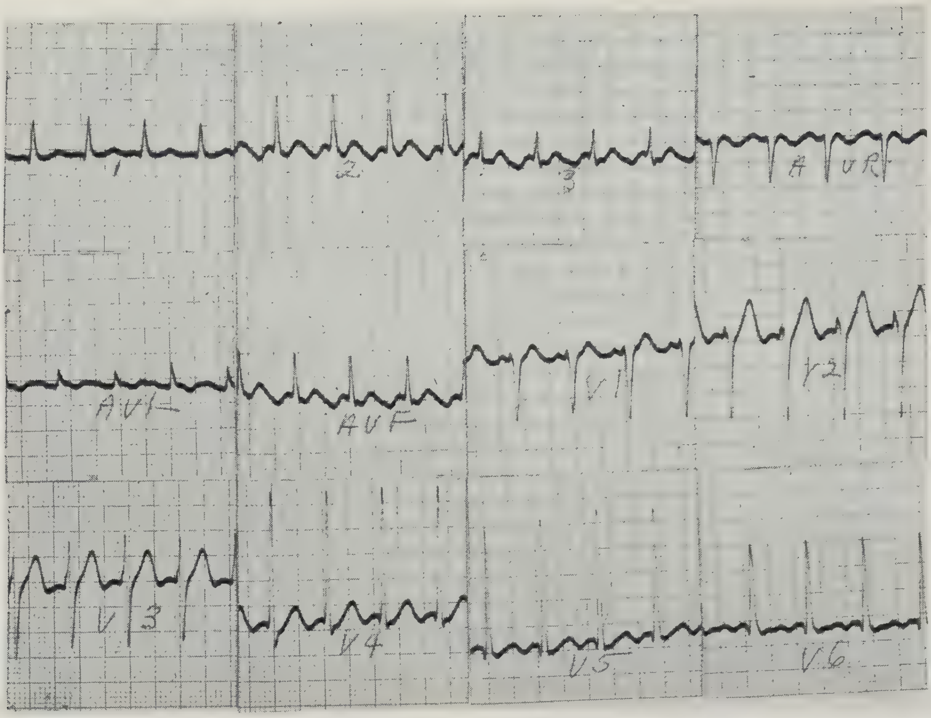

Fig. 753. Atrial flutter. The flutter waves appear as more or less regularly recurring, sawtooth deflections, most prominent in Leads II, III, and aV_F. There is a varying rate of ventricular response, from 2:1 to 3:1. The ventricular rate is 133/min. The atrial rate is 300/min.

tivity as regularly recurring sawtooth oscillations (flutter waves), interrupted by ventricular complexes at regular intervals in response to every second, third, or fourth atrial flutter waves. The form of the ventricular complexes is not altered except by the superimposition of the flutter waves themselves. The frequency of response by the ventricles to the flutter waves may vary in the same electrocardiogram so that the rhythm of the ventricular complexes may become irregular. See Fig. 753.

Rarely, a ventricular complex follows each atrial flutter wave (1:1 ratio). The flutter waves occur at rates of 200-350/min. They are most clearly identified in Leads II and III. Not infrequently they cannot be seen at all or they are much less obvious in Lead I. Fig. 753 illustrates atrial flutter.

Atrial fibrillation

Circus movements are also present in atrial fibrillation, but the pathway is shorter and irregular in its course by comparison with atrial flutter. This results in rapidly and irregularly recurring impulses that pass in an uncoodinated manner through the atrial muscle fibers. This is revealed in the electrocardiogram by absence of P waves as such. The P waves are replaced by small waves that are totally irregular in rhythm, size, and shape. These are termed fibrillary or "f" waves. These waves may at times be absent. They occur at rates of 350-500/min., but the rate is never constant. The ventricular complexes are not altered in form from the usual form for that patient. They occur in a completely irregular rhythm except in those rare instances in which there is complete blocking of the impulses from the atria to the ventricles. The less the degree of block in the bundle of His, the faster and more irregularly do the ventricular complexes occur. Atrial fibrillation may be permanent or paroxysmal. Fig. 754 illustrates atrial fibrillation.

Ventricular fibrillation

Ventricular fibrillation is characterized by the complete loss of the normal characteristics of the ventricular complex. The waves have lost their regularly recurring consistent pattern and are bizarre. They are usually large and wide, vary in size and rhythm, and altogether suggest chaos in the electrical activity of the ventricular muscle. No T waves and usually no P waves can be identified. This is invari-

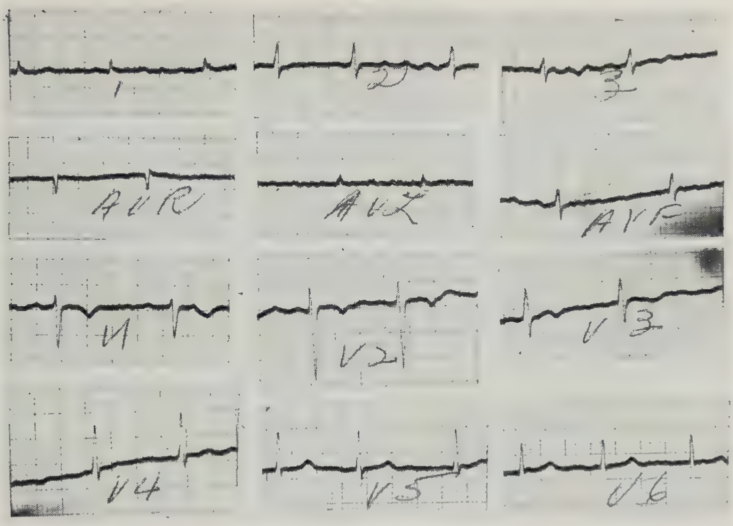

Fig. 754. Atrial fibrillation. The rhythm of the QRS-T complexes is totally irregular. The P waves are absent but are replaced by small, irregularly recurring waves that are unequal in amplitude and contour. These are the fibrillary waves, and they are best seen in Leads II and III.

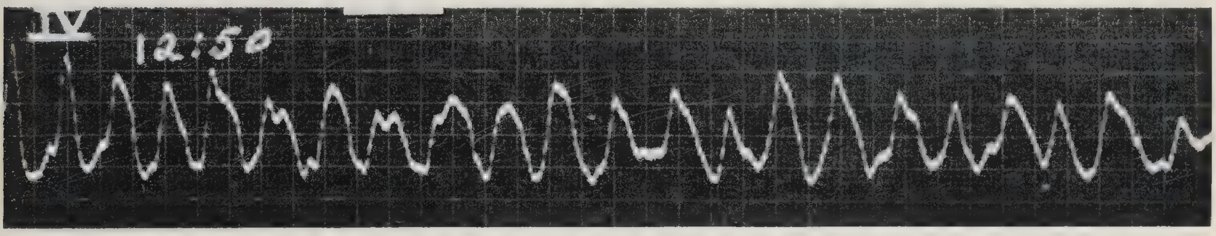

Fig. 755. Ventricular fibrillation. (From Dimond, E. G.: Electrocardiography, St. Louis, 1954, The C. V. Mosby Co.)

ably associated with death unless, as rarely happens, the ventricles can be "defibrillated" and an orderly sequence of electrical events can be restored. See Fig. 755.

Bundle branch block

When conduction of the impulse is completely blocked in either the right or the left branches of the bundle of His, a characteristic electrocardiographic pattern results. The QRS duration is increased to more than 0.12 sec. The deflections of the QRS are notched or slurred and are of large amplitude. The T wave is usually opposite in direction to the chief deflection of QRS and is of increased size. This is termed "bundle branch block." Bundle branch block may be incomplete or complete.

Incomplete bundle branch block: In this situation there is a delay rather than a complete block of conduction through one of the branches of the bundle of His. The tracings resemble complete bundle branch block except that the QRS duration is shorter than 0.12 sec.

It may be seen in both right and left ventricular hypertrophy, myocardial infarction, congenital heart disease, and pulmonary embolism in which there is right ventricular strain.

Left bundle branch block: In left bundle branch block the chief deflection of QRS is up in Lead I and usually down (discordant) in Lead III. See Fig. 756. Occasionally the chief deflection of QRS is also up in Lead III; this is then known as the concordant type of left bundle branch. The term "chief deflection" refers to the deflection of greatest duration or spread and is not necessarily the deflection of the greatest amplitude. The S-T segment is usually depressed in Lead I.

In the chest leads the characteristics are as follows: Over the left precordium the QRS complex is widened to 0.12 sec. or more. The onset of the downward stroke of the QRS complex (the intrinsicoid deflection) is de-

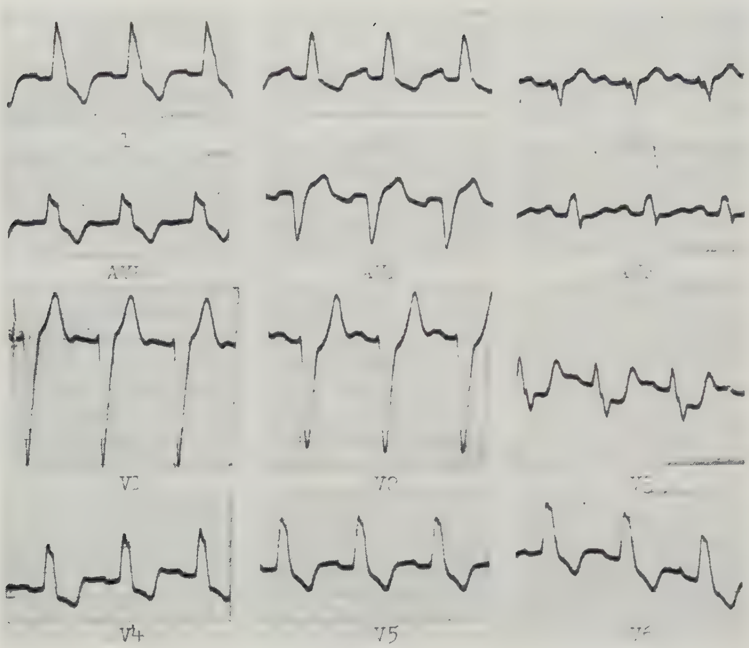

Fig. 756. Left bundle branch block (common type of bundle branch block). The QRS complex in Lead I is upright, slurred, notched, and widened with a duration of 0.12 sec. In Lead III the main deflection of QRS is down, slurred, and notched. The S-T segment in Lead I is depressed and in Lead III it is elevated. The T wave in Lead I is inverted, whereas in Lead III it is upright. In the left precordial lead (V_6) the Q wave is absent, the QRS complex being monophasic, upright, wide, and notched. The duration of QRS in Lead V_6 is 0.14 sec.

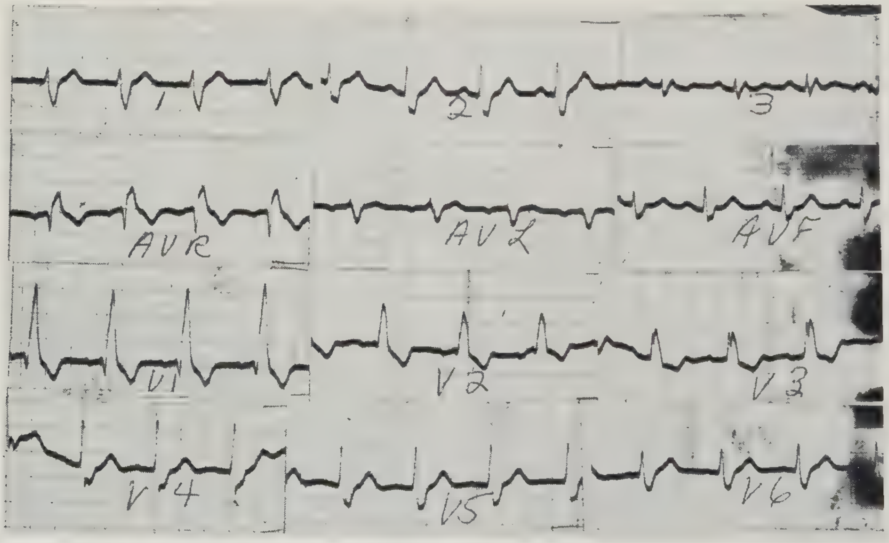

Fig. 757. Right bundle branch block. Duration of QRS is 0.13 sec. In Lead I, the R wave is relatively small and short in duration. The S wave is wide and notched and of relatively large amplitude. In Lead III there is rsr. In Lead aV_R the R′ forms a main deflection and is wide, slurred, and notched. In Lead aV_F, note that the S is wide, slurred, and notched. Most characteristically in Lead V_1, R is minute, S is small, and R′ is tall, wide, and slurred. In Lead V_6, as in Lead I, the S is wide, slurred, and notched, whereas the R is of normal duration and is relatively quickly inscribed.

layed to as much as 0.1 sec. or even more. The QRS amplitude is usually greater than normal. The S-T segment is depressed, and the T wave is usually inverted. An important feature is that the Q wave in Lead V_6 is absent, although this may not be true if infarction involves the septum itself or if there is marked counterclockwise rotation of the electrical axis of the heart.

Over the right precordium the R wave is small and is inscribed quickly (normal duration), or it may be absent. The S wave is slurred and widened. The T wave is upright, and the S-T segment may be elevated. These characteristics may be modified by variations in the electrical axis of the heart.

Left bundle branch block is seen more often than is right bundle branch block, and it is usually significant of serious organic heart disease, although it may occur in individuals otherwise considered to be normal.

Right bundle branch block: In right bundle branch block the chief deflection of QRS is directed downward in Lead I and usually upward in Lead III (Fig. 757). Another type of right bundle branch block occurs in which the R is tall and narrow and is followed by a shallow but widened S wave in Lead I.

In the right chest leads there is rsR′ configuration.* The time interval from the onset of the R to its apex and the beginning of the downward stroke is delayed from 0.04 to 0.08 sec. and is more prolonged in complete right bundle branch block as compared with incomplete right bundle branch block. The S wave in the left precordial lead is broad and slurred, but the R is normal in duration and the T is upright. The onset of R is early and of the R′ is late in the right precordial leads. Not infrequently a small R′ deflection in the right precordial leads may occur normally and may be considered to be right bundle branch block. Therefore the clinical significance of right bundle branch block must be interpreted with great caution.

Arborization block: In certain hearts there may be lesions not so much of the bundle branches as of the Purkinje fibers of the ventricles. This is sufficient to cause an abnormal widening and slurring of the QRS complex, but the QRS pattern does not have the other characteristics of either right or left bundle branch block. This represents a delay in intraventricular conduction and is termed "arborization block."

Peri-infarction block: This occurs usually in the presence of advanced heart muscle disease, usually myocardial infarction, and is characterized by widened QRS complex, a prominent Q wave, and a delayed wide R in leads in which Q is deepest. This comes about and is called "peri-infarction block" because the infarcted area cannot conduct the impulse and it must go around the infarct, thus taking a longer time to reach the epicardial muscle (Fig. 758).

Wolff-Parkinson-White syndrome

This is an infrequently seen type of electrocardiographic picture which bears a superficial resemblance to bundle branch block. It is characterized by a **shortened P-R interval** in contrast to the other types of bundle branch block in which the P-R interval is normal (or lengthened when a lesion involves the bundle of His as well as the bundle branch). The QRS is only slightly widened, 0.1-0.12 sec., and is relatively slightly notched and slurred. The most characteristic feature is a sloping and slurring of the initial ascending portion of the R wave. This is known as the "delta" wave (Δ). The RS-T segment and T are usually though not necessarily directed opposite to the direction of R. The diagnosis of Wolff-Parkinson-White syndrome is made only by means of the electrocardiograph.

That the patterns of the Wolff-Parkinson-White syndrome may vary widely has been pointed out by Burch and Kimball.[5] These authors classified the variations in these patterns into 5 groups, ranging from QRS complexes that closely resembled those of complete left bundle branch block to those QRS complexes that were of normal duration in all the standard leads. However, the shortened P-R interval was present in all these groups and gave the clue to the true nature of the condition. The author[6] has encountered a rare instance in which the type of Wolff-Parkinson-White syndrome characterized by shortened P-R interval and slurred basal portion of QRS complex with normal duration reverted spontaneously to normal patterns and then back to the Wolff-Parkinson-White patterns during the taking of the electrocardiogram.

The Wolff-Parkinson-White syndrome is not ordinarily associated with organic heart disease. However, patients who exhibit this

---

*Small letters refer to the small amplitude deflections of the QRS complex, whereas the capital letters refer to the large amplitude deflections. The designation prime (′) is used to refer to a second upward (R′) or downward (S′) deflection in the QRS complex.

electrocardiographic manifestation are likely to have episodes of paroxysmal tachycardia that on rare occasions have resulted in sudden death. Fig. 759 is an example of this interesting type of electrocardiographic pattern.

Atrioventricular block

Mention was made, in discussing the effects of rheumatic fever on the heart, of the involvement of the junctional tissues, either at the A-V node or at the bundle of His, by disease processes. Not only rheumatic fever but other types of disease as well can inhibit conduction of the impulse in the junctional tissues. These are principally degenerative diseases, drugs such as digitalis, and neurogenic influences.

First degree heart block: Degree of interference with conduction varies widely. In the milder forms there is only a slight delay in the speed of conduction so that the impulse reaches the ventricle after a greater than normal interval. The rhythm of the heart is regular, with each QRS complex following each P wave, but with a P-R interval greater than 0.2 or 0.21 sec. This degree of heart block is termed "first degree" heart block and is often referred to as "delayed atrioventricular (A-V) conduction." An electrocardiogram is invaluable in ascertaining its presence, since it is usually impossible to recognize it clinically. Fig. 760 illustrates first degree heart block.

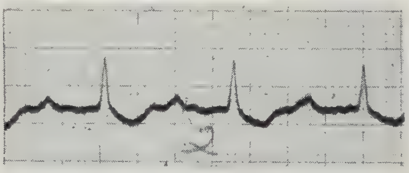

Fig. 760. Delayed A-V conduction (first degree heart block). Each atrial complex (P) is followed by a ventricular complex (QRS-T) at an interval greater than the normal of 0.2 sec.—in this instance, 0.32 sec.

Second degree heart block: As interference in conduction of impulses from the atria to the ventricles increases, some of the impulses may be completely blocked from reaching the ventricles so that the ventricles do not respond to certain of the atrial impulses, and ventricular complexes are dropped. These dropped beats may occur at infrequent intervals or as often as every other cycle. Frequently the P-R interval becomes steadily longer until eventually a ventricular complex is dropped. The P-R interval then again becomes relatively short, then progressively longer, until another ventricular complex is dropped. This is known as the "**Wenckebach phenomenon.**" Fig. 761 illustrates second degree heart block and the Wenckebach phenomenon.

Third degree heart block (complete heart block): In this type of atrioventricular block, conduction in the atrioventricular pathway is so markedly inhibited that all the impulses are prevented from reaching the ventricles. At the onset of this mechanism there is complete standstill of the ventricles for a variable length of time, ranging from a very few seconds to as much as a minute or even longer. Then the ventricles respond to their own pacemaker just below the area of blocking, either in the lower part of the bundle of His or in the ventricles themselves.

It is during this period of ventricular standstill that patients are prone to lose consciousness (**Adams-Stokes syndrome**). If the pause is longer than about 3 min., death is likely to occur.

With the response of the ventricles to their own independent pacemaker, the ventricles contract at a much slower rate than formerly, usually 30-40 times/min., or slower, and with a regular rhythm. The atria continue to contract in response to their own pacemaker in the sinoatrial node but at a much faster rate than the ventricles. Thus in the electrocardiogram the P waves and the ventricular com-

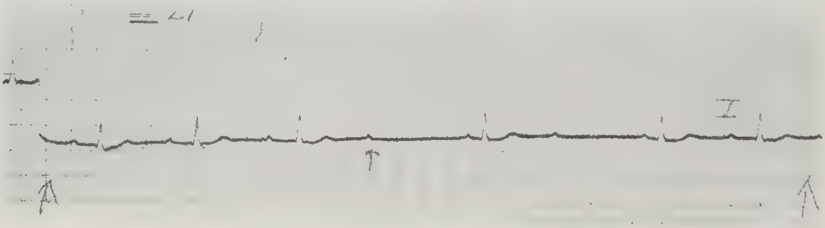

Fig. 761. Second degree heart block (partial A-V block with dropped ventricular complexes). This electrocardiogram shows that the dropped ventricular complex is preceded by progressively increasing P-R interval (Wenckebach phenomenon). Arrow indicates atrial contraction without its corresponding ventricular response.

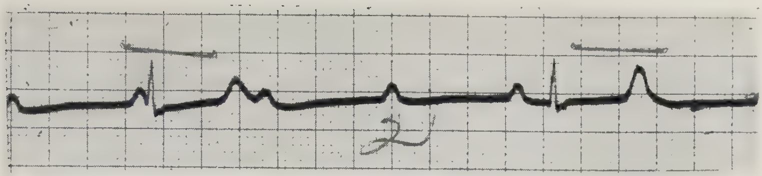

Fig. 762. Third degree heart block (complete A-V block). There is no fixed relationship between the P and QRS complexes. The atrial rhythm is regular at a rate of 92 and the ventricular rhythm is likewise regular at a rate of 30.

plexes will show no constant relationship with each other.

The form of the complexes will not vary from the usual form for the patient in heart block of any degree, since the manner of spread of the impulse through both the atria and ventricles is normal. If the complete heart block has been caused by digitalis or is congenital in origin, the ventricular rates are likely to be faster than 30-40/min. Fig. 762 is an example of complete heart block.

UNUSUAL DISTURBANCES OF MECHANISM

Pararrhythmias

Pararrhythmias represent a form of "double rhythm" in which 2 pacemakers, one of which is usually the S-A node, are active. The secondary pacemaker may be in the atria, the A-V node, or the bundle or its branches, and it may produce impulses slower or faster than those of the sinus node.

There are 2 forms of double rhythm: A-V dissociation and parasystole.

In A-V dissociation the rhythm of the atria is directed by the S-A node and that of the ventricles by the A-V node. The A-V nodal impulse has no effect on the S-A node, whereas the S-A nodal impulses do spread to the A-V node. When the S-A nodal impulse arrives at the A-V node, this causes a transitory disturbance in the rhythm set by the A-V node, provided that at that instant the A-V node and the conduction system below it are not in a refractory state. This type of rhythmic disturbance is called "dissociation with interference" (Fig. 763).

In parasystole the impulses arising in the S-A node are dominant. However, the second impulse maker, usually in the ventricle, is not influenced by the impulses from the S-A node and produces its own rhythm at a slower rate and thus one sees separate rhythms—one produced by the S-A node and the other by a regularly recurring impulse arising somewhere in the ventricles. (Fig. 764.)

The degree of disturbance of the rhythm in both these instances depends upon the relative rates of the 2 pacemakers and the refractory period of the conduction system and the ventricular muscle.

A-V dissociation may be confused with A-V heart block. The fundamental distinction is that in A-V heart block there is **depression** of conduction of varying degree in the conducting system, whereas in A-V dissociation the conduction system is normal but the S-A impulse fails to affect the ventricle because it has arrived at the ventricle during its normal refractory period.

The clinical significance depends on the cause. It may occasionally occur in an otherwise normal heart or during inflammation of the heart from rheumatic fever, toxic causes, or as a result of digitalis or quinidine therapy. The treatment depends on the cause. Both these interesting and unusual types of rhythms are not significant symptomatically and are detectable only by means of the electrocardiograph.

CONCLUSION

It must be emphasized that this section is intended to give the reader only an introduction to the subject of electrocardiography and its clinical and laboratory applications. The usefulness of the electrocardiograph in clinical medicine is established beyond question. This usefulness can, however, be impaired if one fails to recognize the many pitfalls in interpretation, such as the wide variation in normal patterns, changes due to artifacts and to faulty technic, and improper standardization of the instrument. It must be remembered that the electrocardiogram reflects changes in the myocardium which affect its electrical conductivity whatever the cause may be, and that these changes may be due to a great variety of causes, either organic or nonorganic. Such widely different causes as autonomic nervous system imbalance, position of the patient during the electrocardiographic

recording, and actual degenerative changes in the myocardium may result in quite similar effects on the electrocardiogram. It is only after thorough familiarity with the theories and principles underlying electrocardiography and after considerable experience in its clinical application and recognition of its limitations that one can realize the full usefulness of this instrument. As previously indicated, in only a relatively few instances does the electrocardiogram give pathognomonic information, and of these instances acute myocardial infarction is an outstanding example. Many arrhythmias and conduction defects can be recognized only by the use of the electrocardiogram; these may be due to a wide variety of diseases or to functional causes. For correct clinical deductions from the electrocardiogram, the electrocardiographer should have as full a knowledge as possible of the clinical aspects of the patient's condition. It must again be emphasized that a normal electrocardiogram does not necessarily indicate the absence of heart disease; on the other hand the presence of a definitely abnormal electrocardiogram does not necessarily indicate the presence of organic heart disease. All electrocardiographic findings must be interpreted in the light of the clinical picture.

Chapter 113

Model of a clinical laboratory in a nonuniversity-affiliated general hospital

W. HAROLD CIVIN

The present-day demands on a laboratory in a large private general hospital unaffiliated with a medical school may be as great and as varied as those on a nosocomium connected with a university facility. These demands depend upon the makeup and interests of the professional staff of the hospital. Even routine laboratory work becomes more complex as medicine progresses.

If, as is now so commonplace, the professional staff is a progressive one, demands for tests are forthcoming as soon as the printer's ink describing them is barely dry. The laboratory may then be faced with the choice of refusing to perform a test while admitting its inability to do so or using a procedure that (for the laboratory in question) is as yet untried. One solution is to farm out such procedures, and another is to work out the procedures and adapt them as rapidly as possible to laboratory routine.

We have adopted the philosophy that our laboratory should function as an independent ancillary unit as far as possible and perform all feasible tests that are ordered. The laboratory being described is in a general hospital of 400 beds with a training program for internes and residents. A large expanse of water separates the area wherein the hospital is located from any undergraduate or postgraduate medical facility. This latter status may be remedied in the near future according to a number of observers on the local and national scenes. The laboratory has the full cooperation, when required, of the State Board of Health Laboratory, the State Blood Bank Laboratory, and a large military hospital laboratory. Despite this, our location and my philosophy have combined to establish the machinery to develop as nearly as possible a self-sufficient unit for performance of laboratory procedures.

Not only is our unit steered toward autonomy but it is also directed toward efficiency. To accomplish this we must deal with the factor of acquiring trained personnel. We have a chronic shortage of registered technologists, and its severity waxes and wanes. No laboratory is any better than the technologists it hires. It is important that unwise so-called economy not be allowed to run rampant to the extent of utilizing inefficient, untrained, or careless personnel because they work more cheaply. The patient suffers directly from such a pseudoeconomy, and when the attending physicians become acquainted with this state of affairs, the hospital suffers. Furthermore one must not follow in the footsteps of the legendary efficiency expert who wanted to reduce the size of symphony orchestras since various instruments were silent for varying periods of time. Laboratory technologists must not be gauged by the amount of time they spend on their feet. They are professional personnel and should be allowed to perform as such. Stresses and strains take their toll, and more efficiency is elicited by allowing technologists to pace themselves. As professionals they should naturally feel a responsibility toward the patient and a certain compulsion toward accurate performance. If they do not, they can by no stretch of the imagination be considered real technologists.

We do not use house staff members for performing laboratory procedures because we believe that this is unfair to the patient since the occasional "test performer" cannot be properly cognizant of many of his errors. We do encourage house staff members, however, to ask questions concerning procedures and results, to witness performance of tests, and even to spend 6 mo. or so in the clinical laboratories.

Because of our shortage of technologists we train some of the more capable nonprofessional employees to do certain laboratory procedures and add to their knowledge as their capabilities permit. They, however, are carefully supervised by the registered technologists.

The laboratory functions 24 hr. a day, in keeping with my philosophy. The laboratory and to some extent the technologists are departmentalized (sectionalized). Each department or section is in a separate room. This occurred originally because the wing housing the laboratory was used for surgery, and the physical divisions were already present when we moved in. The wing is air-conditioned. It is our belief that the separation of sections into individual rooms in a laboratory our size is of value. True, the pathologist cannot keep constant watch on the various sections, but members of a profession should not require foremen. The technologist is given leeway commensurate with his or her occupational status. Our technologic departmental chiefs serve to answer questions, establish procedures, and consult with the chief technologist who also acts as a coordinator of departments, orders equipment, and arranges schedules. We believe that policing technologists is not a duty for supervisory personnel nor a job for the pathologists. The technologist should have been adequately screened prior to being hired and during any probationary period. The compartmentation has been helpful to morale by promoting self-respect and self-confidence.

The departmentalization as far as technologists are concerned exists in our so-called regular or 7:00 A.M.-3:30 P.M. shift. It is during this shift that most of the routine examinations are performed. It requires an explanation to practicing physicians that the more experienced technologists are on this shift. The physicians are informed that if a great deal of routine work is done by the smaller afternoon or night shifts, emergencies are unable to be handled. It might be worthwhile here to elaborate on "stats." These are the bane of laboratory existence. In our hospital, custom maintains that technologists obtain the blood specimens for tests. This often requires a long trip from one end of the hospital to the other and back and interrupts the other work of the technologists. Quite often an explanation to the practicing physician by one of the pathologists can result in an agreement to get the result on the chart by a certain time. An occasional breakdown of this latter occurs unless the messenger service is well established. This is not always so. Phoning results may be the answer if adequate personnel is available. Pneumatic tubes although expensive are timesaving and nerve-sparing. One answer to blood drawing would be the use of ward personnel, including nurses and even house staff, plus good messenger service. For this, good rapport is needed with all departments of the hospital.

The technologists on the afternoon and night shifts are jills (or jacks) of all trades. Since their work is more varied, they cannot be as expert as the individuals who work in one discipline. The complaint that the departmentalized technologist will be bored is to a great extent unfounded because in actuality she becomes expert enough to know the ramifications of her section and can then better understand and appreciate the significance and challenge of her work. This by no means belittles the necessary work of the general personnel, and an excellent general technologist is a rarer commodity than a superb specialist.

The departments of the laboratory are those of histology, serology and blood banking, chemistry, bacteriology, hematology and clinical microscopy, electrocardiography and basal metabolism, and two special ones. The divisions were influenced by the separate rooms available and are a segmentation of technologists according to separate disciplines. Certain deviations occur, however, as dictated by local custom; e.g., prothrombin times are done in the chemistry section.

In addition to the previously specifically mentioned divisions, a department concerned with special tests and laboratory research has been established. Personnel of this unit adapt special tests to specific laboratory sections performance by working on them until their sensitivity and specificity are determined, and by then a reasonable monetary value can be assigned them. Until such times the tests are performed gratis and have not been allowed to be overemphasized in the evaluation of patients' conditions. Without this department the establishment of new procedures is almost impossible at the rate these new procedures reach the literature. Even with such a department, keeping abreast of the current literature is difficult, but depending on the size of the laboratory and on the ability of its personnel, some approach to adequately developing recent tests can be made. Since some tests are described in obscure or unlikely journals, a good index of current literature is necessary. In addition to current literature the laboratory has access to much of the other major publications including books in the field. Of course, before the pathologist can discard a test as useless or impractical, he should have had it undergo a fair trial.

The use of new equipment is often commenced in the laboratory research section. With new automatic devices the routine work of the technologist may be somewhat diminished, but this only frees technologists for more complex technics. We are attempting to avoid replacing one technologist by two electronic engineers.

There is also a section of tissue culture. This came about through a series of coincidences unlikely to be repeated. Nevertheless this section can serve a multiplicity of functions. Some viral work, chromosomal studies, atherosclerosis elaboration, and tumor research can be performed here. Such a laboratory can function to a large extent as a replacement for an experimental animal unit.

The histology section is responsible for all tissues both gross and microscopic, both necroptic and surgical. Special staining technics are performed here. We have found an automatic knife sharpener and an automatic technic for preparing paraffin blocks to be very useful. The automatic technic for hematoxylin-eosin stains, although not used by our technologist, is satisfactory in my experience. This latter statement does not alter the fact that most perfectionists in the field prefer staining by hand.

The technologists at our hospital make regular rounds to collect specimens 6 times a day for the clinical laboratory sections.

The chemistry section has gone along with the modern trend for automation. An automatic device for performing certain blood chemistry determinations is available here. Without entering into the debate concerning the pros and cons of automation, suffice it to say that we have found it extremely satisfactory in accuracy and more than satisfactory in volume output. I had recommended an automatic device to the large military hospital previously mentioned, where it is considered invaluable. All blood, solid material, and nonendocrinologic urine chemical analyses are

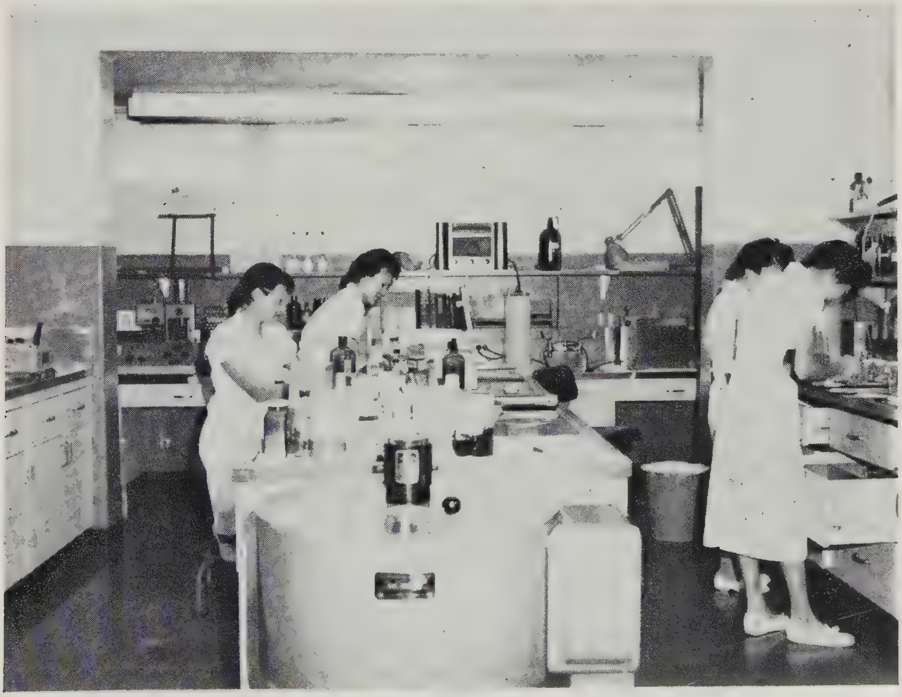

Fig. 765. Chemistry laboratory. Flame photometer is in left background. Spectrophotometer is in front and to left of flame photometer.

performed here in this section. In addition, toxicologic, electrophoretic, and chromatographic studies take place here. Wherever possible 3 standards are used along with so-called normal controls. The standards relate to low, mid, and high normal values for the material being tested. In addition, we are strong proponents of quality control. All prothrombins are standardized as regards new thromboplastin with the old batch. Precalibration technics are never utilized. Technics are micro and so-called ultramicro wherever indicated.

The section on bacteriology and mycology includes sensitivity studies. Disks are used most often and in most situations have proved adequate. Test tube sensitivity tests are performed if required. Agglutination and precipitin technics concerned with bacteriology are taken care of here. This section is extremely busy during epidemics, evaluation of new germicides and soaps, etc.

The department dealing with blood banking also deals with serology tests. We are fortunate that a statewide blood bank functions on the hospital grounds so that we have a precheck on blood type of the donor. We check the recipient's type and perform the cross match. The blood bank checks on reactions, although we also do so to a certain extent. The Coombs technics and Wiener or Grubb antiglobulin inhibition, heterophil, latex fixation, and Rh antibody determinations are done here. We perform the Kahn, Kline, VDRL, and Hinton tests. The VDRL has been a good screening test in our hands. *Treponema pallidum* immobilization and Reiter protein complement fixation tests are sent out. When we can get a good enough antigen we shall do the latter.

The department wherein hematology is performed is the one in which we do routine urine analysis and clinical microscopy. Again, we have been able to develop confidence in an automatic blood counter. This allows an accurate red cell count to be added to the physician's group of results by which he can better evaluate the patient. Since the machine actually counts the cells, the technologists are able to spend more time on differential and bone marrow counts in the knowledge that the cell enumerations will be accurate. This section also checks for ova and parasites.

Basal metabolic rates and electrocardiograms are taken care of in a special room away from the routine laboratories. Basal metabolic rates are gradually being displaced by protein-bound iodine tests, which are performed in an isolated room in the special research chemistry section. Electrocardiograms

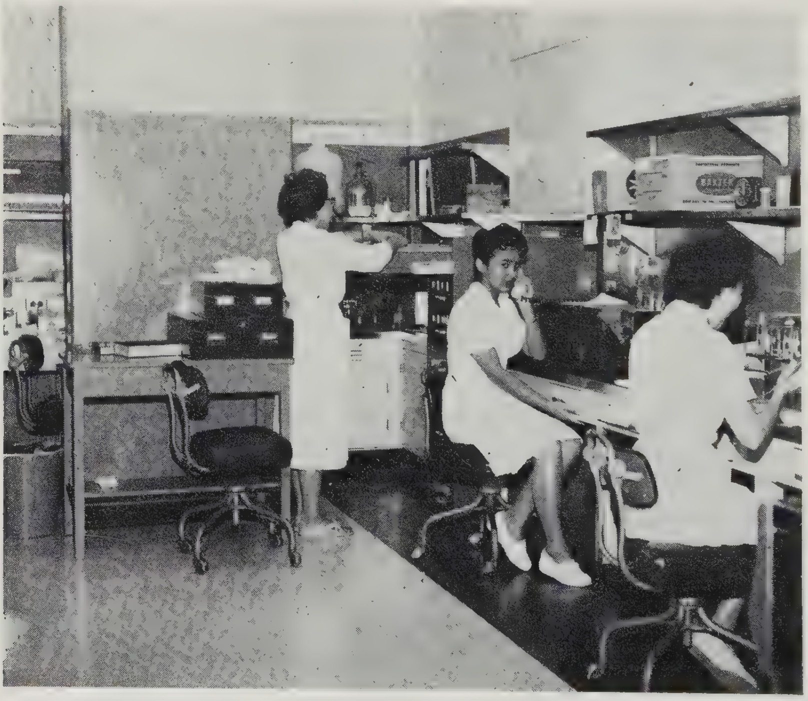

Fig. 766. Hematology laboratory. Automatic counter is on counter at right.

are often performed with a portable machine elsewhere.

All trained technologists give practical on-the-job instruction to student technologists who rotate through the various services. As the student (who spends a set amount of time in each section except special research and tissue culture) becomes more proficient, he or she is allowed more freedom in performance of more procedures. Student technologists are present only during the early shift. This is because of the lesser supervision possible by the fewer technologists on other shifts and because more detailed instruction can be given at this time by the more specialized personnel.

The pathologists select and evaluate tests and work out problems in their performance and interpretation, all in relation to the patient's clinical picture. The pathologist is a consulting physician. He should make rounds and attend clinical conferences, according to our philosophy.

This is a cursory picture of our laboratory. This review, at the request of the late Dr. Gradwohl, for whom I had great respect, will be of value if it can help laboratories either install or definitely delete any or all of the factors mentioned here according to whether they may fit any individual hospital laboratory operation.

Chapter 114

The hair in police investigation*

GENERAL CONSIDERATIONS

In an extensive paper presented before the Academy of Science of Havana, *The hair of the races in Cuba,* Dr. Israel Castellaños, Director-General of the National Bureau of Identification, Havana, Cuba, pointed out that valuable researches have been made in comparative microscopy, but there have been very few contributions concerning the hair in police technic. The most important work in this field was done in Europe. There is an abundant bibliography of anthropologic and medicolegal studies of the hair, but there are only short references to its value in police work. This may perhaps be accounted for on the basis of Gross's exclamation, in 1904: "How seldom clothes are examined, with a view to finding some hair! And if it is found, by mere chance, how seldom is it submitted to examination by an expert!"

The intensive anthropologic investigations by Castellaños on the hair of Cubans and his official position in a country in which the inhabitants have been accustomed to slaughtering domestic animals, such as pigs, sheep, goats, etc., in the courtyards, especially on church holidays and national feasts, has shown the eminent importance of hair in police science.

Gross, the Father of Criminology, has insistently called the attention of scientific investigators and of the police to the importance of hair found at the scene of a crime. "It is the duty of the magistrate," he wrote, "to give his full attention to finding and delivering such hair immediately to experts, as a hair, in spite of its insignificance, may lead us to the discovery of the delinquent." (In Austria, the magistrate exercised direction over police investigation not paralleled in English-speaking countries. Dr. Gross was a magistrate.)

Criminal investigators pay considerable heed to the points made by Gross in his very valuable book. Castellaños does not accept his doctrine with respect to examination of hair, however. Gross suggested a simple procedure for establishing the position of the tip and the root of the hair. The method is efficient with respect to that object, but it requires cleaning the surface of the hair, eliminating the dust, dirt, etc. that has settled on it.

Care in handling hair: Waldeyer, in his classic work, which appeared 20 yr. before Gross's *Criminal investigation* was published, very appropriately observed: "The dirt adhering to the hair is often more important than the hair itself." When a hair is found, therefore, it should never be rubbed between the fingers. In most cases use of a magnifying lens will enable one to determine the direction of the tip or root of the hair.

It is of utmost importance in many cases not to touch any hair found if it can possibly be avoided. Gross recommended that the hair be placed on paper, fastened thereon by means of 2 glued paper strips, and that the ends be marked with the letters A for root and B for point. At the same time a sketch is made and lettered accordingly, with letters corresponding to those of the specimen, so as to leave no doubt about the original position of the hair. In countries such as Cuba and the United States, where there is a mixed population, this may be difficult because all hair cannot be mounted in this fashion. Whereas the hair of most Caucasians can be mounted on paper in this manner, that of mulattoes will seldom permit it and that of Negroes almost never. Hairs of these people are therefore preserved in clean white papers or in small envelopes.

---

*Much of the material on hair in police technic and identification through the hair by both microscopic and chemical methods is abstracted by permission from the book by Castellaños, Israel: Identification problems—criminal and civil, Brooklyn, 1939, R. V. Basuino.

Searching for hair: The smooth, lank hair of white persons and the straight, stiff hair of American Indians and Chinese are more likely to remain between the fingers of a victim than are those of other races. The more spiral the form of the hair, the less likely is it to stick between the fingers and be found in the hands of the victim, although his struggle with the aggressor may have been very fierce.

Because of the anatomic structure of its outer covering, hair sticks to clothes. The curlier it is, the tighter it sticks. This brings to mind an interesting case reported by Chief Hugh D. Harper, of Colorado Springs, Colo., at the thirteenth convention of the International Association for Identification.

> A white girl had been attacked by a Negro youth, and a suspect was arrested. The Negro people of Colorado Springs said that the accused man was innocent, the defendant's lawyer contending that the crime had been committed by a white man disguised as a Negro. The technical assistance of Dr. L. A. Bennet was requested. He found a long fair hair in the necktie of the youth, which he identified as having come from the raped girl. On the underclothing of the girl Dr. Bennet found pubic hair of a Negro, which he subsequently identified as having come from the arrested man. Thus the hypothesis of the defense was destroyed.

In America, where the population is composed of different racial types, knowledge of hair of various races is needed in police technic. The anatomic structure and the shape of the hair often indicate a definite ethnic type and thus facilitate police researches di-

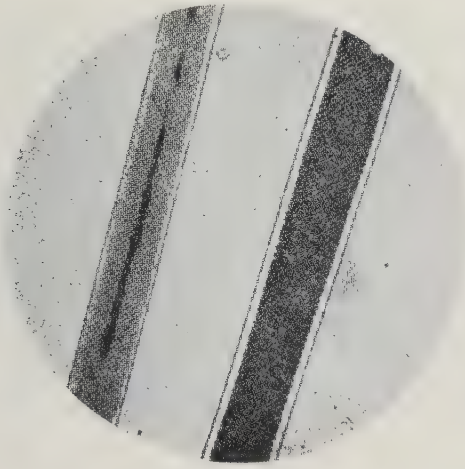

Fig. 767. Human hair (left) and animal hair (right). These are differentiated by their constituents—cuticula, cortex, and medulla. In man the cuticula is thin, slighted serrated, and imbricated. In animals it is just the opposite. In man the cortex shows small homogeneous pigment. In animals the pigment is irregular and larger than in man. In man the medullary channel is narrow, whereas in animals it is much better developed, to such a degree that the greater part of the hair consists of the medulla. (Courtesy Dr. Israel Castellaños.)

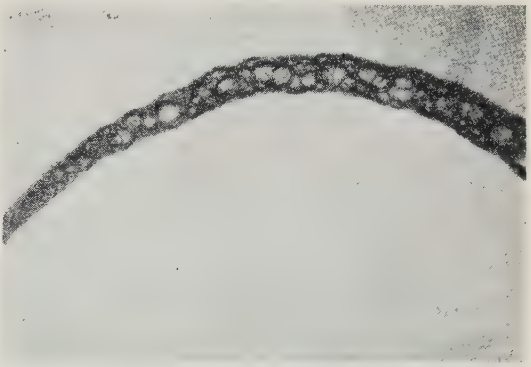

Fig. 768. Bubbles that form inside of the hair when it has been exposed to a high temperature without burning. Hair submitted to excessive heat in a permanent wave by inexpert hairdressers has an appearance similar to this. (Courtesy Dr. Israel Castellaños.)

rected toward persons of some predetermined race. If, for example, a crime has been committed, and on the site of the crime one or more thick rigid hairs are found, it is assumed that a Chinese or an American Indian is involved. Likewise, if a kinky hair is found, some Negro must have been at the scene of the crime. Hair thus directs the investigation to persons of definite races.

EXAMINATION OF THE HAIR

It is advisable to keep the hair in bottles with ground glass stoppers in order not to lose its specific odor.

It is best to examine the hair as it is found. Pick it up with forceps and place it on a slide. Cover with a cover glass. Do not touch the hair with the fingers since this might remove any matter on the surface—dust, pollen, coal dust, etc.

Examine the hair under a microscope. Then, as Waldeyer recommends, without having cleaned the hair add distilled water and examine under increasing magnification. In this way one can often discover blood, spermatozoa, pus, parasites, vegetable or metallic particles, etc., all of which can be identified. There are numerous instances in which the hair is surrounded by substances which are found only on persons engaged in specialized occupations.

After having verified these preliminary observations, proceed to clean the hair with water, tissue paper, or a small brush.

Removal of pigment: If the hair contains much melanin, as is the case with Negroes and dark individuals, or if the medullary canals are full of air, it is difficult to observe the structural details of the hair or to determine the medullary index. To avoid this difficulty, authorities recommend removing the color from the hair by soaking it in nitric acid for several minutes if the examination is urgent, or in oxygenated water for several hours if there is sufficient time.

In a great many cases the action of the nitric acid is protracted, and the hair under investigation is destroyed, arguments which might be brought out by either the prosecution or the defense. J. Delgado Roig, of Sevilla, Spain, has eliminated these difficulties by using oxygenated water and nitric acid; he uses 15% sodium carbonate, in which he leaves slightly pigmented hair for 30 min.; hair with much melanin is kept 5 hr. in this solution. The hair is then mounted in Canada balsam, which is recommended by all authors. This method not only permits exact comparisons between 2 or more hairs but also identification of the hair at any later date since the bleaching reagent does not impair or destroy the hair, even though it has been mounted for considerable time.

Cross section of hair: A portion of the hair should be cut in cross section.

Cleanse the hair in 95% alcohol for 5-10 min.

Immerse in 10% sodium hydroxide 5-10 min. or longer, depending upon how soon the hair becomes softened by the solution.

Immerse in 20% alcoholic hydrochloric acid 5-10 min.

Gonzalez suggests a convenient method of sectioning hair prepared as described.

Partially incise a small segment of formalin-fixed liver on one side and stretch the hair out in the bed of the incision. The natural elasticity of the liver section will hold the hair in place. Then fix, harden, and embed the tissue in celloidin or paraffin. Cut it in the usual manner and mount the unstained section in balsam.

Gram stain of hair:

Stain with Gram stain, wash rapidly in 95% alcohol, and mount in balsam without counterstain.

The cuticula is outlined in violet wavy lines on the surface of the hair. If the hair is dark, it may be necessary to remove the pigment before staining by bleaching it with a mixture of hydrogen peroxide and ammonia water.

Improved technic for sectioning hairs—method of Kirk[1]

It is often necessary and desirable to observe the hair in cross section. This is especially true when dealing with animal hairs. The transverse aspect is often highly diagnostic of a family with modifications in the genera. The usual methods of embedding lead to an angular section, which gives a distorted picture of the true contour of the fiber. Embedding in collodion is somewhat more successful, but the collodion-coated hair must ordinarily be mounted secondarily in paraffin to make it rigid. The problem of bending and distortion is therefore a serious obstacle to properly sectioned hair.

Kirk described an improved method for sectioning hair. He advised a small microtome, developed by Hardy, with which a person after some experience can make a cross section in a very short period of time. The method combines embedding on a wood base with the use of a hand microtome which allows sections of 0.01-0.015 mm. in thickness or thicker.

Procedure:

Cut strips of balsa wood 1 cm. wide and 3 in. long from ¼ in. thick balsa planks.

On one of the centimeter-wide surfaces, apply a single layer of cellulose-acetate glue and spread out evenly to cover the wood strip completely in its central portion. Slow-drying Comet model airplane cement has been found to be readily available, convenient to use, and quite satisfactory as an embedding medium.

While the film of cement is still wet, lay the hairs to be sectioned on the cement parallel to the long axis of the balsa base.

As the film becomes tacky, apply a second layer of the embedding medium and spread so as to completely cover the hairs.

Label the block on the reverse side and place in a closed container, such as a small box, to dry slowly.

Observe 2 precautions. Do not apply more than the 2 necessary layers of cement because thicker films are much more difficult to cut; also do not accelerate the drying process since numerous and abnormally large bubbles are thereby formed which, if they surround the hair, tend to decrease the tenacity with which it is held. Upon drying, small bubbles are seen throughout the embedding medium. These do not ordinarily interfere with the quality of the final sections.

Sections may be cut within 30 min. if necessary, but they are thick and wedge-shaped since the embedding cement is not completely dry, which tends to make them yield in front of the cutting edge. At least 12 hr. or overnight is recommended as a satisfactory drying time.

Before embedding, clean and dry the hair by washing thoroughly in acetone or alcohol-ether mixture and allowing it to dry on filter paper for a short while. This process takes only a few minutes.

If a number of hairs of a known source are to be embedded on the same block, they may be oriented while drying, with all proximal or distal extremities in the same direction. This procedure facilitates handling the specimen while affixing it to the block.

When thoroughly dry, place the wood strip carrying the embedded hair in the specimen clamp of a table model hand microtome.* Adjust the microtome until the portion of the hair desired for sectioning is even with the blade holder guides. Always use a razor blade holder, designed for the instrument with a fresh sharp blade. Make the cut with a short slicing motion, through the embedding layers and hair, **but only as far as the underlying wood base.** Make the next cut in the same fashion, after advancing the block the amount desired. As many cuts may be made successively as required.

If another portion of the hair must be sectioned, adjust the block to the region of interest and repeat the cutting process. As the fiber is always in view through the cellulose-acetate layer, it is convenient to obtain sections close to the ends, in the center, or in any other area of the hair. The severed but unsectioned parts of the hair remain attached to the uncut block in their original relative position and may be recovered by dissolving away the lacquer with acetone. The block has suffered little damage and may be resurfaced with sandpaper and used repeatedly.

Using a pair of fine-tipped forceps, lift the hair sections, set in a slide of cellulose-acetate 0.5-1 mm. deep and 1 cm. wide from the block, and place in a small evaporating dish. Dissolve the lacquer with 1 or 2 ml. acetone. When the acetone evaporates, the resolidified cellulose acetate will be seen to have migrated up the sides of the dish, leaving the clean, free sections in the bottom.

Observe under a stereoscopic binocular microscope and transfer to a previously albuminized slide by touching each with the tip of a sharpened dissecting needle, to which they cling, then depositing them on the slide.

Inspect the slide briefly under the stereoscopic binocular microscope. Any sections standing on edge can be gently teased into their transverse plane with a needle.

A slightly faster procedure is to separate the lacquer slices and mount them on a slide. However, the lacquer slice surrounding the hair sections somewhat interferes with definition of the contour of the hair.

Apply a permanent mounting medium and cover slip. Clarite X dissolved in xylol is excellent. This medium infiltrates the hair and clears it very well for observation.

This technic has been useful in our hands. One potential difficulty in mounting the hair in the proper position is due to the fact that not all the lacquer is removed from the hair before mounting.[2] By using 2 or 3 washings with removal of the acetone each time, the lacquer is all removed.

POINTS IN INVESTIGATION

During the struggle that at times takes place in crimes of violence and which usually precedes the death of one or the other antagonist, often the hair or beard is grasped. Therefore, one must look for hair in the hands of the victim and on the clothes of the aggressor. If the victim died by strangulation, search not only the fingers but also the areas under the fingernails of the victim and the suspect. In cases of rape, the underclothing is examined. Most published cases refer to such findings.

A review of the cases of death by shooting shows that the literature gives little information concerning investigation of hair in these cases. Investigators often do not look for hair or examine it in cases which appear to be suicides or homicides but rely too much in certain instances on the necropsy findings. Forensic study of wounds and collection of data by the police should coincide since police technic and forensic technic complement each other.

As an example of the part played by hair investigation, Castellaños cites the following case.

> A woman, an alien, was found dead in a bathtub, the body being in a state of advanced putrefaction. There were 3 large wounds on her head. It was alleged that she had died an accidental death, having slipped and fallen while bathing, and that her skull was fractured when it struck the faucets of the tub. Public interest in the case was great; some agreed with the accident hypothesis, others insisting that this was a criminal death. Some days after the corpse had been found, Castellaños' bureau was called upon to make an investigation.
>
> A thorough search was made, and in the tub and on the walls of the bathroom at approximately the height of the corpse, police recovered an abundance of hair. This was compared with that of the victim and found to be identical.
>
> The roots were examined; they presented indisputable evidence of having been violently torn out of the scalp. Some of the shafts were bruised; others had been cut with a rather blunt instrument. The hair thus changed the situation and led the police from the hypothesis of suicide to the certainty of homicide. To complete the demonstration, Castellaños proved that there was blood in the bathtub and that this blood had flowed from the victim; there was blood on the floor of the bathroom, which had been washed. And finally, blood which the perpetrator of the crime had washed from his hands was found on the basin. When dressing before

---

*Model 900, American Optical Co., Buffalo, N. Y.

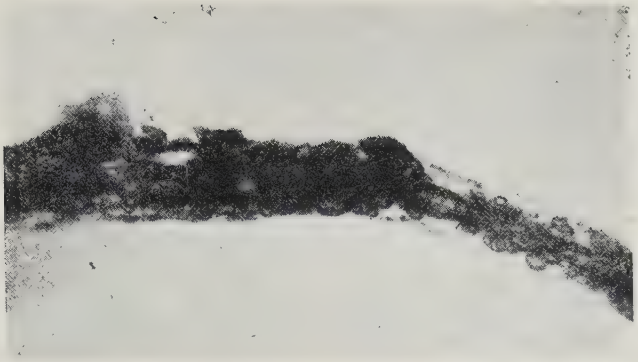

Fig. 775. Appearance of the hair from a person who committed suicide by shooting himself. The hair is burned by a point-blank shot with black powder. Note presence of bubbles produced by the heat in the mass of the medulla and the residue left by the shot on the outside of the hair. (Courtesy Dr. Israel Castellaños.)

making his escape, he had left some gray hair between the teeth of a comb, which the Cuban Bureau is still holding. The medical examiner reported that a murder had been committed, and the police confirmed this thesis.

There are a great many homicides and murders by shooting which give the appearance of suicides. On the other hand, some cases of suicide present the appearance of murder. In these cases study of the hair often helps solve such medicolegal problems.

Effect of firearm wounds on hair: The first investigator to study the effect of firearm wounds on hair was Minakow. Daake, confirming the tests of Minakow, showed that the microscopic examination of hair is decisive in determinating the distance at which the shot was fired.

If the shot is fired from a very short distance, the hair of the victim is burned. Microscopically the hair shows countless bubbles inside, but no change can be detected by the naked eye. Changes are greater after black powder has been fired than when smokeless powder is used. Schwalbe has performed magnificent researches in connection with this problem.

Temperature at which hair burns: Piedelievre and Zebouni, using electric stoves, showed that at 100° C. hair shortens and loses weight; at 150° it presents gaseous bubbles in its medulla; at 300° it is carbonized. These data are useful for determining to what temperature the body of the victim has been exposed. As an example, one case is cited.

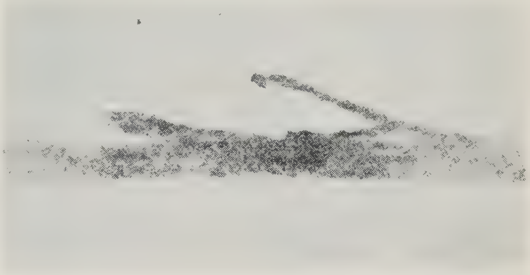

Fig. 776. In this case the shot was fired from a short distance and smokeless powder was used. The cortex has been broken and raised by the unburned grains of powder, which always escape from the barrel of pistols or revolvers. Note that the outside of the hair also shows residue from the shot. (Courtesy Dr. Israel Castellaños.)

In a village of the province of Santa Clara, Cuba, there lived a widow with her idiot daughter. The mother married a baker and moved with her daughter into the baker's shop. The stepfather forced the idiot to carry logs for the oven and in many ways was cruel to her. One day he beat her until she was almost dead. The poor idiot's cries were pitiful. After that incident she disappeared. The mother announced that she had left home, but the neighbors were inclined to doubt her story and were suspicious that the baker had murdered her. An examination of the baker's quarters was ordered. Police searched the oven, and there they found countless carbonized hairs. Upon further examination and under questioning, the baker was proved to have murdered the girl and to have tried to destroy the evidence of his crime by burning the body in the oven.

IMPORTANCE OF EXAMINING HAIR

All authors dwell at length on the different features of human and animal hair; the specific signs of hair cut with sharp instruments, of bruised hair, of hair torn out by violence, of hair that has fallen out spontaneously, in the course of its renewal; the details indicating the region or part of the body from which the

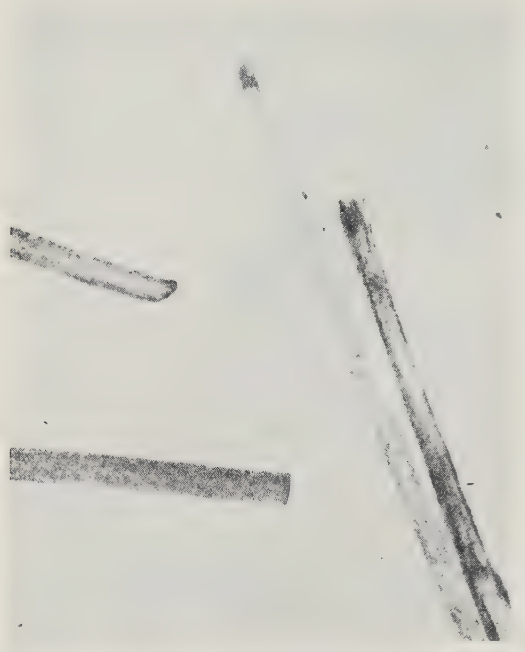

Fig. 777. The point ending in a sharp angle and the one below, perfectly flat, with clean edges, were recently cut with the sharp scissors of a hairdresser. These hairs came from a woman. The lighter points, lying vertically, which are from less pigmented hair of another woman, are split, indicating the use of tweezers. The irregular or spread ends show that it has been a long time since the hair was cut. (Courtesy Dr. Israel Castellaños.)

hair comes; the data permitting deductions as to whether it belongs to a man or to a woman; the age of the person from whom it came; and the changes due to dyeing, curling, or combing it. These are but part of the program of identification. One must remember that hair, like bloodstains, reconstructs the crime in many cases by confirming the correct and scientific findings of the autopsy, as in the case just cited. It may help to differentiate homicides from accidents; it helps to distinguish suicides and murders by proving the distance at which shots were fired; it offers definite proof in some cases of sodomy, as Kutter and Sonnenschein have shown; it may determine the race of the victim or aggressor in even the most complex and difficult cases. For these reasons a search for hair must be made in all criminal cases; it must be properly recovered and perfectly preserved so that examination of such hair will give the best possible scientific results.

Hair should be searched for not only in some types of crimes of personal violence, such as rape, strangulation, etc., where it obviously is likely to be found, but also in every crime, from robbery to murder, from infanticide to rape, from suicide to sodomy.

MICROSCOPIC EXAMINATION OF HAIR

The importance of the microscopic examination of hair in criminal investigation has been described by many authors. Rolffs in 1840 referred to the problem given the experts by a number of black hairs, obtained in 1832 in connection with a homicide. Orfila in 1835, Ollivier in 1838, Schuermeyer in 1846, Falk in 1856, Lender in 1863, Kutter in 1865, and many others thereafter have published case histories and insisted on the necessity of studying the hair in order to decide a multitude of legal cases scientifically. In the introduction to the work of Glaister it is pointed out that since 1851 British judges have considered hair to be valuable circumstantial evidence in criminal cases.

Hair is a distinctive specialized anatomic structure. It consists of a shaft, a point, and a root. That part of the hair which is not embedded in the skin is called the **shaft.** The shaft terminates in a free end called a **point.** The part that is inserted in the skin is called the **root.** The root swells into a more or less ovoid form called the **bulb.** The bulb contains an indentation, very much like the bottom of a bottle, in which is contained the **papilla,** a projection of the skin, which is the organ which produces the hair. Each of these parts—the shaft, the point, and the bulb—offers important details. A hair may be compared with a fine pin, in which the head is the bulb, the body is the shaft, and the sharp extremity is the point.

The shaft is composed of the **medulla,** the innermost core of the hair; the **cortex,** the intermediate layer which surrounds the medulla and which is the thickest and most distinctive part of the shaft; and the **cuticula,** around the cortex. The medulla looks like an irregular cylinder and contains air spaces and some scattered cells of various sizes and shapes. The medulla often disappears toward the distal end of the shaft. The very fine type of human hair might not contain a medulla. The cortex is composed of elongated, spindle-shaped, longitudinal, horny plates attached closely to each other. They contain pigment granules. The cuticula is composed of non-nucleated overlapping polygonal cells, the free edges of which are directed toward the distal end of the hair.

Age of individual from whom derived: Oesterlen gives the following average diameters of hair of different age groups:

12 days	24μ
6 mo.	37μ
18 mo.	38μ
15 yr.	53μ
Adults	70μ

Lanugo hairs on the fetus are very fine, have no medulla, and are almost colorless. The average diameter of the hair increases with age as can be seen in Oesterlen's table. The hairs of infants and children are usually finer than those of adults; they usually have no medullary cavity until after puberty and contain less pigment than do adult hairs. Gray and white hairs appear in middle life. This is due to loss of pigment from the shaft. Gray hair without pigment is usually translucent or may even be transparent. The diameter of the hair in the aged is less as a rule than that of younger adults.

It was formerly thought that the morphology of the medulla of human hair depended on the age of the individual, but E. M. Wynkoop showed that this is in proportion to the diameter of the shaft of the hair and is not due to age.

The hair of young people has a lower pigment content and a smaller diameter than that of adults. In elderly people the hair tends to become scarcer and finer, and the bulb degenerates. The shaft also shows signs of degeneration.

Race: Scalp hair is usually examined to study race. The color of the hair of the Caucasion race varies from light to dark. The shaft may be fairly straight or wavy and curly, with varying caliber throughout the length. The shaft is ovoid. The medulla is central in straight hairs or slightly eccentric in curly hair. In dark individuals of the Caucasion race the cortex contains much pigment and is dark brown. In fair individuals the hairs are lighter brown, or they may be reddish or blond.

American Indians and Chinese and other Asiatics usually have long straight coarse black hair with a deeply pigmented large shaft. Cross sections show cylindrical or triangular shafts, with the medulla centrally situated.

Hair of Negroes is usually kinky and black, the caliber varying greatly along the entire length of the hair. A large amount of pigment is to be found in the cortex. The hair in cross section is ovoid and narrow or may be almost flat. The medullary canal is eccentrically placed.

Sex: It was formerly possible in many cases to identify hair from female subjects by the length of the hair, but since women cut their hair frequently today and also shave the armpits and legs, the length and shape of the point are of much less value than formerly for differentiating hair. The best rule, as indicated by Glaister, is that a woman's hair generally shows a more delicate structure and a much finer granulation of pigment than that of a man. A study of the cross sections shows that the sexual difference in the weight of hair is due to the difference that exists in the area of cross section and the difference in the amount of pigment. M. Bernstein and S. Robertson of Chicago showed that male hair is heavier than female hair.

Region from which the hair is derived: To determine the region from which the hair is derived, consideration is given to the length, the diameter, the shape of the point, the material which covers the surface, and the shape of the cross section of the hair. Hairs from the beard are usually larger and curlier than those from the scalp. They usually show the effects of shaving, although if undisturbed will taper to a point. Hairs from eyebrows, eyelids, nose, and ears are as thick as the hair from the scalp but are much shorter and taper rapidly to a point. Medullary cavities are consistently present. Hairs from the axilla and pubic regions are fairly long and uneven, with eccentrically placed medullary canals. The hair has a tendency to curl. Hairs on the trunk and extremities vary in thickness and have less pigment than other hairs. There is a fine medullary cavity, although this may be absent.

The mere presence of certain substances indicates the region from which the hair came. A hair covered with fatty matter unquestionably came from the armpit; a curly hair, with crystals and vaginal secretion, can come only from the genital region of a female, etc.

Glaister summarized the bases of diagnosis as follows: (1) the total length of the hairs, (2) their texture and contour, (3) the character of both ends, (4) the general thickness, (5) whether sweat, vaginal secretion, seminal fluid, fecal material, food, nasal secretion, or wax adheres to them, and (6) the exact character of the cross sections.

Miscellaneous facts: Hair that has been recently cut shows the cut end more or less clean, according to the sharpness of the instrument used. At times hair is found in caps or hats, with both ends cut, one cut being recent and the other much older. In all cases when the cut is recent, the edges are clean, neat, and form more or less acute angles. After 3 days the point of the cut hair begins to become rounded or convex because of the continuous rubbing of substances against it.

Pincus estimated that an individual 20 yr. of age loses 70 hairs of his head daily; this figure decreases until the age of 50 yr. when only 22 hairs are lost each day. Hair that falls out by itself shows a full bulb, replete, as it has reached full growth. On the other hand, hairs that have the bulb hollow or excavated, because they have not attained full growth, show that they were pulled out. When the pull has been very violent, the root is found to have particles or cells of the surrounding skin clinging to it. In some cases hair that has been pulled out is found to have numerous cells of the skin adherent to the root, and the shaft is more or less noticeably bruised. This always occurs when the victim was attacked with a heavy, blunt, and crushing instrument.

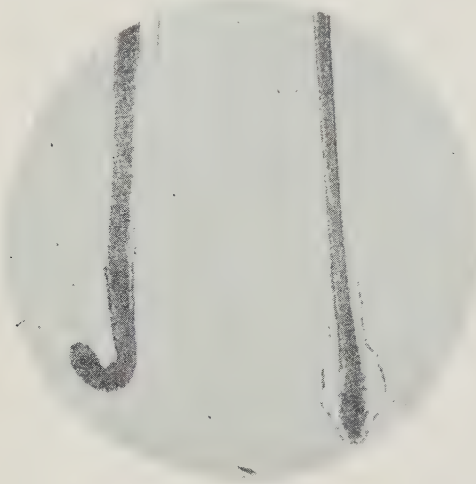

Fig. 778. Root portion of hairs that have been torn out. Note typical appearance of the bulb. The one at the right carried part of the follicle sheath. (Courtesy Dr. Israel Castellaños.)

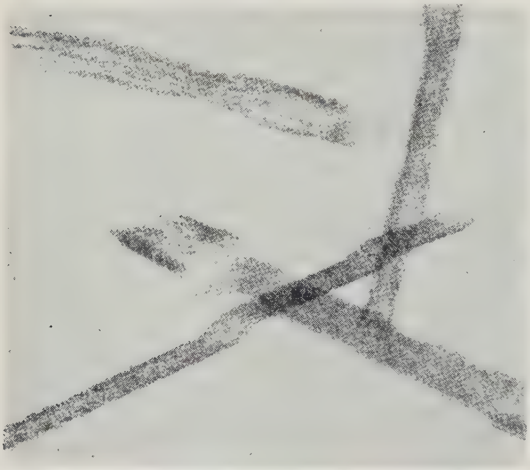

Fig. 779. Microscopic appearance of several hairs that have been struck with an instrument or weapon without a cutting edge. It can be seen how part of the hair shaft is bruised. (Courtesy Dr. Israel Castellaños.)

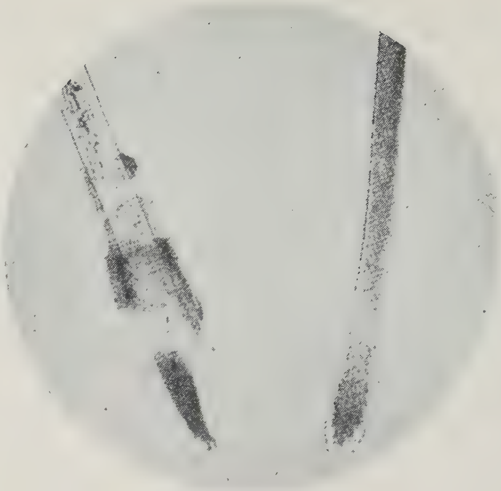

Fig. 780. Root portions of 2 hairs. The one at left was torn out and the one on the right fell spontaneously. Note typical appearance of the terminal portion in this fallen hair. (Courtesy Dr. Israel Castellaños.)

Bleached or dyed hair: Bleaching of the hair is more difficult to determine than the fact that the hair has been dyed. Dyes are easily discovered, because they leave a homogeneous or irregular layer on the periphery of the hair, which can be seen perfectly under the microsrope. Tests for determining the dye used are based more on chemical analysis than on microscopic examination.

Dyes of a metallic salt base, bismuth, silver, or lead, or those having a base of organic substances, such as vegetable dyes, can be determined by chemical analysis.

Many criminals do not hesitate to make use of surgical means to disfigure themselves and thus evade the action of the police; they may also use wigs for that purpose. It is necessary, therefore, to be able to distinguish between hair that has recently fallen out and false hair.

PROCEDURE FOR EXAMINATION OF HAIR

If one finds hairs in the hands of the victim which the victim pulled from the head or beard of his aggressor during a struggle, note must be made of the position of the hairs in the victim's hand. For greater exactitude, as Gross suggested, make a drawing of the hand to fix that position exactly. It is often possible to tell the root at a glance by the enlargement of the bulb, which is always visible with an ordinary magnifying glass. It is then unnecessary to take steps to decide where the point lies and where the root is.

The material adhering to the surface of the hair should not be dislodged since, as Waldeyer stated, "often the dirt adhering to the hair is more important than the hair itself." For this reason, any hair that may be found must be neither rubbed nor cleaned.

The hair from the victim should be placed in bottles labeled Victim, and any hair from a suspected aggressor should be placed in bottles labeled Suspect.

When no hair is found in the hands of a dead body and none is found at the scene of the crime or in the place where the victim was found, search should be made of articles of personal use, such as towels, combs, etc. Hair commonly adheres to clothing, not only to caps and hats but also to stockings. It can frequently be found in the nap of towels, and it may be in the hair of the victim or of the aggressor. It is rare not to find hair in the teeth of combs. Such hair may be from the deceased when he last used the comb, or it may have come from the aggressor if he combed his hair before leaving the scene.

Hair may also be found on sheets and pillow cases. It consists of hair that has fallen out while the victim was resting or sleeping in the bed or hair that has been pulled out violently in the struggle which preceded death.

Hair comes out not only because of the periodic renewal to which it is subject but also because of a tug given by an individual in defending himself or by the aggressor in an attack. The hair falls unnoticed and remains at the scene of the crime as a silent witness to the tragedy and as circumstantial evidence of the crime. If the investigator searches for it with a magnifying glass, he will find that it contains a varied number of substances, according to the nature of the crime: blood from a mortal wound, black or smokeless powder from a fatal shot, semen, etc.

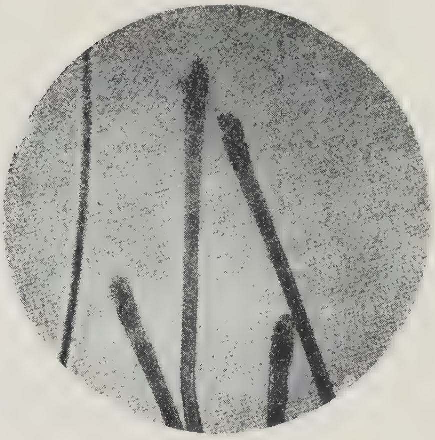

Fig. 781. These hairs show that in fallen hairs the root sheath is missing. In cases of falling hair, part of this sheath always remains embedded. (Courtesy Dr. Israel Castellaños.)

Finding a hair, according to Glaister, makes it necessary to answer these questions.

1. Is the hair that of a human being?
2. If it is human hair, is it the hair of a male or a female subject?
3. What is the approximate age of the individual from whom the hair has been derived?
4. From what part of the body has the hair been derived?
5. Has the hair been dyed or is it of natural color?
6. Has the hair fallen out, been pulled out, or cut?
7. If it has been cut, was a sharp or a blunt instrument used?

Lambert and Balthazard suggest the following program.

1. Is the hair that of a human being or of an animal?
2. From what part of the body does the hair come?
3. Is the hair from a male or female individual?
4. What is the age of the individual from whom the hair came?
5. Was the hair cut and at what time?
6. Was the hair pulled out, or did it fall out accidentally?
7. Is the hair dyed, and if so, by what process?
8. Did the hair under examination come from a living person?
9. What is the identification of the hair?

Castellaños' questionnaire is longer because he makes additional examinations to determine the following facts.

1. The trade of the individual from whom it came.
2. The distance at which the fatal shot was fired in cases of gunshot deaths.
3. The kind of powder used in the fatal shot in such cases.
4. The poisoning of the subject from which it came.

HUMAN AND ANIMAL HAIR

Most authors begin the investigation by determining whether the hair found is from a human subject or from a lower animal. At present there is no one known identifying specific characteristic of human hair, just as there is no illness which can be diagnosed by a single symptom; but the hair of no one animal combines the various anatomic characteristics found in the hair of man. In the outline that follows the characteristics of human and animal hair are compared (see also Figs. 767, 769, 770, and 782).

- I. Medullary (center) channel
  - A. Man
    - 1. Aerial net with fine granules
    - 2. Invisible
    - 3. Medullary cells not previously dissociated
    - 4. Value of medullary index (relation of diameter of the medulla to shaft diameter) inferior to 0′ 30
    - 5. Downy hair without medulla
  - B. Animal
    - 1. Aerial content of vesicles more or less voluminous
    - 2. Medullary cells very apparent
    - 3. Value of medullary index over 0′ 50
    - 4. Medulla in steps in the downy hair
- II. Cortical (outer) substance
  - A. Man
    - 1. Constitutes a thick muff
    - 2. Pigment in very small homogeneous granulations
  - B. Animal
    - 1. Constitutes a very thin tube
    - 2. Pigment in irregular granulations; always larger than those of man
- III. Cuticula
  - A. Man
    - 1. Thin scales; lightly serrated (sawtoothed); strongly imbricated (tilelike)
  - B. Animal
    - 1. Thick scales; less imbricated than in man; markedly serrated

INDIVIDUAL IDENTIFICATION OF HAIR

It is after having settled all the points just discussed that the investigator undertakes what may be properly called the identification of the hair, that is to say, the individualization thereof, or, in other words, the determination of whether the hair found comes from a definite suspect or from a given individual.

Measurements are taken of the length of the hairs under comparison and their average diameter, and the maximum measurements are noted. If the different data coincide and the pigmentation of the hair is identical, as determined by the Fischer chromatic scale, one has reason to believe that the origin is the same. To make the examination definitive, minutely study the individual signs or characteristics of the hair. Observe the peculiarities of the **medullary canal** and the **point.** The coincidence of wear or degree of rubbing of the free point of the hair, with the coincidence of the length and the coincidence of the diameter, consolidates the identifying diagnosis. The coincidence of arrangement, abundance, and coloring of the pigmentary granulations makes identification or individualization of the hair certain.

In addition to these details, purely anatomic, there are many others that contribute to make identification of the hair more eloquent, such as racial characteristics, the existence of identical vegetable substances, metal particles, pathologic changes, parasites, etc.

The presence of foreign particles, such as coal, pollen, etc., may prove to be indications of the trade in which the individual was engaged.

Finally, it has been shown that with adequate chemical methods, presence of arsenic in the hair can be shown when the individual has been poisoned with arsenicals.

It may be concluded that microscopic, chemical, and bacteriologic study of hair offers a fertile field of criminal investigation. From Castellaños' experience of many years he has found on numerous occasions that

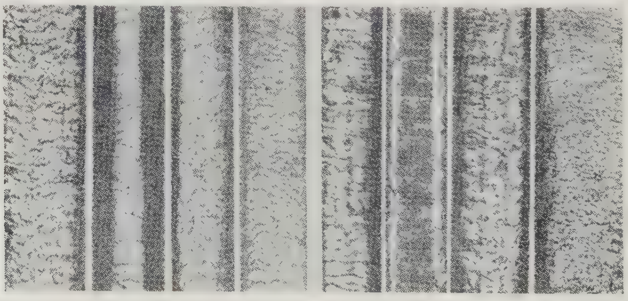

Fig. 782. Hair characteristics. Left to right, hair of Negro, Mulatto, white man, white woman, dog, cat, horse, and pig. (Courtesy Dr. Israel Castellaños.)

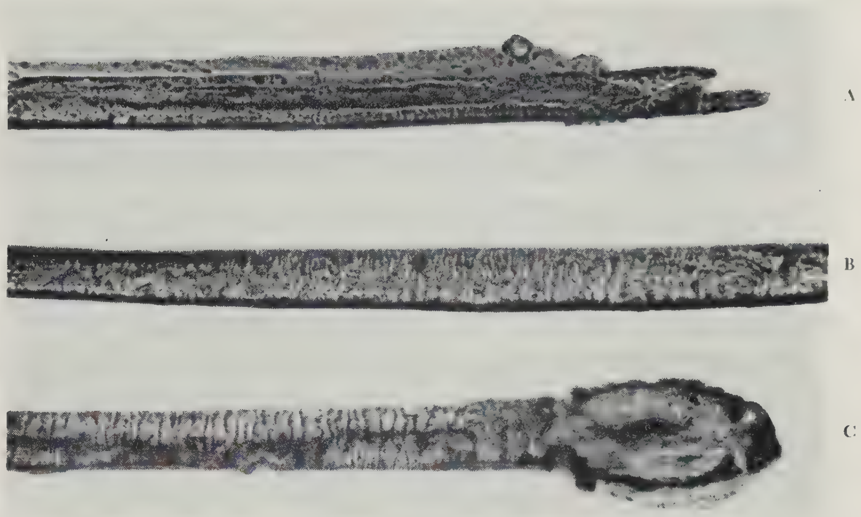

Fig. 783. Exhibit A, Case 1. **A,** Photomicrograph of the severed end of the hair found in the slit of a screen door. **B,** Photomicrograph of the middle portion of the same hair. **C,** Photomicrograph of the root of the same hair. (Courtesy Dr. Israel Castellaños.)

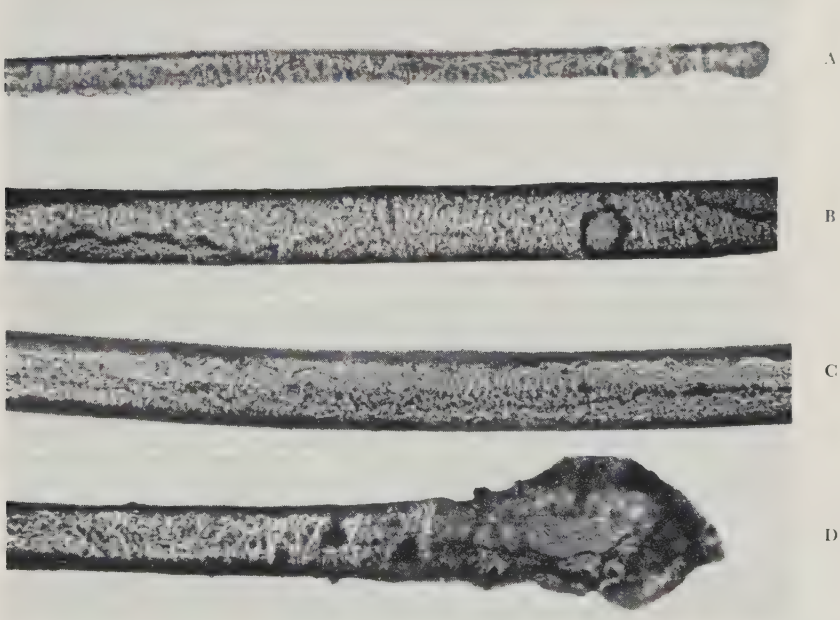

Fig. 784. Photomicrographs of one of the hairs taken from the left arm of suspect B, Case 1. **A,** End portion of the hair. **B,** Portion near the middle of the same hair. **C,** Portion beyond the middle of the same hair. **D,** Root of the same hair. (Courtesy Dr. Israel Castellaños.)

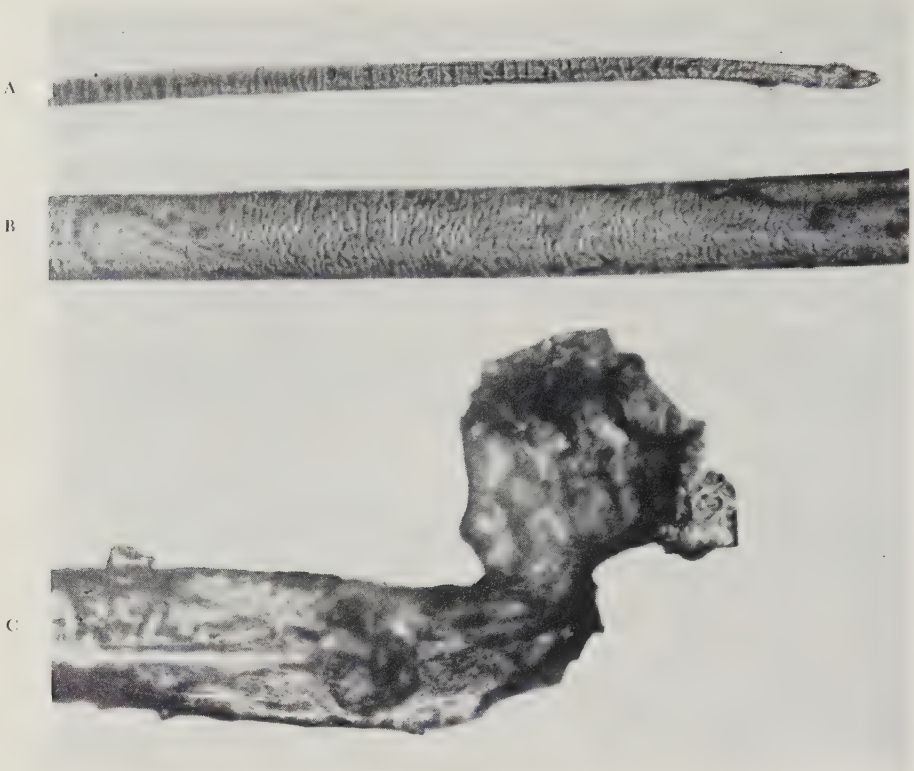

Fig. 785. Photomicrographs of one of the hairs taken from the left arm of suspect C, Case 1. **A**, End of the hair. **B**, Middle portion of the same hair. **C**, Root of the same hair. (Courtesy Dr. Israel Castellaños.)

when the usual investigation had failed and the criminal seemed about to be freed, he was able, from a few hairs which he had obtained in some cases weeks after the tragedy, to identify the persons involved in the crime and to deliver the guilty to justice.

In a personal communication, May, 1947, Dr. Castellaños furnished R. B. H. Gradwohl with records taken from his own files of cases in which the identification of hair contributed an important part to a medicolegal procedure.

Case 1: In Louisiana, the screen door of a camp hut was found broken. Investigators found a hair caught in the broken screen wires and, using the necessary precautions, took it for examination. Specimens of hair were also taken from suspected persons, those near the camp hut during the night. These were submitted for comparison.

The hair taken from the slit in the screen door was labeled Exhibit A (Fig. 783). Those from the 2 suspects were labeled, respectively, Exhibit B and Exhibit C. Examination of Exhibit A established the following:

1. That said hair is human hair.
2. That it came, not from the head, but from an extremity.
3. The color of the hair is light blond.
4. The free end of this hair appeared to have been cut transversely by an edge which was rather thick and not extremely sharp. If the hair had been cut by a very sharp edge the free end would show a straight, clean cut instead of the jagged cut, as seen in Fig. 783, *A*.
5. Examination of the full length of this hair revealed that the stem was not injured or compressed, since all of its elements were intact. The regularity of the hair and the integrity of the cuticula can be seen in Fig. 783, *B*. The diameter varied from 22-56μ.
6. That the root of this hair presented all of the characteristics found in hairs which have been pulled out, as is seen in Fig. 783, *C*.

Examination of Exhibits B and C showed the following:

1. That these are also human hairs taken from the extremities.
2. That Exhibit B comprised 9 hairs the length of which ranged from 8-28 mm.
3. That Exhibit C comprised 5 hairs the length of which ranged from 11-27 mm.
4. That the diameter of the hairs in Exhibit B varied from 14-66μ.
5. That the diameter of the hairs of Exhibit C varied from 12-134μ.
6. That the hairs taken from Exhibit B were light like those of Exhibit A, whereas the hairs taken from Exhibit C were darker or pigmented.
7. That the similarity of color of the hairs of Exhibits A and B was clearly visible, and micro-

scopic comparison proved that the tone or chromatism of both exhibits was identical.

8. That although the disparity between Exhibits A and C was clearly visible to the naked eye, microscopic comparison proved the chromatic discordance between these exhibits.

9. That through macroscopic and microscopic examination and the micrometric measurements taken of the 9 hairs sent as Exhibit B, their anatomic structure, characteristics of cuticula or outer covering, the nature of the medullary structure, and the tone and arrangement of pigmentation proved that they were identical to those of Exhibit A.

10. That through all of the aforementioned anatomic details it was proved that the 5 hairs sent as Exhibit C were completely different from those of Exhibit A.

11. That all the scientific observations made proved that all the macroscopic, microscopic, anatomic, metric, and chromatic characteristics found in Exhibit B are also found in Exhibit A, whereas the contrary is true of Exhibit C.

12. That all these data coincided to establish the fact that the hairs taken from the left arm of Suspect 1 were exactly the same as those found in the slit in a screen door in the rear entrance to a camp hut. Fig. 786 shows that the hair of Exhibit A coincides exactly with that of Exhibit B as registered by examination with the Spencer comparison microscope.

Case 2: A man was struck and killed by a motor vehicle. A passenger bus had been seen in the vicinity at about the time the man was killed. The driver of this bus was questioned by the police. He stated, under questioning, that he had felt a slight jar at about the place where the body had been found. It was quite dark. He had stopped his bus and looked around and, finding nothing wrong, had driven on.

An examination of the bottom of the bus revealed the presence of one strand of hair and a small fragment of what appeared to be human tissue. Later a quantity of hair was taken from the dead man's head for comparison.

Castellaños received 2 specimens marked, re-

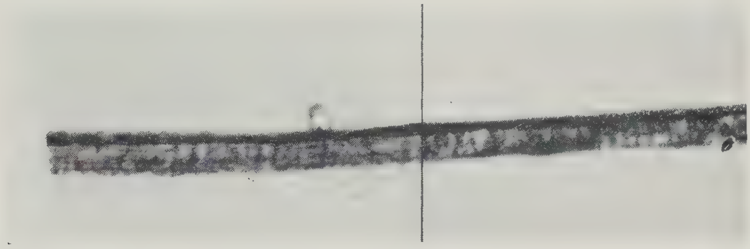

Fig. 786. Photomicrographs of Exhibit "A" and "B," Case 1, as seen under the Spencer comparison microscope. (Courtesy Dr. Israel Castellaños.)

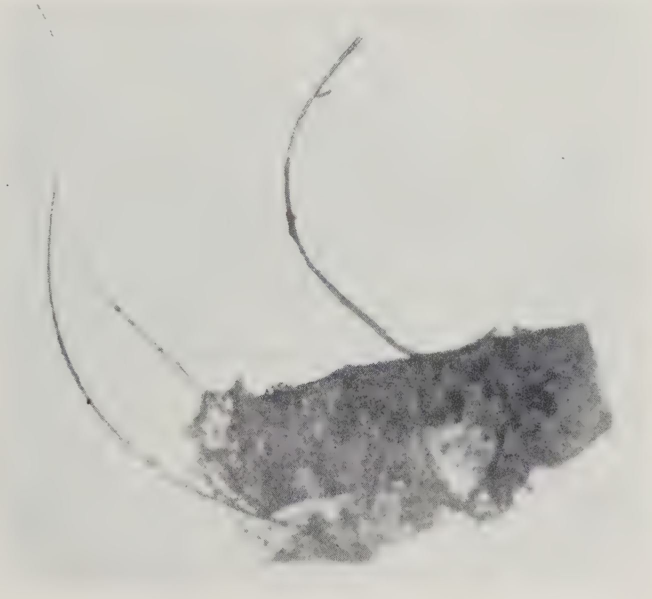

Fig. 787. Tiny fragment contained in envelope marked "Questioned." Case 2. (Courtesy Dr. Israel Castellaños.)

spectively, Victim and Questioned. The envelope marked Questioned contained the tiny fragment seen in Fig. 787. This tiny fragment, when placed upon slides, showed 2 objects, the details of which may be noted in Fig. 788.

The dirt was removed from the small organic fragment by washing it in saline solution which does not alter the anatomic structure or the color. The cleansed fragment was then prepared for microscopic examination, which revealed that the fragment was connective tissue, as seen in Fig. 789. The preliminary microscopic examination revealed that the material clinging to the small fragment was hair and not fiber.

As can be seen in Fig. 788 the hairs which were clinging to the fragment were dirty. Before they could be submitted to complete anatomic examination, they were thoroughly cleansed in saline solutions. Saline solutions make not the slightest alteration in the structure or coloring of hair. These hairs, removed from the connective tissue, were 1-2 cm. long and were arched. The hairs terminated sharply or in a point. The stem or body of the hairs was bruised, crushed, or broken. Fig. 790 shows a crushed portion on the right-hand side. There are portions or fragments, however, in which the structure is normal, as seen in Figs. 791 and 792.

The hairs removed from the small piece of connective tissue were examined under natural and transmitted light and classified according to the Bertillon chromatic classification as light brown.

The cuticula of these hairs, especially in the stem or body, was definitely imbricated. The end, which is the portion opposite to the root, was disintegrated; parts were lacking so that the cortex was exposed. Such disintegration shows that these hairs had been altered mechanically by repeated friction and crushing. The stem of one of the hairs showed a greenstick fracture, in which the body of the hair is split open. The medulla was disunited in some regions and in others it was not visible but showed a granular airlike network.

The examination of the diameters of the shortest hair, approximately 1 cm. long, showed the following: maximum diameter, 98μ; minimum diameter, 17μ; average diameter, 56.1μ; medullary index, 0.25.

Measurements of diameters of the longest hair, approximately 2 cm. long, showed the following: maximum diameter, 98μ; average diameter, 56.1μ; medullary index, 0.25.

The hairs of the Victim were light brown according to the Bertillon chromatic scale. Since all of these hairs had been cut, none of them showed the root. These hairs had a definitely imbricated cuticula. On some it was torn, as seen in Fig. 792, *A*, but there were large portions in which the hair was perfectly normal.

As seen in Figs. 792, *B*, and 793, some of the hairs were crushed and broken, thus showing enormous mechanical action. There are large portions, however, in which normal anatomic structure can be observed.

Diameters of the hair coming from the Victim were as follows: maximum, 73μ; minimum, 17μ; average diameter, 41.5μ; medullary index 0.23.

The medulla of these hairs was disunited in some regions and invisible in others.

In comparing the results of the examinations of hairs marked Questioned and Victim, there can be noted a marked resemblance in the type of the cuticula cells (definitely imbricated) and the pigmentation or coloring. Furthermore, the lesions in the hairs of the Questioned are similar to those in the hairs from the Victim.

Diameters are not the same in the 2 specimens, but such discrepancies are found when the hairs come from different regions of the body. If hairs from different regions are compared, measurements are of secondary value. Anatomic characteristics, color, pigmentation, the morphologic type of hair, etc., are the decisive factors in making the diagnosis. In Case 2 all details are alike except the measurements.

The fragment of connective tissue was too small to be submitted to all the biologic tests. There was not enough to test it serologically to determine whether it was of human or animal origin. It was found with human hairs clinging strongly to it, and the histologic examination does not deny that it is of human origin so that it can be assumed to be human.

Investigations of hairs are always slow, but such investigations are extremely important.

Chapter 115

Solutions for the preservation of museum specimens

Kaiserling method

The Kaiserling method gives by far the best results for the ordinary pathologic and anatomic preparation when the color of the red blood cells is to be preserved. If any of the faint yellows or greens (due to bile staining or other causes) are to be kept, one of the chloral hydrate fluids, preferably Klotz, gives excellent results, with Kaiserling solution III as a permanent preservative.

Specimens must be obtained fresh from the autopsy or operation and must not be allowed to soak in water for more than a few moments. Only the superfluous blood should be washed away, remembering that the one color available for preservation lies in the hemoglobin of the red blood cell, and that this, therefore, must be preserved. The basis of the methods of color preservation which are to be recommended lies in the chemical change produced by the action of formaldehyde upon the hemoglobin of the red cell and its subsequent fixation as the red alkaline hematin by alcohol.

It is necessary to enlarge on the proper laying out of the specimens in the solution I. No cloth, metal pins, or paper must be allowed to come in contact with them. Cotton wool to hold in shape and stretching on glass frames with cotton thread is all that is necessary. Large bodies of fresh fluids must be used. After careful comparison both abroad and at home, the following process has been found to give the best results.

Kaiserling solution I:

Potassium acetate	170 gm.
Potassium nitrate	90 gm.
Formalin (water white formaldehyde), 40% . .	1600 ml.
Water	8000 ml.

Care should be taken to use only high-grade chemicals.

1. Water white formaldehyde must be as free from formic acid as possible. It is not necessary to buy the chemically pure grade. A white deposit, due to freezing (paraformaldehyde) is sometimes seen in the formalin. This lessens the concentration of formaldehyde gas, and consequently the color and fixing processes are not correct. Always buy formalin in the spring of the year and see that there is no white deposit present. Do not boil it unless the amount of formalin used in making the solution is restored.

If the formaldehyde is found to be acid, it can be neutralized with sodium carbonate or sodium hydroxide.

To make a 2% (w/v) formaldehyde solution:

Formalin	5 parts
Water	95 parts

4%: Use 10 parts formalin to 90 parts water.

6%: Use 15 parts formalin to 85 parts water.

2. Potassium acetate. We recommend Mallinckrodt potassium acetate.
3. Potassium nitrate.
4. Glycerin, water white, c.p. Do not use dynamite glycerin since it produces a change in color.
5. Chloral hydrate.

The length of time the specimen should remain in the Kaiserling's first fixation fluid has caused a great deal of comment. It is of secondary importance to thorough hardening. The specimen should be fixed so that no blood will ooze out when firmly pressed between the fingers. In fact, good color results have been obtained in specimens that have stood 2-4 mo. in the solution I. These are, of course, exceptional cases. Intestines should not be left for more than 10-12 hours. Other specimens or organs should be left in the solution 1-5 days. In all instances they must be thoroughly fixed. Formalin increases the firmness of tissue. The tissue loses its natural color and assumes an aged and grayish appearance.

Great care must be taken to wash the specimens thoroughly in running water after removal from this solution.

Kaiserling solution II: Use 95% alcohol. It may be used at once without the intermediate stage of 80% alcohol recommended by Kaiserling. The specimens must be left here until the natural colors, which have disappeared under the action of the formalin in the first solution, return, the process being watched in the same way as in the development of a photographic plate.

The strength of the alcohol should not be allowed to go below 80%. To avoid this the specimens should be transferred to a second alcohol of the original strength. The time in which the specimens remain in the alcohol varies according to the particular character of the tissue.

In this stage again the specimens must be carefully washed in water; no traces of the formalin or alcohol used in the first and second solutions are to be carried to the final fluid. If either the alcohol or the Kaiserling III solution used gives off any odor of either formalin or alcohol, it must be thrown away. This is absolutely necessary.

When specimens have been left in alcohol for too long a time, color can be restored by leaving them in equal parts of Kaiserling solution III and glycerin for 24 hr., allowing for the amount of glycerin already in the Kaiserling fluid.

Kaiserling solution III:

Potassium acetate . .	4 lb.
Glycerin	2000-4000 ml.
Distilled water . . .	10,000 ml.
Phenol (preservative)	20 gm.

Kaiserling solution I is not satisfactory for preserving veterinary or anatomy specimens. The best results have been obtained by Klotz, increasing the formalin possibly to 6%, then placing in the alcohol, and preserving in Kaiserling solution III.

When specimens in Kaiserling solution III in open jars are used to pass around a class, care must be taken not to allow the surface to dry or the fluid to be contaminated with molds. One infected jar may cause contaminations in many others and necessitate putting them through solutions I and II just as would be done with a fresh specimen.

To clarify Kaiserling solutions: To clarify Kaiserling solution III, connect a 5 gal. vessel with an air compressor. Run the Kaiserling solution through a Berkefeld filter. This takes 20-30 min. Run water through the filter to clean it. Be sure to connect the filter with the water main.

Another method of clarifying Kaiserling solution III is as follows: For 10,000 ml. Kaiserling solution III, 5 funnels are required. Prepare filter paper. Do not fold it. Place the 5 filters in a row. Use 1 tbs. charcoal (very fine bone charcoal) for each funnelful. Put the charcoal in a jar and shake well with Kaiserling solution III. Run the solution through the funnels slowly. Refilter the first filtrate that comes through the funnels.

In making Kaiserling solution III do not use tap water. Use distilled water; tap water contaminates the solution.

Kaiserling solution III dissolves plaster of Paris.

Klotz formerly used a little formaldehyde in Kaiserling solution III. This is not recommended as it causes an undesirable chemical reaction. Phenol is now used. It makes a specimen slightly gray but prevents the growth of fungi.

Important points to remember: There must be no odor of formaldehyde or alcohol in Kaiserling solution III. Wash out both of these materials thoroughly so that no trace of odor remains.

Overharden in a Kaiserling solution I rather than underharden.

Always sacrifice color to permanency.

Avoid infecting the jars. If a jar is infected, the specimen must be treated again with Kaiserling solutions I, II, and III.

Formalin will not penetrate either liver or lungs. In order to fix and preserve color, these specimens must be either cut into slabs or injected.

For red blood cell color preservation, place the specimen in a Novy jar and cover with Kaiserling solution I. Then saturate with carbon monoxide gas from any gas jet. To eliminate excess gas, burn off the exhaust or connect a tube to the Novy jar and extend it out of the window.

Always protect a specimen from the direct rays of the sun even after it is completed. Colors are affected by sunlight. Diffuse sunlight will not affect them. Heat will destroy color. Keep specimens in a cool place.

Never preserve a specimen in pure glycerin. A spleen preserved in pure glycerin will shrink to ½ its size.

Be careful of the concentration of alcohol in Kaiserling solution II because it will lose its strength. Keep above 80%. Use a small alcoholometer employing a small test tube.*

Frost sugar solution

Frost sugar solution is sometimes used as a preservative.

Sodium fluoride	80 gm.
Chloral hydrate	80 gm.
Potassium acetate	160 gm.
Cane sugar	3500 gm.
Saturated thymol water . .	8000 ml.

Sodium fluoride many be omitted. Never under any circumstances use beet sugar.

---

*Arthur H. Thomas Co., Philadelphia, Pa.

Chapter 116

Semen appraisal

The examination of seminal fluid with special regard to defective spermatogenesis in otherwise healthy men has been elaborately studied by Cary and Hotchkiss.[3] They present a method of fixing and staining a microscopic specimen which differentiates component parts of the cell without distorting the protoplasm and enables any physician familiar with the use of the oil immersion objective to recognize and classify abnormal sperm cells and in specimens of doubtful character to count the percentage of these cells as an added index of deficiency or improvement.

The examination of the semen is divided into 3 steps: (1) collection of the specimen, (2) gross or macroscopic investigation, and (3) microscopic study.

GENERAL CONSIDERATIONS

Collection of specimen

Collection of the specimen may be accomplished by any one of the following 3 methods, named in the order of preference: (1) specimen produced at the office of the examiner, (2) specimen collected outside the office of the examiner by external emission, and (3) specimen collected by the condom method.

Specimen produced at office of examiner: If accuracy is stressed, and a quiet, suitable room is provided, many men are not averse to this method, and the physician is in constant control of the ejaculate.

Collection outside office of examiner by external emission: For this purpose the patient is given a glass graduate and a small (1 oz.) wide-mouthed bottle. After collection in the glass graduate, the specimen is allowed to liquefy so that it will not adhere to the glass surface, and it is transferred to the bottle, which is then corked, placed under the clothing about the torso, and brought to the office.

Condom method: Patients are advised to prepare the condom in advance by washing the preservative powder from the surface that is to receive the specimen and carefully drying it. This precaution is taken because not only do foreign bodies hinder the microscopic examination, but there is also a chance of harm to the specimen by the various ingredients in these powders. After coitus the condom is tied, gently wrapped in a handkerchief (not clinging, absorbent cotton), concealed under the garment next to the skin, and thus delivered.

Patients are warned not to attempt artificial warming of the specimen, but gentleness in handling and maintaining as far as possible at body temperature should be borne in mind. The laboratory should be ready for examination of the specimen when it arrives. The necessary implements, cleansed in plain hot water and thoroughly dried, should be kept ready for the examination. At the appointed hour, all the apparatus should be ready, including the microscope, to avoid thermal shock to the semen and the annoyance of misty lenses.

Gross examination

This examination includes a notation of the amount, which, when complete, and from men under 40 yr. of age, should exceed 3.5 ml. Lesser amounts should arouse suspicion of deficiency and premature weakening by vaginal acidity, otherwise negligible. Extended periods of sexual abstinence may impart a slightly yellow tinge to the normal grayish opaqueness. Normal specimens commonly show a slight degree of viscosity, which is easily demonstrated by slowly expelling a drop of semen from a pipet. Absence of viscosity with a lessening of opaqueness points to reduced cell content, although the reverse deduction does not hold.

An alkalinity of pH 8.1-8.4 has been so constant that it seems an unnecessary refinement except in research study; the significance of wider variations in reaction is not yet known. It has been pointed out also that the loss of carbon dioxide alters the body chemistry of the specimen.

Microscopic examination

Two specimens, one thick and one thin, are promptly prepared for microscopic examination by gently protecting a full drop and a fractional drop with cover glasses, the former permitting a gross impression of the density and motility of the cellular content and the latter allowing a preliminary study of individual cell morphology. In the thicker preparation, semen of relatively high fertility presents a field teeming with spermatozoa, many of which are rapidly propelled by fast-whipping tails. While universal cell activity would constitute the ideal, one usually notes in comparatively vigorous specimens that these fast travelers are colliding with a certain number of inactive (average 25%) and a variable number of sluggish and impotent cells, which gradually sink toward the lower strata of the field. Familiarity with this picture under standard dry high-power magnification constitutes the measure by which motility is judged. It is a practical observation that a motile field, though definitely subnormal, is apt to convey a favorable impression on the inexperienced or occasional examiner, but reverse errors in interpretation are rarely made. The practical aspects of motility are that a large number of highly motile cells are essential to fertility, and when a specimen of normal quantity and rich cellular content shows 25% or more of these dynamic cells, a rating of relative fertility must be assumed unless strongly disproved by other indices to be described. Such specimens usually meet other major requirements of fecundity.

Richness of cellular content, in terms of millions per milliliter, has been given emphasis by Macomber, Meeker, and other workers as a further index of appraisal. Although significant degrees of oligospermia are usually apparent to the experienced examiner on microscopic examination, there is no verbal picture that will adequately provide such an index. It may be said, however, that such specimens usually present other evidences of subnormality, such as lowered motility, increased number of abnormal cells, early crystal formation, and sometimes considerable indescribable debris. Such specimens may contain several round, granular cells in each field. These may be leukocytes or cells from the seminiferous tubules. The larger granular cells are spermatocytes; there are usually 4 nuclei, which may be demonstrated by the staining process later described. Cell counts are probably modified by the amount of the seminal fluid, and although in agreement with other observers that counts above 70,000,000/ml. are found in fertile specimens, Cary and Hotchkiss hesitate in setting a medium arbitrary count below which fertility is impossible. On the other hand, they have found a count as high as 112,000,000 in a highly defective specimen which measured less than 20 minims total quantity. This specimen promptly improved after treatment, and pregnancy followed.

Duration of motility is one essential to fecundation that can be easily determined. For this purpose the edge of the cover glass on the thicker smear should be protected by a layer of petrolatum, or new smears should be made from hour to hour from the total specimen. A normal specimen exhibits little cessation at the third hour after emission, and considerable cellular activity should be found at the fifth or sixth hour. Complete or considerable subsidence of motility within this limitation should be regarded as a further index of deficiency, but it should be noted that the few motile cells that were originally active in a highly defective specimen occasionally survive for many hours. Reciprocal studies between the direct male specimen and its behavior in female secretions tend to indicate that duration is practically synonymous with early vigor of motility, but there may be exceptions to this rule.

An improved staining process to define more clearly the exact morphology of the spermatozoon has been devised.

It has been found that Schaudinn solution is ideal for the fixation process, for it not only preserved the normal morphology of the cells but also removed the objectionable debris. The next problem was to devise a balanced stain that would demonstrate all portions of the spermatozoon, yet spare the chromophilic substance from overstain.

The method of Cary and Hotchkiss (p. 2072) permits illustration of the head, midsection, and tail of the sperm.

In appraising seminal specimens deduct the percentage of abnormal forms found from the total cell count. The resultant figure, when correlated with other data, is of great importance in the more accurate evaluation of the semen. For instance, 40% of inactive cells with

25% abnormal forms would indicate more serious impairment and need for greater improvement in a specimen with a count of 60,000,000 or less than would obtain with a cell count of 100,000,000.

Weisman method of counting spermatozoa

Weisman[4] uses a simple method which obviates the necessity of blood counting pipets and special diluting fluid. Dilution with ordinary tap water serves not only to dilute the sperm cells so that they may be easily counted in a Neubauer blood-counting chamber, but it also causes immediate cessation of motion of the sperms, facilitating the count.

Procedure:

1. Place 1 ml. well-mixed whole semen in an ordinary test tube, graduated at 20 ml. Add ordinary tap water, cold, up to the 20 ml. mark. This technic kills all the spermatozoa at once and by dilution of 1:20 diminishes the error which occurs when using the small amounts of semen usually utilized in the blood-counting pipet technic.
2. Fill the counting chamber. Count the sperms in the same fashion as white cells (p. 1105). Count and recheck the sperms in 1 sq.mm. (the 16 small squares in one corner of the chamber); multiply by 10 to obtain the number of sperms found in 1 c.mm. Multiply this by 1000 to find the number in 1 ml. diluted semen. To obtain the number in 1 ml. whole undiluted semen, multiply this by 20. In other words, multiply the actual average count in the 1 sq.mm. field by 2 and add 5 zeroes.

MEDICOLEGAL EXAMINATION OF SEMINAL STAINS

The identification of seminal stains is frequently of great value in medicolegal work in cases of alleged rape, sexual homicide, or even adultery. Specimens are sent to the laboratory often dried on clothing, sometimes admixed with blood, sometimes in dry masses adherent to hair. Spots on the specimen may be found very readily if submitted to examination by ultraviolet light. Seminal stains give a greenish white fluorescence which may aid in finding the stained areas. This fluorescence is not specific for semen.

Seminal stains are detected definitely by finding spermatozoa under the microscope. The spermatozoa are not readily destroyed unless the stain has been subjected to too much washing or exposure. After they become dry, they are very brittle, and the tail is easily separated from the head. To identify them absolutely, it is necessary to find perfect bodies with head and tail complete. It is best if motility can be shown (only possible when specimen is fresh and moist). Great care must be exercised in handling stains that are to be examined for the presence of spermatozoa.

If it is possible to obtain a fresh specimen, spermatozoa may be found by putting a small sample of the semen in a drop of physiologic saline and examining microscopically; motility may be found in recent specimens. The slide may be stained by various methods.

The spermatozoa, or male germ cells, are developed in the convoluted tubules of the testes. They are actively motile in the seminal fluid, which is a secretion of the accessory sexual glands, and are seen in enormous numbers in the normal ejaculate. A spermatozoon is a slender elongated flagellated structure 50-70μ in length and possesses a head, neck, a body or connective piece, and a tail.

The head is pear-shaped, measuring from 3-6μ in width. The neck consists of the anterior centrosome; the body is rodlike and connects the head and neck with the tail. The tail is divided in 2 portions, the chief piece and the end piece.

Spermatozoa are actively motile in the fresh state.

Seminal fluid or semen is a mixture of secretions of the epididymis, the ductus deferens, the seminal vesicles, the prostate, the bulbourethral or Cowper's glands, and the urethral or Littre's glands. Average amount of ejaculate is 2.5-5 ml., and each milliliter should contain 100,000,000 or more spermatozoa.

Methods of staining spermatozoa

Method of Cary-Hotchkiss[5] (1934)

Preparation of specimen:

1. Prepare thin cover-slip smears as used in the preparation of blood for staining.

Fixation in Schaudinn solution:

1. While still wet immerse for 1 min. in 7% corrosive mercuric chloride, 2 parts, and absolute alcohol, 1 part.
2. Immerse for ½ min. in 50% alcohol.
3. Immerse for ½ min. in distilled water, 3 oz., and tincture of iodine, 2 drops.
4. Wash in tap water.

Staining process:

1. Immerse for ½ min. in 5% aqueous solution of eosin.
2. Immerse for 1 min. in 50% alcohol, 3 oz., and concentrated hydrochloric acid, 2 drops.
3. Wash in distilled water.
4. Immerse for 2½ min. in hematoxylin.
5. Immerse for 1 min. in distilled water, 3 oz., and glacial acetic acid, 2 drops.
6. Wash in distilled water. Dry and mount.

This method gives excellent contrast between the nuclear material, which stains blue, and the cytoplasm, which stains red.

Method of Meaker[6]

1. Fix with heat.
2. Wash with 0.5% Chlorazene to remove mucus.

3. Wash with water.
4. Wash with 95% alcohol and dry.
5. Stain with carbolfuchsin and bluish eosin (carbolfuchsin, 2 parts, filtered bluish eosin, 1 part, alcohol, 1 part).
6. Wash with water.
7. Stain with methylene blue (methylene blue, 1 part; water four parts).
8. Wash with water.

Method of Gelarie[7]

This is a 1 min. method for the staining of spirochetes, spirilla, spermatozoa, and related organisms.

Preparation of solutions:

1. Fixing solution.
    (a) Dissolve 2.5 gm. recrystallized zirconyl chloride ($ZrOCl_2$) in 100 ml. 10% sodium chloride solution.
2. Citric acid solution.
    (a) Make 10% solution of recrystallized citric acid in distilled water to which a few crystals of thymol are added to prevent the growth of fungi.
3. Staining solution.
    (a) Dissolve 0.25 gm. gentian violet in 100 ml. N/10 solution sodium lactate; pH of this mixture should be approximately 8.4; if not, adjust.
4. K_2HgI_4 solution.
    (a) Dissolve 0.5 gm. mercuric iodide in 100 ml. 0.5% potassium iodide solution.
5. Counterstain.
    (a) Dissolve 0.2 gm. methylene blue in 100 ml. distilled water and add 0.2 gm. phenol (for photographic purposes use aqueous carbolfuchsin instead of methylene blue).

Procedure: According to Gelarie, the material to be examined is smeared on the slide in a thin layer and allowed to dry in the air (not over the flame).

1. Cover with the zirconyl chloride solution, allow to stand for 5 sec., and then wash with water. This acts as a fixative.
2. Then place a few drops of the 10% citric acid solution on the smear, allow to remain for 10 sec., and wash again with water. The slide is now ready for staining.
3. Place a few drops of the staining solution on the slide, allow to remain for 30 sec., and then wash off with water.
4. Follow by momentarily covering the smear with a few drops of the complex mercuric iodide solution and again wash with water. While a good stain is obtained at this point, uniformly excellent results may be secured by counterstaining with aqueous carbol methylene blue solution for 5 sec.
5. Then wash the slide, dry, and examine by means of the oil immersion objective.

Counterstaining is not recommended for obtaining exact detail of spermatozoa, however, due to overstaining of the organism. Without it the different parts—head, neck, and tail—with their components can be readily distinguished.

Although the above technic is simple, it is believed that some of the more complicated stains show up much more detail of the spermatozoal head.

Method of Holbert[8]

The Holbert method is similar to that used by Williams.

1. Make a thin smear like a blood film.
2. Shake until dry.
3. Flame gently.
4. Flood slide with 0.5% Chlorazene for 2 min.
5. Wash gently with running water.
6. Flood slide with 95% alcohol and let stand for 1 min.
7. Tip off excess alcohol and allow to dry.
8. Stain with 0.5% aqueous gentian violet for 3 min.
9. Rinse with water.
10. Rinse with 95% alcohol.
11. Rinse with water.
12. Counterstain with 1% aqueous rose bengal for 1 min.
13. Wash with water.
14. Allow to dry.

This method is recommended.

Methods of Williams et al.[9, 10]

Williams has 3 methods of staining spermatozoa. The smear is made in the same way as a blood film, dried in the air, fixed with moderate heat, and treated with 0.5% Chlorazene solution for 2-4 min. to remove the mucous film that overlies the spermatozoa. Wash slide gently with distilled water and then with 95% alcohol. Stain as follows.

Method I—crystal violet and rose bengal:

1. Cover film with 0.25% aqueous solution crystal gentian violet for 2-3 min.
2. Wash with water.
3. Decolorize with 95% alcohol for ½-2 min.
4. Wash with distilled water.
5. Counterstain with 1% rose bengal (aqueous) for 8 sec.
6. Wash in water and examine under microscope.

If the spermatozoa have not taken up sufficient rose bengal to impart a distinct reddish color to the acrosome and the nuclear membrane, repeat the staining interval with rose bengal until this is accomplished. Care should be taken not to overstain with rose bengal; if overstained, the contrast between the nucleus and the acrosome will be lost.

Method II—Wollschwarz, methylene blue, and rose bengal: Stain in 1% solution of Wollschwarz for 5 min. as follows, preparing 3 solutions.

1. Solution A.

Wollschwarz, 1% aqueous .	4 ml.
Sulfuric acid, 2%	0.025 ml.

2. Solution B.

Wollschwarz, 1% aqueous .	4 ml.
Sulfuric acid, 2%	0.05 ml.

3. Solution C.

Wollschwarz, 1% aqueous .	4 ml.
Sulfuric acid, 2%	0.075 ml.

The smear on the microscope slide is marked off into 3 divisions with a glass-marking pencil, and the solutions of stain having the different concentrations of sulfuric acid are applied to each of the divisions, respectively (dilutions A and C may be omitted).

1. Wash with water.
2. Counterstain for 6-8 sec. with Loeffler methylene blue that has been diluted in 15 parts

of water. This acts as a mordant to the Wollschwarz, serving to fix it in the nucleus. It imparts a rather greenish hue to the otherwise yellowish-stained nucleus.
3. Wash with distilled water.
4. Counterstain with 1% aqueous rose bengal for 6 sec. or until the rose bengal is set in the acrosome and the nuclear and cell membranes to give the desired contrasts.
5. Examine slide after each application of stain so as to guide its intensity.
6. Wash with distilled water.
7. Dry, mount in neutral Canada balsam, and apply cover slip or examine without mounting.

Method III—carbolfuchsin, eosin-B, and methylene blue: Prepare the following 2 staining solutions.

1. Stain 1.

Saturated alcoholic solution of eosin (bluish)	1 ml.
Ziehl-Neelsen carbolfuchsin . .	2 ml.
Alcohol, 95%	1 ml.

Mix the eosin and carbolfuchsin solutions together in a dry watch glass. Immediately on mixing, an insoluble precipitate and a metallic film form. Filter the mixture, and to the filtrate add 1 ml. 95% alcohol.

2. Stain 2.

Loeffler methylene blue . .	1 part
Distilled water	6-8 parts

Apply Stain 1 to the film for 2 min. Wash film gently with distilled water. This is best done by immersing it in a basin. Counterstain with Stain 2 for 4-8 sec. Wash slide with distilled water and dry.

Method of Pollák-Joël[11]: Use 2 separate films and stain them differently. One stain brings out the structure of the entire spermatozoon and the second affords better visualization of the cell structure. Thus the stains complement each other.

1. Stain I—hemalum-eosin (for visualizing spermatozoal structure).
   (a) Fix for 2 min. with methyl alcohol and then rinse in water.
   (b) Stain for 20 min. with hemalum.*
   (c) Steep in running water for 30 min. with fresh hemalum, rinse for 10 min. in water, stain for contrast for 3 min. with 3% alcoholic eosin solution.
   (d) Differentiate in an alcohol sequence of 70, 90, and 100%.
   (e) Clear in carbolxylene and embed in Canada balsam under a cover glass.

2. Stain II—azure-eosin (for the cellular structure).
   (a) Fix for 2 min. with methyl alcohol.
   (b) Stain for 20 min. with a diluted Giemsa stain.
   (c) Rinse in distilled water and embed in Canada balsam under a cover glass.

The staining solution is prepared fresh each time; to 5 ml. distilled water add 10 drops of Giemsa stain.

Examination for spermatozoa in seminal stains

If the stain is such that a fragment can be removed with the point of a knife, the examination is fairly easy. Remove a portion of the scaly stain with a knife point and place it on a glass slide on which has previously been placed a drop of distilled water. Allow the stain to soak in the water for several hours. Keep the specimen moist under a bell jar or in a large closed Petri dish. Separate the scales very cautiously with a teasing needle, allow to dry, fix in methyl alcohol, and stain with dilute Giemsa stain (1 drop in each ml. neutral distilled water) for 30 min., repeating the stain for an additional 30 min. if necessary. If restaining is attempted, dilute fresh stain. Wash gently with distilled water, stand the slide on end, and allow to dry. Examine for spermatozoa under the oil immersion objective.

If the stain is on unstarched cotton or linen cloth the finding of spermatozoa presents a much more difficult problem. Select a thread of the cloth near the center of the stain; select the side of the cloth which contains the more seminal fluid. Place a thread from the dry stain on a glass slide in a drop of distilled water. Make many such preparations. Each specimen is allowed to soak in the water for 2-24 hr. Provision must be made to prevent drying of the water during this time.

At the end of the digestion period tease the fibrils apart **very cautiously** with fine pointed needles. Take care not to break the spermatozoa. Continue with the staining process just described.

The cloth itself may be stained according to the **method of Baecchi.**[12] A piece of the cloth containing the stain is cut 1 cm. square and placed in 1% acid fuchsin or methylene blue solution. It is then washed in 1% hydrochloric acid, after which it is dried in the air or dehydrated in absolute alcohol. Next it is cleared in xylol and then mounted in Canada balsam. If the spots are not fresh, they are placed for ½-24 hr. in 20-30% ammonium hydroxide solution and then in distilled water preliminary to the staining process.

Hektoen and Rukstinat[13] describe a **method** of making a stained specimen from spots of spermatozoa on cloth. Their method makes use of Mallory-Wright chloride of iron-hematoxylin stain.

1. Soak the stained cloth in 1% ammonium hydroxide solution in water for 12-24 hr.
2. Select a single thread and stain 2 min. in 5% aqueous solution of erythrosin.
3. Wash quickly in distilled water.
4. Stain with 10% aqueous solution of ferric chloride 2 min.
5. Transfer directly to 2% aqueous solution of hematoxylin for 2 min.
6. Wash quickly in distilled water.
7. Transfer to 0.5% aqueous ferric chloride and tease out fiber to its finest shreds. Remove from this solution when threads are reddish pink or light brown.
8. Wash in distilled water quickly.
9. Dehydrate in absolute alcohol.
10. Clear in creosote.
11. Mount in balsam.

Better results are obtained if the differentiation is carried out slowly in 0.5% ferric chloride solution than in stronger solutions. Boiling the cloth for 1 min. in water after soaking in ammonia solution helps preserve the tails. When the stain takes well, the head of the spermatozoon is stained dark purple to black in the posterior two thirds, whereas the anterior third is pink, and the tail is pink to lavender. The connecting piece frequently is evident. The threads of the cloth may stain more or less pinkish.

---

*Hemalum is similar to hematoxylin but not identical. It is a 2% solution of crystalline hematin in 95% aqueous solution of $KAl(SO_4)_2 \cdot 12 H_2O$, 100 ml.

Weisman[14] refers directly to the technic of Hankin[15] and Windsor.[16] This is a special technic for warm climates. Hankin examined the suspected stains directly on the cloth, after first fixing the material with a cellular fixative, then adding dilute sulfuric acid, and finally staining the material with gentian violet. Windsor fixed the cloth in Müller solution and then stained it. Williams suggested the special Wollschwarz stain. Soak and scrape the semen-stained cloth, obtaining a turbid suspension. Centrifuge the soakings. In an old specimen some of the tails will be missing or bent or abnormally twisted. Care must be taken not to confuse the sperm heads with spores, pus cells, or artifacts.

Florence test for identification of semen

Reagent:

Potassium iodide	1.65 gm.
Iodine	2.54 gm.
Distilled water	30 ml.

Rub up the iodine and the potassium iodide in a mortar and then add the water. Filter before using.

Procedure:

1. Remove a minute fragment of the stained specimen by means of a pair of fine-pointed forceps and sharp-pointed scissors.
2. Transfer to a slide.
3. Treat with a small drop of distilled water.
4. Allow to soak for 1-2 min.
5. Add a small drop of the reagent to it in such a way that the 2 drops of fluid come in contact at their edges and then cover immediately with a cover glass.
6. Examine microscopically for seminal crystals. These look like the hemin crystals obtained with the Teichmann test for blood (Fig. 681).

Weisman states that a positive reaction is not significant since other body fluids give such results with this test. Our own experience confirms this statement. A negative test, however, informs the investigator that the suspected substance is not semen, and this is the only value of the Florence test.

Peltzer[13] uses the following technic for the Florence method:

1. Moisten the suspected spots with hydrogen peroxide. If semen is present, much foaming occurs.
2. Centrifuge substance.
3. Place on slide and stain with 2% aqueous eosin.

If positive, long lancelike crystals appear. The addition of I-KI solution to the slide colors the crystals brown. The crystals disappear and are recrystallized by the addition of more I-KI solution. The presence of Florence crystals denotes the presence of body fluids, possibly semen.

Puranen test

Puranen[18, 19] and Tarsitano[20] advocated a microchemical method for identification of spermatozoa. Naphthol yellow sulfur in aqueous solution reacts differently with human semen at neutral and slightly alkaline reactions. A positive reaction is denoted by formation of microcrystals, which are characteristically large, have a strong double refraction, and are of a definite orange hue.

Niederland test[21]

This test employs dilute sulfuric acid. When added to a suspected specimen, the test is always positive in the presence of semen, but this test is also positive with practically all other body secretions. Weisman states that its only value lies in the fact that, when the test is negative, further search for spermatozoa can be abandoned. The crystals formed are probably sulfates of calcium and other salts found in semen and body fluids.

Marcille method[22]

This is nothing more than the Florence test coupled with the addition of Gram-eosin staining of the centrifuged precipitate after maceration of the specimen in physiologic saline solution.

Borgarius test

This test is similar to the Florence test, except that phosphomolybdic acid solution instead of the I-KI solution is used to precipitate crystals. The crystals obtained by this technic are characteristic, but they are also found with other body fluids.

AuI_3 (auric iodide) test

Villamil[23] has shown that solutions of AuI_3 give characteristic crystals with diluted semen as well as with solutions of spots and stains produced by semen. The crystals are distinct. He considers this reaction to be more sensitive than that obtained by most other microcrystalline tests.

Test for hydrogen ion concentration[24]

If a drop of distilled water is added to suspected semen and well mixed, the hydrogen ion concentration of the solution when tested with Nitrazine paper and compared with a colorimetric chart will give evidence of definite alkalinity.

Fluorescence or ultraviolet light test

Ito[25] first demonstrated that semen stains give a characteristic color effect under ultraviolet light. He obtained this same effect with other tissues and described its use in forensic medicine.

Simonin[26] showed that dried sperm gives a brilliant characteristic fluorescence under ultraviolet light but stated that other organic liquids also give some fluorescence, so that the test is probably not specific. Husson[27] reported that seminal spots, irrespective of spermatozoa or azoospermia or the age of the spot, show a characteristic fluorescence in ultraviolet rays between 4200 and 4900 Å.

Microchemical identification of seminal fluid—acid phosphatase method

Determination of acid phosphatase activity affords an excellent means for specific microchemical identification of seminal fluid and seminal stains. This procedure employs a principle postulated by Ove Riisfelt of Denmark in 1946.[28] It is of definite medicolegal value in the identification of seminal fluid as an adjunct to the demonstration of spermatozoa, but it is of particular value in cases in which spermatozoa cannot be demonstrated in the specimen.

Kaye found that male ejaculate produces a very high acid phosphatase activity in comparison with the very low acid phosphatase activity of the other body fluids (saliva, perspiration, urine, etc.) and the common vegetable and fruit juice stains. The differences are so marked and definite that it leaves little room for doubtful interpretation of the results. The average seminal fluid contains approximately 2500 King-Armstrong units of acid phosphatase/ml., the upper limits ranging to 3500 King-Armstrong units and the lower to above 500 units. Ejaculates in cases of aspermia give comparable high results.

Semen is characteristic in that it gives these high values, whereas other body fluids give values of much less than 5 King-Armstrong units/ml. The enzyme is resistant to all known body fluids including vaginal secretion; it might, however, be inhibited by vaginal disinfectants and contraceptives. Seminal fluid aged 2 wk. in a condom-type contraceptive showed no appreciable loss of acid phosphatase activity. Known seminal stains proved to be strongly positive even after many months, 6 or more.

The materials listed in the accompanying outline contain less than 5 King-Armstrong units of acid phosphatase/ml. concentrated pure substance and in the cases of vaginal fluids, perspiration, feces, nasal discharge, and pus, per unit sq.cm. saturated control cloth.[29]

I. Body fluids
    Vaginal fluids
    Urine
    Blood (serum) (in carcinoma of prostate with metastases, this value may be appreciably increased)
    Blood (whole)
    Blood (menstrual)
    Saliva
    Perspiration
    Pus
    Nasal discharge
    Gastric juice
    Feces
    Rectal smears
II. Food stains
    Tea
    Coffee
    Egg white
    Egg yolk
    Vegetable juice (V-8)
    Orange juice
    Prune juice
    Beer
    Milk
    Cream
    Mushrooms
    Corn
    Alkaloids, such as quinine, atropine, and procaine
    Meat gravy
    French dressing
    Beet juice
    Custard
    Starch
    Mayonnaise
    Chop suey
    Soapy water (Ivory)
    Onions
    Albumin
    Choline

Walker acid phosphatase test for identification of seminal fluid[30]

Principle: The portion of the garment to be tested is immersed in a bath at pH 5.0 containing alpha-naphthyl phosphate as a substrate and a suitable diazonium salt. The acid phosphatase of the semen acts on the phosphate ester to liberate alpha-naphthol. This immediately reacts with the diazonium salt to form a brilliant orange-red azo pigment, which is insoluble under the conditions of the test, and which becomes adherent to the background at the site of acid phosphatase activity.

Substrate-reagent bath:

1. Dissolve 23 gm. sodium chloride, 0.5 ml. glacial acetic acid, and 2 gm. sodium acetate trihydrate in 90 ml. distilled water.
2. Add 1 ml. 1% aerosol containing a suspension of 30 mg. anthraquinone-1-diazonium chloride (III) and 50 mg. calcium-1-naphthyl phosphate.
3. Dissolve the aerosol in warm water without shaking.

Preparation of anthraquinone-1-diazonium chloride (III):

1. Dissolve 10 gm. 1-amine anthraquinone (Eastman technical grade) in 85% sulfuric acid and pour into a large volume of water. Collect the precipitate with suction and wash free from acid with water.

2. Treat the wet product with 20 ml. concentrated hydrochloric acid to form a grayish white crystalline sludge.
3. Diazotize at 30°-40° C. by running an equivalent of sodium nitrite, 3.2 gm. in 50 ml. water under the surface with stirring.
4. Pour the reaction mixture into 10 times its volume of water at 70°-80° C.
5. Add 0.5 gm. sodium nitrite.
6. Filter rapidly.
7. Add sodium chloride to salt out the diazonium chloride in shiny, yellow platelets.
8. Collect the crystals, wash with cold water, alcohol, and ether, and dry.
9. Protect from light and store at room temperature, or in a refrigerator. Refrigerated they are stable at least 18 mo.

The diazonium compound is available commercially as Naphthanil Diazo Red AL. It contains 5% zinc chloride and 12% aluminum sulfate. The metal ions completely inhibit acid phosphatase present in the cell nuclei of liver and kidney, whereas the cytoplasmic acid phosphatase is altered slightly. This finding is suggestive of a third variety of acid phosphatase present in cell nuclei.

Preparation of calcium alpha- or beta-naphthyl phosphate*:

1. Dissolve 14.4 gm. alpha- or beta-naphthol in 15 ml. dry pyridine.*
2. Dissolve 15.3 gm. phosphorus oxychloride solution in 10 ml. dry pyridine.
3. Add the phosphorus oxychloride solution drop by drop, or the entire material will be lost.
4. Add the naphthol solution in portions to the phosphorus oxychloride solution. Heat is developed, and a white precipitate separates as a sludge.
5. Allow to stand at room temperature for 10 min.
6. Cool and add in portions to a solution of 30 gm. calcium acetate in 200 ml. distilled water and 100 gm. ice. An oily material separates which slowly dissolves and comes out as a white precipitate.
7. Add 150 ml. alcohol.
8. Collect the white precipitate with the aid of suction.
9. Wash with 95% alcohol and ether and dry.

Procedure:

Immerse the garment to be tested in a substrate reagent bath. If acid phosphatase is present, a brilliant orange-red pigment will appear and adhere to the background at the site of acid phosphatase activity. The phosphatase activity of a fresh, dry seminal stain is so intense that within 30 sec. a distinctive, visible coloration occurs, and within 2 min. the test is complete.

When the semen is mixed with blood, as occurs in rape, an interesting color change occurs. The blood turns to a dirty brownish gray when immersed in the substrate bath. Wherever semen is present, this color is gradually replaced by the orange red of the phosphatase-catalyzed pigment. Bloody stains should be developed longer than others, so that the pigment formed by the semen may be visible above the background.

If the suspected stain occurs on an unfavorable background, such as a red wool dress, the red pigment of the developed test is not clearly visible. In this case, and in any case in which it is not desirable to apply the reagents directly to the specimen, a portion of the phosphatase of the stain may be transferred to a white filter paper, and its activity can be detected thereon.

Moisten the filter paper, press it firmly against the suspected area for several minutes, and then immerse the paper in the substrate-reagent bath. Some of the acid phosphatase of the stain on the garment will have diffused into the filter paper sufficiently to cause a print that can be developed.

If desired, place a small portion of the suspected material on dry filter paper. Moisten with a drop of water. Development of the paper will show a red rosette if semen is present.

Even if the fabric is tested directly with the substrate-reagent mixture, the procedure does not interfere with the subsequent microscopic search for spermatozoa. The seminal fluid takes on a peach-pink color, but the spermatozoa are not colored, for they do not contain sufficient acid phosphatase. If the specimen is then stained with carbolfuchsin, the spermatozoa stain with the dye. The test serves the double function of demonstrating high acid phosphatase activity and at the same time indicating where a search for spermatozoa is likely to be successful. The phosphatase activity is largely concentrated at the periphery of the stain. Spermatozoa are more plentiful in the central area, where they may be demonstrated microscopically.

Phosphatabs-Acid* may be used in place of the Walker test.

1. Cut cloth ¼ in. × ½ in., put in a 50 ml. beaker, and add 10 ml. distilled water.
2. After 30 min. remove the cloth, stir the liquid in the beaker, and allow the particles to settle.
3. Place 4 drops of the clear supernatant liquid in one of the wells in the Warner-Chilcott kit.
4. Add a silver foil tablet, crush with a glass rod, and allow to remain at 20° C. for 22 min. (time varies with temperature).
5. Add a gold foil tablet and crush.

An immediate dark purple color indicates a high acid phosphatase content.

Precipitin test for identification of human seminal stains

Precipitin tests for the differentiation of semen of human and animal origin can be made by carrying out the test described below.

---

*Reagent pyridine contains enough water to decompose the phosphorus oxychloride extensively. Dry by refluxing with anhydrous barium carbonate for several days, distill, and store with sodium hydroxide pellets.

*Warner-Lambert, Morris Plains, N. J.

In the examination of stains in cases of suspected rape, finding spermatozoa is by far the most conclusive evidence of the presence of semen. The procedure just described for the identification of seminal fluid, however, is of value in proof of the presence of semen especially in cases of aspermia or in those cases in which complete spermatozoa cannot be identified (twisted tails, etc.).

The injection of rabbits with the semen of man, swine, bull, or horse induces the formation of specific precipitins for the homologous fluid.[31-36] In most cases precipitins develop also for the homologous blood serum, as already known. Extracts of human spermatozoa in salt solution appear to give the same result as the seminal fluid. Seminal precipitin reaction reveals the presence in semen of a substance or substances peculiar to it, and consequently the reaction may be of value in studying the nature of suspected spots and stains.

Precipitin for identification of human semen is made by injecting rabbits intramuscularly 4 or 5 times at intervals of 3-4 days with increasing quantities of human seminal fluid. The first injection is 2 ml., the next 4 ml., each successive injection being 2 ml. more than the preceding one. Six or 8 days after the last injection the animals are bled, and the blood is collected in sterile 50 ml. Rockefeller tubes with cork stoppers. After the blood has clotted, the clot is shaken loose, and the tube is centrifuged at 1500 r.p.m. for 20 min. to separate the serum. The serum is removed with all sterile precautions and placed in another sterile test tube. Serum precipitates are removed from the rabbit's blood serum by mixing it with equal parts of a 1:200 dilution of human blood serum in saline. Allow the mixture to stand at room temperature for 1 hr. and then place in a refrigerator overnight. Centrifuge it at high speed for sufficient time to sediment the precipitate formed from the mixture of the rabbit and human serums. Use the supernatant serum for precipitin tests to identify seminal fluid stains.

Procedure:

1. Extract the suspected seminal stain in physiologic saline for 4-8 hr., using very small amounts of saline.
2. Concentrate the extract slightly and then centrifuge to remove any sediment that may be present.
3. Remove the supernatant fluid, placing it in a clean, dry test tube.
4. Dilute with physiologic saline until, upon shaking, the amount of foam indicates a 1:1000 dilution. Be sure the diluted extract is neutral.
5. Place 0.1 ml. antisemen precipitin serum in the bottom of a small heavy walled capillary tube.
6. Allow the extract of suspected seminal fluid stain to run down the side of the tube so that it forms a layer above the serum but does not mix with it.
7. Allow to stand at room temperature for 1 hr., observing the reaction at 10-15 min. intervals.
8. At the same time run a control test using an extract of an unstained portion of the cloth on which the seminal stain was found.

A positive reaction is indicated by a white precipitate at the point of contact between the 2 fluids. This reaction is like the reaction in the precipitin test for the identification of human blood (pp. 1613ff).

EVIDENCE IN SUSPECTED SEXUAL ASSAULT

In rape of a child or virgin there is usually ample evidence in the form of hemorrhage and laceration of tissue. Further evidence may be obtained by looking for traces of semen either on the external portions or in the vagina. The length of time that spermatozoa may be found in the vagina after an alleged assault is varied, some reporting that spermatozoa are found as long as 2 days after intercourse. Although this is true in rape cases without death from the assault, in those cases in which death has occurred, spermatozoa apparently may not live very long in the vagina.

In the assault cases spermatozoa may be found on the clothing by one or more of the tests already described. In addition to the examination of the victim and her clothing, the clothing should be further examined for fibers of the assailant's apparel. One should also examine the clothing of the victim and suspected persons for evidence such as grass, fibers, soil, etc., which may be related to the locality where the crime was committed. In many cases there will be found scratches and skin changes due to the fingernails of the assailant or the victim. The suspected person should be carefully examined, particularly for skin, hair, and cosmetics, which may be identified as coming from the victim. The scrapings of the nails of the victim should also be examined.

The technic of examination of the victim's vagina for spermatozoa is as follows:

1. Gently spray physiologic saline solution over the vagina and perineum of the victim, collect the washings in a clean dish placed under the patient, and then examine.
2. Gently wash the vaginal wall with a small amount of saline solution injected into the vagina with a clean glass syringe and rubber bulb such as is used in blood cell washing in serologic work.
3. Withdraw the contents of the vagina with the same syringe or pipet and after centrifugation, examine microscopically.
4. Also wash the suspect with saline solution sprayed over the entire penis, collect, centrifuge, and examine the sediment microscopically.

Identification of blood group of semen is described on p. 1543.

Chapter 117

Chemical analysis of water and milk

CHEMICAL ANALYSIS OF WATER

For the chemical analysis of water, a liberal sample of fresh water should be submitted to the laboratory. This sample, at least 1 gal., should be representative of the entire water supply which is to be examined. Procedures described here are largely those recommended by the United States Army and the American Public Health Association.*

Most of the equivalents in water chemistry calculations are computed on a parts per million basis. Suggestions for interpreting the quality of the water are given in Table 369.

Turbidity

Turbidity of water is due to suspended matter in the water. To determine turbidity of the specimen, compare with standard suspensions or standard disks ranging from 5 to 100 p.p.m. Report turbidity as less than 5 p.p.m. or between 10 and 15 p.p.m. or as 5 p.p.m., etc.

Standard suspensions:

1. Place 5 gm. Fuller's earth in 1 L. distilled water.
2. Agitate intermittently for 1 hr. and allow to stand for 24 hr.
3. Withdraw the supernatant liquid without disturbing the sediment.
4. Dilute successive portions of the sediment with distilled water to prepare the various standards ranging from 5-100 p.p.m. Use a candle turbidimeter for standardization.

Standard disks: Permanent turbidity standard disks are available from most large chemical supply houses. The disks may be used in place of the turbidity standard suspensions.

Combination water color and turbidity test sets, United States Geological Survey Standard, may be purchased from any large chemical supply company.

Procedure: The standard unit of turbidity is that produced by 1 p.p.m. silica in distilled water.

1. Thoroughly shake the water to be tested. Pour a portion of it into a 125 ml. glass-stoppered bottle and shake.
2. Shake the standard suspensions and compare in a dark box turbidimeter. Record turbidity in p.p.m. Permanent standard disks may be used in place of the standard suspensions. If the Jackson candle method is used, report in turbidity units.

Color

Color disks, calibrated from a platinum-cobalt color scale, may be purchased from any large chemical supply house.

1. Place the glass disks on the end of a metal tube containing distilled water.
2. Place the water to be tested in a second tube.
3. Compare and record the color number.

Odor

Odor of water specimens may be described as musty, aromatic, fishy, moldy, etc., and as negative, faint, moderate, and strong. If an odor is detectable in the sample, the odor concentration must be determined.

1. Place 200 ml. sample in a 500 ml. flask.
2. Add 200 ml. water free of odor. This is a 1:2 dilution.
3. Mix without unduly exposing to the air. Do not agitate unnecessarily.
4. Add 200 ml. this dilution to 200 ml. water free of odor in another 500 ml. flask. This is a 1:4 dilution.
5. Mix and continue with the dilutions to obtain 1:8, 1:16, 1:32, and further dilutions, until the second dilution beyond which the odor of the specimen is no longer detectable. If the odor is very strong, omit some of the lower dilutions.
6. Shake and examine each flask in order, beginning with the strongest dilution and proceeding to the weakest until an odor is just detectable in one of the flasks. This is the

---

*Standard methods for the examination of water and waste water, ed. 11, 1960, American Public Health Association.

threshold odor and is recorded as the odor concentration.

7. Report the **odor concentration** as the reciprocal of the dilution; e.g., 1, 2, 4, 8.

Hydrogen ion concentration

The determination of pH may be done with pHydrion or Nitrazine test papers or with a pH meter.

Total residue—loss on ignition

1. Shake the sample thoroughly but do not filter.
2. Place 100 ml. of sample in a weighed platinum dish.
3. Evaporate on a water or steam bath.
4. Dry the residue at 103°-105° C. for 1 hr.
5. Weigh the crucible and contents. Subtract the weight of the platinum dish from the total weight to obtain the total solids or residue on evaporation. This gives the residue at 103° C.

Loss on ignition and fixed residue:

1. Ignite the residue in the platinum dish at low red heat. Note any significant change in color or odor.
2. Allow the dish to cool.
3. Moisten the residue with distilled water, then dry at 103° C., cool, and weigh.
4. Subtract this figure from the weight recorded as "residue at 103° C." This figure represents the **loss on ignition.** The weight of the residue is recorded as the **fixed residue.**

Alkalinity

Reagents:

1. Phenolphthalein indicator.
    - (a) Dissolve 5 gm. phenolphthalein in 1 L. 50% alcohol.
    - (b) Neutralize with N/50 sodium hydroxide.

The alcohol should be diluted with distilled water which has been boiled and cooled quickly.

2. Methyl orange indicator.
    - (a) Dissolve 5 gm. methyl orange in 1 L. distilled water. Keep the solution in the dark.

Procedure with phenolphthalein:

1. Add 4 drops phenolphthalein indicator to 50 or 100 ml. water sample in a white porcelain casserole or in an Erlenmeyer flask over a white surface. If the solution becomes colored, hydroxide or normal carbonate is present.
2. Titrate with N/50 sulfuric acid from a buret until the color disappears. This is the end point.

Calculation: Ml. N/50 sulfuric acid used × 20 = phenolphthalein alkalinity in p.p.m. calcium carbonate if 50 ml. of water sample were used. If 100 ml. were used, multiply by 10 instead of by 20.

Procedure with methyl orange:

1. Use 2 drops methyl orange indicator to 50 or 100 ml. water sample. The solution develops a yellow color in the presence of hydroxide, normal carbonate, or bicarbonate.
2. Titrate with N/50 sulfuric acid to the first faint pink color, i.e., until the yellow color is no longer a pure yellow.

Calculate as for phenolphthalein.

Total hardness (soap method)

Reagents:

1. Stock standard soap solution.
    - (a) Dissolve 100 gm. pure powdered castile soap in 1 L. 80% alcohol.
    - (b) Allow to stand overnight.
    - (c) Decant.

This solution is approximately 10 times stronger than needed for the working solution.

2. Working soap solution.
    - (a) Titrate the standard soap solution against a standard calcium chloride solution, 1 ml. of which is equivalent to 1 mg. calcium carbonate.
    - (b) Dilute the stock standard solution with 80% alcohol in accordance with the titer so that 1 ml. is equivalent to 1 ml. standard calcium chloride solution.
3. Standard calcium chloride solution.
    - (a) Dissolve 0.5 gm. pure calcite with a small amount of dilute hydrochloride acid.
    - (b) Wash down with carbon dioxide-free distilled water and neutralize with ammonium hydroxide.
    - (c) Add a small amount of ammonium hydroxide to produce slight alkalinity.
    - (d) Dilute with carbon dioxide-free distilled water to 500 ml.; 1 ml. is equivalent to 1 mg. of calcium carbonate.

Procedure:

1. Place 50 ml. water to be examined in an 8 oz. glass-stoppered bottle.
2. Add from a buret the working standard soap solution, using small amounts (0.5 ml.) at a time.
3. Shake vigorously after each addition.
4. Continue adding the soap solution until a strong permanent lather, which stands 5 min. with the bottle laid on its side, is secured. This is the end point. When approaching the end point, reduce the addition of the soap solution to 0.1-0.2 ml. at a time.

A blank titration should be made using distilled water against the soap solution. The result of this titration is referred to as the **lather factor.**

Calculations: Subtract the lather factor from the titration results and multiply by 20 to obtain the total hardness in terms of calcium carbonate in p.p.m.

If a hardness test requires more than 15 ml. soap solution, dilute an aliquot of the water to 50 ml. with carbon dioxide-free distilled water so that the final lather point will be less than 15 ml. Deduct the lather factor (blank) and multiply the result by 20 and then by the dilution factor to obtain the correct hardness value.

If the water is acid, render it neutral to methyl orange using N/50 sodium carbonate solution before determining the total hardness.

Total iron

Reagents:

1. Standard ferric iron solution (1 ml. = 0.1 mg. Fe).
    - (a) Dissolve 0.7022 gm. of crystallized ferrous ammonium sulfate ($FeSO_4(NH_4)_2SO_4 \cdot 6H_2O$) in 50 ml. distilled water and 20 ml. concentrated sulfuric acid.
    - (b) Warm the solution and add potassium

permanganate solution until the iron is completely oxidized. Dilute to 1 L. with distilled water.

2. Dilute hydrochloric acid.
   (a) To 3 vol. distilled water add 1 vol. concentrated hydrochloric acid, specific gravity 1.2. This is an approximate 3N solution.
3. Potassium permanganate solution.
   (a) Dissolve 6.3 gm. of potassium permanganate in distilled water in a liter volumetric flask and dilute to 1 L. with distilled water. This is an approximate N/5 solution.
4. Potassium or ammonium thiocyanate.
   (a) Dissolve 2 gm. potassium or ammonium thiocyanate in distilled water in a 100 ml. volumetric flask and dilute to 100 ml. with distilled water.
5. Hydrochloric acid.
   (a) Concentrated hydrochloric acid free from iron.
6. Nitric acid.
   (a) Nitric acid, specific gravity 1.42, free from iron.
7. Nitric acid.
   (a) Nitric acid, specific gravity 1.195. Use 382 ml. this concentrated nitric acid/L. solution. This is approximately a 6N solution.

Procedure:

1. Evaporate 100 ml. (or less) of the sample to dryness. With silt-bearing samples of water the quantity of iron is sometimes so great that it is necessary to use as little as 10 ml. sample. In such cases add 5-10 ml. concentrated hydrochloric acid to the sample. If the sample contains much organic matter, destroy

Table 369. *Safe limits of chemical impurities in drinking water*

Impurity	*Desirable*	*Limit*
	Less than:	Not greater than:
Odor	None	Free from odor
Color	5	20
Turbidity	5	10
Ammonia nitrogen	0.04	0.9
Albuminoid nitrogen	0.05	0.1
Nitrite nitrogen	None	0.7
Nitrate nitrogen		0.5
Oxygen consuming power	1	2
Chlorides	50	250
Free residual chlorine	At least 0.2 (at tap)	Must not cause objectionable odor or taste
Total hardness (as $CaCO_3$)		250 10.2
Noncarbonate hardness	Relative to total hardness	
Acidity	Free mineral acids must be absent	
Total solids		500
Loss on ignition	Is a relative not a precise determination Represents not only organic matter but volatile decomposition products from carbonates, nitrates, and other components of residue	
Alkalinity (as $CaCO_3$)	It is desirable to have total alkalinity below 400 p.p.m.; however, alkalinity usually of no significance unless there is phenolphthalein alkalinity In case of nontreated waters, phenolphthalein alkalinity should not be greater than half of total alkalinity In chemically treated waters, phenolphthalein alkalinity (calculated as $CaCO_3$) should not be greater than 15 mg./L. plus 0.4 times total alkalinity; in case of waters softened by lime soda process, total alkalinity produced should not exceed hardness by more than 35 p.p.m. (calculated as $CaCO_3$)	
Minerals		
Silica		250
Magnesium	30	100
Calcium	Unimportant	50
Iron and manganese	0.1	0.3
Sulfates		250
Sodium and potassium	0	50
Aluminum		0.3
Toxic ions		
Arsenic	None	0.05
Lead	None	0.1

Zinc	None	15.0
Selenium	None	0.05
Barium	None	None
Molecularly dehydrated phosphates (chemical treatment)	Less than 10.0	10.0

the organic matter by ignition so that the iron dissolves only with difficulty.

2. Heat the dish to drive off excess of acid if the residue was not ignited.
3. Cool and add 0.8-1 ml. of 3N hydrochloric acid.
4. Warm on the water bath taking care to avoid evaporation to dryness by adding small quantities of distilled water from time to time.
5. Rinse the hot solution into a 50 ml. Nessler tube, filtering if necessary.
6. Add 1-2 drops of potassium permanganate solution. If the color of permanganate does not persist for at least 5 min., add more permanganate solution, drop by drop.
7. Cool and dilute to the mark with distilled water.
8. Prepare iron standards by placing in matched Nessler tubes 0.05 ml., 0.1 ml., etc., up to 4 ml. (or more) of standard iron solution covering the range of standards required for the determination at hand. Dilute each to about 40 ml. with distilled water.
9. Add 0.5 ml. 3N hydrochloric acid and 1 or 2 drops potassium permanganate solution to each tube. Dilute to the mark.
10. Add 5 ml. thiocyanate solution to the unknown and to the standards. Mix each tube thoroughly and compare immediately.
11. If the sample is low in organic matter, boil 50 ml. with 5 ml. 6N nitric acid for 5 min., add 3 drops of permanganate solution, and cool. Add 5 ml. thiocyanate solution and compare immediately with standards prepared from the standard iron solution with 6N nitric acid instead of with 3N hydrochloric acid.

Silica—Gravimetric method

1. Evaporate 500 ml. sample in a platinum crucible. When the residue is nearly dry add 1 ml. dilute hydrochloric acid (1:2), moisten the sides of the dish, and evaporate to dryness. If much organic matter is present, char in a radiator.
2. Add a few drops hydrochloric acid, dissolve in hot water, and filter.
3. Ignite and weigh the insoluble residue.
4. Add 2 drops concentrated sulfuric acid and a little hydrofluoric acid, volatilize the acids, ignite, and weigh again.
5. Report the loss in weight as silica (SiO_2). A weight of nonvolatile matter exceeding 0.5 mg. should be analyzed.

Interpretation of chemical analysis of drinking water

In Table 369 are given the ordinarily considered safe limits of impurities in drinking water of good quality from a **chemical** standpoint. The results are expressed in **p.p.m.** Drinking water must never be considered safe, however, without a satisfactory **bacteriologic** analysis.

CHEMICAL ANALYSIS OF MILK

Reagents

N/10 sodium hydroxide:

1. To about 50 ml. distilled water in a 100 ml. volumetric flask add 10 ml. N/1 sodium hydroxide solution.
2. Dilute to 100 ml. with distilled water.

Benedict volumetric solution:

1. The method of preparing and titrating Benedict volumetric solution is found on pp. 1813ff.

Bogg reagent for protein:

1. Phosphotungstic acid	25 gm.
Distilled water	125 ml.
2. Concentrated hydrochloric acid	25 ml.
Distilled water	125 ml.

When the phosphotungstic acid is completely dissolved, mix the 2 solutions. This reagent is quite stable if kept in a dark glass bottle.

Alcoholic phenolphthalein, 1%:

1. Dissolve 1 gm. phenolphthalein in 100 ml. 95% alcohol.

Milk-fat mixture:

1. Equal parts of concentrated hydrochloric acid and amyl alcohol.*

Sulfuric acid, 75%:

Distilled water	25 ml.
Sulfuric acid, c.p., concentrated	75 ml.

Caution: Add the sulfuric acid slowly to the distilled water in a Pyrex flask, cooling it under running tap water.

Reaction

Usually pHydrion or Nitrazine paper is sufficient. If a more detailed analysis is required, the following procedure may be used.

Procedure:

1. Make a preliminary determination of the reaction with test paper (litmus, pHydrion, or Nitrazine). If the milk is alkaline, the degree of alkalinity is determined by titration with hydrochloric acid; if it is acid, titrate with sodium hydroxide.
2. Place 10 ml. milk in a casserole.
3. Add about 50 ml. distilled water, and 2 drops 1% alcoholic phenolphthalein.
4. Add the N/10 sodium hydroxide (or HCl) drop by drop from the buret, stirring constantly, until the first permanent pink color is obtained. This is the end point.
5. Read from the buret the number of ml. N/10 sodium hydroxide (or HCl) used. Multiply this number by 10 to obtain the degree of acidity.

Example: If 1.5 ml. N/10 sodium hydroxide were used to neutralize 10 ml. milk, the degree of acidity is 10 × 1.5 or 15°. The degree of acidity is equal to the number of ml. N/10 sodium hydroxide required to neutralize 100 ml. milk. An acidity of 15-25° may be observed within 6 hr. after milking; 48 hr. after, the acidity is generally between 100 and 125. This applies more to cow's milk than to human milk.

---

*Make fresh each day.

Specific gravity

Take the specific gravity with a urinometer. If a bacteriologic examination is to be made, transfer enough milk to a sterile container for that purpose before the urinometer is admitted. Normal specific gravity is 1.028-1.032. The milk should be cooled to 60° F. before taking the specific gravity.

Color

The normal color of human milk is pale bluish white.

Lactose

1. Fill a buret, graduated in 0.1 ml., with milk. Place 25 ml. Benedict volumetric solution in a casserole. Add 5-10 gm. sodium carbonate and a pinch of powdered pumice.
2. Bring the solution in the casserole to a boil and continue boiling until the end point is reached.
3. Add the milk to the Benedict solution in the casserole, a drop at a time, stirring after the addition of each drop. The milk should be added very slowly to the solution in the casserole, and some time should be allowed to pass before the addition of each drop, as reduction of the copper takes place very slowly.
4. Continue adding the milk and boiling until the blue color of the copper sulfate has entirely disappeared and is replaced by a gray color. This is the end point.
5. Read from the buret the number of ml. milk used; 25 ml. Benedict volumetric solution are reduced by 67 mg. lactose.

The number of ml. milk that were used to bring about the reduction of the copper sulfate, therefore, contained 67 mg. lactose. From this figure, the number of gm. lactose/100 ml. milk, or the percentage of lactose, can be computed according to the following example.

Example: It required 4.0 ml. milk to reduce 25 ml. Benedict volumetric solution. 4.0 ml. milk, therefore, contain 67 mg. lactose. 1 ml. milk contains 67 divided by 4, or 16.75 mg. lactose. 100 ml. milk contain 16.75 × 100, or 1675 mg. lactose. 1675 mg. = 1.675 gm. (1675 ÷ 1000). The percentage of lactose in the milk is therefore 1.675.

Normal percentage of lactose in human milk is 6-7; in cow's milk, 4.3-7.

Fat—Leffmann-Beam method

1. Use the modified Babcock tube, made for 5 ml. quantities of milk. Place 5 ml. milk in the Babcock tube.
2. Add 1 ml. milk-fat mixture. Mix thoroughly by rotating.
3. Add 75% sulfuric acid to the mixture, mixing thoroughly as the acid is added, until the meniscus stands at the 0 mark on the stem. The solution becomes quite hot and must be centrifuged before it cools.
4. Centrifuge immediately at 1000 r.p.m. for 3 min. The fat will be separated and may be read in percentage on the stem. Each mark on the stem is 0.2% of fat.
5. Read the percentage of fat from the stem and record. Read from the top of the meniscus.

Normal percentage of fat in human milk is 3-5; in cow's milk it is 3.5-4.

Protein—Bogg modification of Esbach method

1. If human milk is to be examined, dilute, accurately, 1:10 with distilled water. If cow's milk is being tested, dilute 1:20 with distilled water. Place the milk in an Esbach tube until the bottom of the meniscus stands at mark U.
2. Fill to mark R with Bogg reagent (p. 2082).
3. Mix by inverting several times, taking care to prevent the formation of air bubbles.
4. Allow to stand in an upright position for 24 hr.
5. Read from the graduation marks the number of gm. of dried protein/1000 ml. or the height of the coagulum. Divide this result by 10 to obtain the number of gm. in 100 ml. Multiply this by the dilution of the milk. This gives the number of gm. protein in 100 ml. or the percentage.

Example: Human milk was used, and the dilution was 1:10. The reading on the Esbach tube is 1.25. 1.25 ÷ 10 gives 0.125 or the number of gm. protein in 100 ml. diluted milk. 0.125 × 10 = 1.25 gm. of protein in 100 ml. milk or 1.25% protein.

Normal protein content of human milk is 1-2.25%; of cow's milk it is 1.5-4%.

Protein may also be determined from total nitrogen values. Assay a 1:5 or a 2:5 dilution of milk for nitrogen by the method described on p. 41. The protein value is obtained by multiplying the % nitrogen by 6.34.

Total solids

Total solids are roughly calculated from the lactometer readings according to the following formula:

Let L equal the last 2 figures of the specific gravity.

Let F equal the percentage of fat found in the milk.

Total solids equals:

$$(L \div 4) + (0.2 \times F) + F.$$

Example: Specific gravity was 1.028. Percentage of fat was 4. 28 ÷ 4 is 7; 0.2 × 4 (F) is 0.8; 7 + 0.8 + 4 = 11.8% total solids.

Total solids may also be determined by drying an aliquot of milk to a constant weight. The volume used multiplied by the specific gravity is the original or wet weight. The dry weight times 100 divided by the wet weight is equal to the per cent solids. In this case any volatile material is considered water.

Formaldehyde in milk

1. Place 5 ml. sulfuric acid, c.p., concentrated, in a test tube.
2. Add to it 15 drops 10% ferric chloride solution. Great caution must be taken in the addition of the ferric chloride solution to the sulfuric acid. Do not add it too rapidly and avoid undue agitation of the contents. The

proportion of ferric chloride is 3 drops to each ml. sulfuric acid.

3. Fill a large test tube to within about 1 in. of the top with the milk to be tested.
4. Allow 1 or 2 ml. sulfuric acid-ferric chloride mixture to run slowly down the side of the tube so that it will collect on the bottom of the tube without mixing with the milk.
5. Allow to stand about 5 min.

The development of a reddish ring at the point of contact indicates the presence of formaldehyde.

Care must be taken not to use too much reagent, which may obscure the reaction.

Chapter 118

Skin tests

SKIN TEST FOR DIPHTHERIA
Schick test for susceptibility to diphtheria infection[37]

Schick toxin and controls may be purchased from any reliable biological supply house. This toxin is diluted and ready for use; 0.1 ml. of this mixture is 1/50 the minimum lethal dose of diphtheria toxin. This is the quantity to be injected.

1. Disinfect the flexor surface of the forearm.
2. Withdraw the mixture in the vial using a 1 ml. tuberculin syringe with a 23-gauge ½ in. needle. The syringe should be graduated in 0.1 ml. The beveled edge of the needle should be in line with the graduations of the syringe.
3. Push the needle between the layers of the skin until the point is well covered by the skin. The injection is to be made intradermally; hence, care must be taken not to give a deep inoculation. The point of the needle can be seen under the skin if the injection is made correctly.
4. Inject 0.1 ml. of mixture between the layers of the skin. A small white wheal will form.

Saline control: About 2 in. below this test puncture, inject 0.1 ml. sterile physiologic saline.

Protein control: After the injection of the Schick toxin inject 0.1 ml. heated mixture (control) intradermally about 2 in. below the saline injection. If the reaction is not read until the third or fourth day, this last injection may be omitted. Protein reactions occur within 24 hr. and can therefore be eliminated in the final reading.

Reading the reaction: The patient is instructed to return to the laboratory every day for 4 days. If a reaction occurs within 24 hr., it usually is not a diphtheria reaction. If the reaction is due to hypersusceptibility to saline, the saline control will show a zone of inflammation and a swelling. If the reaction is due to proteins, it is much more vigorous than the true Schick reaction and will reach its height within 24-48 hr.

A **negative reaction** is indicated by absence of change in the skin.

A **positive reaction** is accompanied by swelling and a zone of inflammation around the point of inoculation. The zone of inflammation is about 1 or 2 cm. in diameter around the point of inoculation. The inflammation gradually disappears and is replaced by browning of the skin accompanied by a slight area of necrosis. The slight brown discoloration may persist for several months.

A positive Schick test is indicative of susceptibility to diphtheria infection.

A negative reaction indicates immunity to diphtheria infection.

After the toxin has been diluted with the saline, it cannot be used for a period longer than 24 hr.

SKIN TESTS FOR SCARLET FEVER
Dick test for susceptibility to scarlet fever

Scarlet fever is ordinarily streptococcal sore throat in which the infectious agent is capable of producing erythrogenic toxin, and the patient has relatively low antitoxic immunity. In 1923 Dick and Dick[38] established facts which seemed to prove that the hemolytic streptococcus is responsible for scarlet fever. They showed that filtrates of broth cultures of scarlatinal strains of *Streptococcus pyogenes* (group A) contained a toxic substance which produced a typical erythematous reaction when injected intradermally in a proportion of normal persons who had not suffered from scarlet fever. The administration of larger doses of erythrogenic toxin to susceptible persons induced a generalized reaction with fever, nausea, vomiting, and transient scarlatiniform rash.

Purchase the Dick toxin for skin tests from any reliable biological supply house. This product is made so that 0.1 ml. represents the quantity for injection.

1. Cleanse the flexor surface of the forearm with alcohol.
2. Using a 1 ml. tuberculin syringe, inject intradermally exactly 0.1 ml. Dick toxin.
3. With another syringe, inject 0.1 ml. sterile physiologic salt solution about 2 in. below the test injection. Needles should be the same as for the Schick test.
4. Wait 24 hr.
5. Read the reaction in a good light.

If the saline injection shows a reaction, disregard the result of the test.

If the saline injection shows no reddening, the test may be read.

The readings are as follows:

Negative reaction: Red area less than 1 cm. in diameter.

Slight positive reaction: Red area 1-2 cm. in diameter.

Positive reaction: Red area 2-3 cm. in diameter, with some swelling and tenderness.

Strong positive reaction: Red area more than 3 cm. in diameter that is swollen and tender.

Blanching test for diagnosis of scarlet fever

In 1918 Schultz and Charlton[39] reported that 1 ml. normal human serum injected into skin of a scarlet fever patient produced blanching of the rash in the immediate neighborhood of the injection. Mair[40] viewed the positive reaction as the result of the development of a specific antitoxin which neutralizes the toxin present in the skin of a scarlet fever patient.

The test is now performed with 0.5 ml. of a good convalescent serum or 0.1 ml. of a potent antitoxin, and fading of the rash can be expected in 6-12 hr. A positive reaction establishes the diagnosis of scarlet fever and is useful in differentiating the scarlatinal rash from similar rashes caused by German measles and certain drug idiosyncrasies.

TUBERCULIN SKIN TESTS

Scratch test

Koch's old tuberculin (OT) may be obtained from any reliable biological supply house.

1. Cleanse the patient's forearm with alcohol.
2. Make 3 scratches (superficial) in the skin, each scratch about ½ in. in length, and at a distance of about ½ in. from each other.
3. Into the first 2 scratches (test) rub a small amount of tuberculin, using a sterile matchstick.
4. Into the third scratch rub a small amount of sterile physiologic salt solution (control).
5. Allow these to dry.
6. Instruct the patient to return to the laboratory for examination at the end of 24, 48, and 72 hr.

If the reaction takes place within 24 hr. he need not repeat the visits.

A positive reaction is characterized by a slight swelling along the scratch and an area of inflammation surrounding the inoculation.

The saline control should show no swelling or redness. If there is a reaction due to saline, the result of the test is unreliable.

A negative reaction shows no change in the skin.

A positive reaction persists for several days.

Koch subcutaneous tuberculin test

In this method Koch's OT is used. This is a filtrate of a concentrated broth culture of tubercle bacilli containing the toxin of the bacteria. It produces a focal as well as a general reaction. Before applying the tuberculin test take the temperature of the patient for several days to determine variations. Contraindications to the test are a markedly febrile course, general miliary tuberculosis, acute or advanced tuberculosis, tuberculous meningitis, the terminal stages of other diseases, and during convalescence from acute febrile diseases. The usual dose is 0.5 mg. injected subcutaneously.

A positive reaction consists in an elevation of temperature of at least 1° F., focal reaction, and a local reaction at the site of the injection. If no reaction is produced, repeat the injections, increasing the dosage gradually every 3-5 days until as much as 5 mg. have been given.

Mantoux intradermal tuberculin test

In this test a measured amount of OT is injected between the layers of the skin. For this test the following solutions are needed: 5 solutions of OT—1:10, 1:100, 1:1000, 1:10,000, and 1:20,000. They may be purchased ready for use, and if kept in a cool place, they will remain potent for 3 years.

1. Sterilize a 1 ml. tuberculin syringe and several 26-gauge ½ in. hypodermic needles.
2. Sponge the forearm with alcohol.
3. Fit a needle to the tuberculin syringe, with the bevel of the needle on the same side as the graduations on the syringe.
4. Fill the syringe to 0.2 mark with the OT.
5. Pinch the skin and press in the needle until the lumen just disappears. The injection raises a white wheal.

In patients who have had recent hemoptysis or skin or joint disease, the initial dosage should be 0.1 ml. 1:10,000 solution.

Read the reaction on the second to fourth day. An area of erythema ⅜ in. or more in diameter is positive. The more marked reactions show swelling and at times necrosis. When the reaction is negative, repeat the test, using 0.1 ml. 1:1000 dilution, and if still negative 48 hr. later, repeat, using 0.1 ml. 1:100 dilution, etc.

Vollmer tuberculin patch test*

This is a quick, accurate, painless test obviating the use of instruments as well as injury to the skin.

1. Thoroughly cleanse and defat with acetone the area of the skin of the inner side of the forearm or sternum (recommended for children) or upper spine (recommended for infants).
2. Then apply the patch firmly. Instruct the patient not to disturb the patch for 48 hr. and to avoid getting it wet.
3. The second day after removal, have the patient return to the laboratory for interpretation of the test.

A **positive** reaction appears as an infiltrated elevated reddened square. The central control square appears pale. If the patient is sensitive to adhesive tape, there may be irritation due to the tape, but this does not interfere with reading of the reaction.

---

*Lederle Laboratories Division, American Cyanamid Co., Pearl River, N. Y.

If directions for making and reading the test are carefully carried out, the results will be found superior to the von Pirquet test and comparable to those of the Mantoux test. Late reactions should be reported to the physician.

Rosenthal tine test*

This test is a simple rapid procedure. It correlates closely with the Mantoux test (94.3% for positive reactions and 96.8% for negative reactions).[41, 42]

The tine test is an intradermal test for the detection of tuberculin sensitivity. It is standardized by comparison with the standard intradermal Mantoux test (5 ITU).

Each tine test unit consists of a stainless steel disk attached to a plastic handle. Projecting from the disk are 4 triangular-shaped prongs, or tines, which are 2 mm. long and approximately 4 mm. apart. The tines have been dip-dried into 4 times concentrated U.S. Standard OT (U.S. Standard OT is equivalent to International Standard OT). The unit is disposable, thereby eliminating the need for syringes, needles, and other equipment for tuberculin testing. The package is terminally sterilized by ethylene oxide gas, and each unit is sterile until removed from its individual holder.

The preferred site for accurate and standardized tuberculin testing is the volar surface of the mid-forearm. The skin must be clean and dry. It may be cleansed with alcohol, acetone, ether, or soap and water. Hairy areas and areas without adequate subcutaneous tissue, such as concavities over a tendon or bone, should be avoided.

Grasp the patient's arm firmly with one hand, stretching the skin of the forearm tightly, and apply the time test with the other hand. Momentary stinging may cause the patient to jerk his arm, resulting in scratching. Hold momentarily (1 sec.) and withdraw. Sufficient pressure should be exerted so that the 4 puncture sites and a circular depression of the skin from the plastic base are visible. **Do not reuse the tine test unit.**

Tests should be read at 48-72 hr. **Induration** is the only criterion. Erythema is ignored. It is important to measure the amount of induration exactly by examining under adequate light and by thoroughly palpating the area. Identification of the application site is usually easy because of the distinct 4-point pattern. Two mm. or more of palpable induration around one or more puncture sites is a positive reaction and is equivalent to 5 mm. or more by the standard intradermal (5 tuberculin units or 0.0001 mg. PPD) Mantoux test. With the more positive reaction and is equivalent to 5 mm. or more puncture sites tend to coalesce.

Tuberculin testing should be done with caution in persons with active tuberculosis. However, activation of quiescent lesions is not to be expected.

Interpretation of tuberculin reactions

The tuberculin reaction is a reliable test for hypersensitiveness to the tubercle bacillus; by that we mean past or present tuberculous infection. The negative reaction is of most value in clinical diagnosis. When tuberculosis nears fatal termination, sensitiveness to the tuberculin injection is depressed.

In children, a negative reaction is useful to exclude tuberculosis in chronic cervical adenitis, prolonged anorexia, debility following bronchopneumonia, whooping cough, or measles. If complete healing of a tuberculous infection occurs and the bacilli die, the tuberculin reaction after a time may become negative. Sometimes, infection becomes well walled off, often in a calcified nodule, but still the bacteria remain alive, and a positive tuberculin reaction is noted. A markedly positive Mantoux reaction in a patient with indefinite physical signs suggests some active focal infection which under unfavorable hygienic conditions may spread and form extensive disease.

SKIN TESTS FOR LYMPHOGRANULOMA INGUINALE (VENEREUM)

Frei reaction for lymphogranuloma inguinale (venereum)

This is a method of making the diagnosis of lymphogranuloma inguinale (venereum) by the use of an antigen prepared from the pus withdrawn by aspiration from the bubo. It was published by Frei[43] in 1925. The value and specificity of the test have been demonstrated by Frei in subsequent papers[44-46] in 1927 and 1932 and have been confirmed by Frei and Hoffmann[47] in 1927 and by a number of other workers.

Frei's directions for the preparation of this antigen are as follows: The person from whom the antigen is to be made should be proved free from tuberculosis and venereal diseases by clinical examination and negative tests for syphilis, gonorrhea, and soft chancre. The pus must be withdrawn from a gland that has undergone softening but not fistulation. Aspirate by means of syringe and thick needle, under sterile precautions, obtaining as far as possible blood-free pus. This pus is mixed with physiologic saline in the proportion of 1 part pus to 5 parts saline in a sterile tube and is immediately put up in 0.5-1 ml. doses in hard-glass ampules. It is heated to 60° C. for 2 hr. over a water bath and the following day at 60° C. for 1 hr. This material is tested for sterility by culture under aerobic and anaerobic conditions at room and incubator temperatures. This antigen should give a negative reaction in the skin of normal individuals. The antigen should be preserved at a low temperature and should not be exposed to light. If an ampule is opened, the remaining contents should be discarded or resterilized.

---

*Lederle Laboratories Division, American Cyanamid Co., Pearl River, N. Y.

The method of carrying out the test is as follows. Disinfect the skin with alcohol. Use the skin of the outer forearm. Inject intracutaneously 0.1 ml. antigen. A corresponding area on the other side of the body should be injected with the same amount of physiologic saline. It is well to inject 2 normal controls with the same antigen and the same saline in the same way and at the same time. Read the result after 48 hr. and not before. A positive reaction consists in the production of an infiltrated inflammatory dome-shaped area 0.5 cm. in diameter at least and often larger, which can be felt as well as seen. It is often noted that there is a small area of necrosis in the center surrounded by a red zone.

Antigens usually remain active for several months, sometimes for a year, but not always.

Vesicular test for lymphogranuloma inguinale (venereum)

Because of the difficulty in obtaining material at times for making the original Frei antigen, Ottolina[48] suggested the use of concentrated spinal fluid from a known case, using this material for skin inoculation. This is based upon the fact that in experimental infections of this disease the cerebromedullar axis is prevailingly affected. Spinal fluid, therefore, constitutes a human antigen, easy to obtain, aseptic, and with a small amount of albumin.

The method described by Ottolina is to perform a spinal puncture under aseptic conditions and carry out a vacuum concentration of the fluid. By reducing 10 ml. fluid to 1.5 ml., a colloidal-like solution is obtained which is opalescent and foams upon agitation. If this concentrated fluid is injected intradermally, a vesicle appears 24 hr. later at the point of injection; this phenomenon has been called the "vesicular test." The vesicle may be ovoid, circular, or triangular, but there is a definite trend toward the hemispheric form. The ovoid type measures 4 mm. in length, 2 mm. in width, and 1 mm. in height, whereas the more rounded forms approach approximately 3 mm. × 2 mm. × 1 mm. The color of the skin covering the blister is light or dark brown, sometimes dark gray. The blistered skin always has a darker shade than the surrounding skin.

Twenty-four hr. after the injection the blister preserves the same morphology, the fluid within showing a light tension. Forty-eight hr. later a certain umbilication may be noted, the fluid tension has relaxed, and the blister skin is more colored than on the first day. Three days later there is a distinct flaccidity in the blister and desiccation begins at that time and ends in 4 or 5 days. Five or 6 days after its appearance the blister is only a pigmented spot about 2 mm. in diameter. The vesicular fluid has a light brown color and microscopically shows a few polynuclear neutrophilic and mononuclear leukocytes. This fluid is sterile.

Technic is to concentrate fluid employed from 10 ml. to 2 ml. and inject intradermally 0.3 ml.

It is interesting to note, according to Ottolina's researches, that this test, when applied to the positive patient from whom it was obtained, produced a typical positive reaction. In other words, it is an autoreaction, which emphasizes its diagnostic value.

Grace-Suskind mouse brain antigen* for Frei reaction

Hellerström[49] has shown that antigens made from the brains of monkeys infected through subdural injection give the same specific Frei reaction when used on human beings as when the human antigen is used. Working along this line, Grace and Suskind[50] developed a mouse brain antigen which is more highly potent than that made directly from the same human material used in the preparation of the brain antigen. This antigen is a 10% emulsion of infected mouse brain.

For each test inject 0.1 ml. intradermally, using a 1 ml. tuberculin type of syringe with a 27-gauge needle. If **positive,** the raised papular reaction is noted in from 48-72 hr. If **negative,** no reaction occurs; if one uses an injection of a similar emulsion of normal mouse brain as a control, no reaction appears.

Chick embryo antigen† for Frei reaction

The 3 sources of antigen for the Frei test just described are (1) pus from the inguinal bubo of the patient, (2) spinal fluid from a patient with the disease, and (3) emulsions of the brains of mice intracerebrally infected with virus. Since antigens prepared from human pus and spinal fluid are not readily available, and since considerable doubt has been expressed as to the reliability of the mouse brain antigen, a successful method of producing antigen has been evolved by propagating the virus of lymphogranuloma inguinale on the chorioallantois of developing chicks. This has been successfully carried out by Rake et al.[51] working in the Squibb Institute of Medical Research. These workers developed a method for obtaining a highly potent and purified antigen for this test. The virus was used to inoculate into the yolk sac of 5- or 6-day-old fertile eggs, as demonstrated by Fig. 794.

By suitable methods of purification a virus was obtained which, when undiluted, was about 1 million times more potent than the lymphogranuloma virus obtained from mouse brain. Not only did the yolksac method yield a more potent virus than the other methods,

---

*Lederle Laboratories, Pearl River, N. Y.

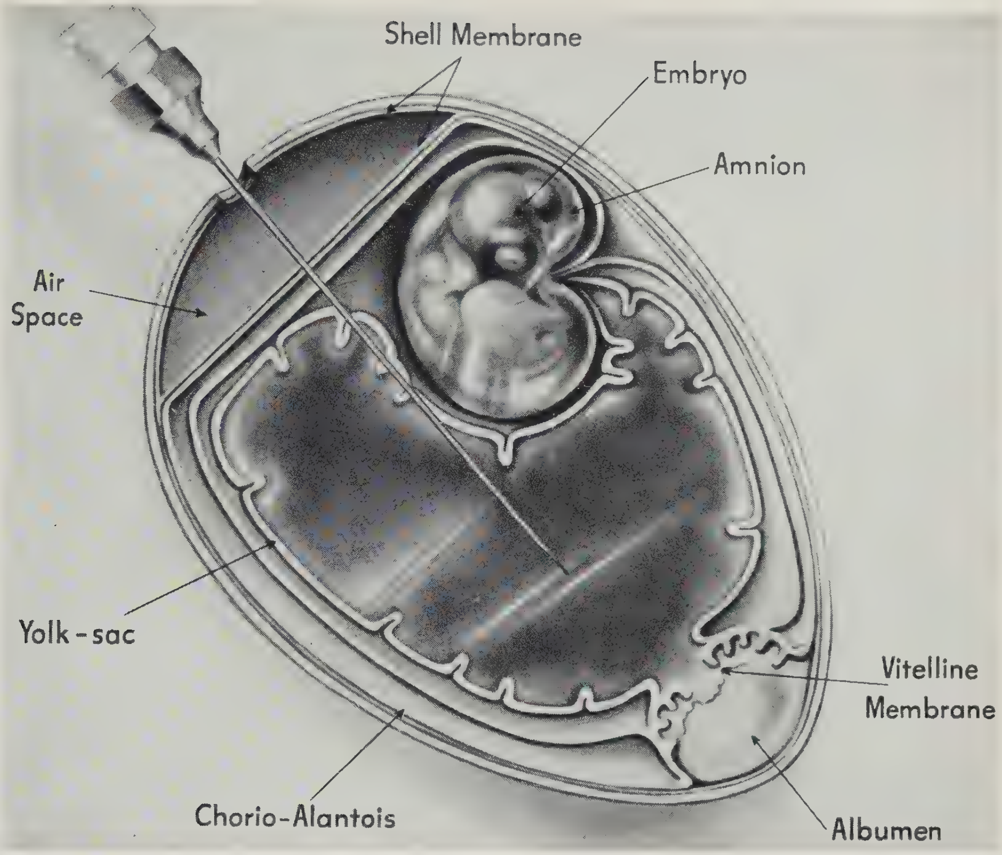

Fig. 794. Method of injecting the yolk sac of a developing chick. (Courtesy E. R. Squibb & Sons, New York, N. Y.)

but also by a process of differential centrifugation, a practically pure suspension of the virus could be obtained. In other words, the extraneous inert material from the yolk sac can be almost completely eliminated.

In a very interesting trial of this material, Sulkin et al.[52] reported 42 patients with active lymphogranulomatous infection or with a history of past infection who were tested with the various antigens. They made a series of intradermal injections on the arm, the proximal injection being made with human Frei antigen, 2 middle injections with egg and mouse brain antigens, and 2 distal injections with the corresponding controls. Reactions were read within 48-96 hr. Of the 42 patients tested, 40 gave a positive, 1 a doubtful and 1 a negative reaction to yolk sac antigen; 34 gave a positive, 5 a doubtful, and 3 a negative reaction to mouse brain antigen; 38 gave positive, 1 a doubtful and 3 negative reactions to human pus antigen. Thirty-three persons had positive reactions with all three antigens.

As these writers point out, any foreign substance when injected intradermally into a human subject will produce an inflammatory response at the site of inoculation, and the severity of the reaction will be influenced by any hypersensitivity to the material. These facts, of course, must be considered in determining the cutaneous response to any Frei antigen. The conclusions of these workers, however, were that the yolk sac antigen is superior to mouse brain antigen for performance of the Frei cutaneous test for lymphogranuloma inguinale and that comparatively few nonspecific reactions are produced with the egg control material as compared with the mouse brain control.

Procedure of the test: Inject 0.1 ml. Frei antigen of chick embryo origin intradermally into the flexor surface of the arm. Read reaction within 48 or 72 hr. In order to eliminate false positives due to chick protein sensitivity, a control is supplied by the manufacturer for each test. This consists of normal chick embryo protein prepared in a manner similar to that of the antigen. A positive test is seen by the appearance of a reddish papule 6 mm. or more in diameter, surrounded by a fainter erythematous area of varying size. This papule must be measured with a millimeter scale. The extent and intensity of the erythematous area around the papule is of no diagnostic significance. Strongly positive reactions may have a papule surmounted by a vesicle, or pustule which may break down and form a crust. The reaction will gradually regress, ending as a faintly pigmented area with or without a scar.

The intradermal Frei test is positive only at the peak of the allergic period when specific antibodies have been formed in the infected organism. This usually becomes positive about 2 wk. after inoculation, sometimes later. It may be negative during the menstrual period and in the not-so-rare cases of florid syphilis if the 2 diseases coexist.

Interpretation of results should be made from the fourth day. The reaction appears in 24-48 hr., reaching a maximum in 3 days, after which it gradually decreases in intensity. A positive reaction consists of a papule, vesicle, or pustule with a diameter larger than 6 mm. It is more intense in inguinal than in rectal cases. The reaction persists for several weeks. Saline control injection should always be made. Nonspecific reactions have a diameter of less than 6 mm. and decrease after 3 days.

Most of the American workers agree that the chick embryo antigen is superior to all others for use in the Frei test.

The sole disadvantage of this test is its delayed appearance. Ravaut et al.[53] proposed a hemoreaction for early diagnosis. Their antigen is injected intravenously, producing a rise of temperature to 102°-104° F. in 12-18 hr. which remains for 24-48 hr. and is accompanied by general malaise, chills, headache, insomnia, weakness, arterial hypotension, and leukopenia. The test has the disadvantage that it can be used only once. It is positive in 97% of the cases.

The complement fixation test may give false positive results, especially in diseases caused by viruses belonging to the same group.

The presence of Miyagawa corpuscles in infected tissues as seen in secretions is considered diagnostic of the disease. These corpuscles can be demonstrated with certain stains: eosin and methylene blue, Macchiavello, Giemsa, and Noble.

The blood picture shows leukocytosis, oligocytosis, neutrophilia, lymphopenia, and monocytopenia.

SKIN TESTS FOR CHANCROID

Greenblatt-Sanderson intradermal chancroid test

In connection with the foregoing remarks on lymphogranuloma inguinale, it must be remembered that every case of venereal disease requires exhaustive laboratory tests to prove the true diagnosis. It has been found that many cases of chancroid infection have been thought to be lymphogranuloma inguinale but a negative Frei test has caused some doubt concerning this diagnosis. Greenblatt and Sanderson[54] have called attention to a very valuable method of including or excluding chancroid infection in a diagnostic survey of these venereal cases. They have originated an intradermal test for chancroid infection using an antigen made from a saline suspension of *Haemophilus ducreyi* bacillus. Their method of growing this bacillus is as follows.

Method of cultivating Haemophilus ducreyi: To tubes of beef infusion agar in slants is added 1 ml. defibrinated human blood. The blood is inoculated with 0.1 ml. from an actively growing culture and placed under partial oxygen tension. To obtain this environment, the cotton plug is cut off short and pushed slightly into the tube; the upper portion of the tube is heated, but not too much, in a Bunsen flame, and the tube is sealed by inserting a tightly fitting rubber stopper. The culture is incubated for 2-3 days at 37° C. During this period good growth takes place in the fluid blood, and a lesser growth appears on the surface of the slant. After the incubation, the blood, as well as the surface growth, if any, is removed with a sterile pipet and added to approximately 25 ml. sterile distilled water in a sterile centrifuge tube of sufficient volume, and the contents are sedimented by high speed centrifugation. The supernatant fluid is removed aseptically and discarded, and the process is repeated. Two such treatments suffice to remove most of the hemoglobin. The sediment of bacilli and red cell debris is suspended in sterile physiologic solution of sodium chloride, 10 ml./slant being placed in sterile vials, and heated for 30 min. at 60° C. A 1:10,000 solution of Merthiolate is used as a preservative. One-tenth ml. is employed for intracutaneous tests, and the reactions are observed in 48 hr.

It must be remembered that some patients with lymphogranuloma inguinale with a positive Frei test are also suffering from a chancroid infection, in which case the intradermal chancroid reaction will be positive. A positive chancroid test is only presumptive evidence and does not necessarily mean that the lesion under consideration is chancroid. A similar conclusion should be borne in mind in the interpretation of a reactive Wassermann as well as of a positive Frei test in every case of genital lesion unless other confirmatory laboratory evidences are present. A negative intradermal test with bacillary antigen is diagnostic so far as it rules out infection by the bacillus of Ducrey. A positive intradermal chancroid test commits one to the diagnosis of chancroid infection only when the Frei test, standard tests for syphilis, and microscopic examinations for malignant disease and granuloma inguinale give negative results. This reaction remains positive for life, and this fact should be borne in mind in dealing with the above considerations.

SKIN TESTS FOR BRUCELLOSIS

Brucella skin test*

As a consequence of the infection by any of the 3 brucellae, the host develops a state of hypersensitivity displayed after further exposure to these organisms, whether live or killed. The injection by intradermal route of small amounts of a suspension of inactivated brucellae or soluble antigens is usually followed by a delayed tuberculin-like dermal reaction which may reach a peak 24-48 hr. after injection. The reaction may last several days and in some cases may be of such a high intensity as to produce local necrosis accompanied by regional lymphatic reaction.

The antigens most commonly used have been heat-killed *Brucella* cells suspended in isotonic saline, broth filtrates known as **melitin or abortin,** certain purified products such as the protein antigen (PPA) of Moreles-Otero, the brucellergen of Huddleson, and the polyvalent antigen (MBP) prepared at the Brucella Center of Mexico. The test is performed by intradermal injection into the forearm of 0.1 ml. of any of the above mentioned antigens.

It is advisable to use antigens that are not capable of stimulating agglutinin response in nonreacting patients.

Since the skin test is likely to be positive not only in active cases of brucellosis but also in any person previously exposed to the infection, one has to be aware of the inconvenience of using this procedure as diagnostic evidence of actual infection. Furthermore, it has been observed that the skin test is not always positive during the evolution of clinical brucellosis. It is expected that the test will be negative during the first weeks of illness, but even in the third month there may be as many as 48% negative tests in bacteremic cases. The percentage of negative tests drops to 31 in the sixth month and to 23 from the sixth to the twelfth month. In nonbacteremic cases the test is generally positive, particularly in chronic cases.

Because of the difficulty of properly interpreting the skin test, one must consider it as an additional evidence of infection together with other tests. It is occasionally of help in deciding doubtful cases with symptoms compatible with brucellosis but with low agglutinin titers and negative blood cultures. However, the final decision must await further evidence. On the other hand, a persistently negative skin test is of value in ruling out brucellosis in patients with chronic illness.

By means of carefully standardized allergens such as the polyvalent MBP, it has been observed in epidemiologic surveys that reacting persons living in endemic areas, healthy at the time of the test, have shown reactions of moderate intensity. If after treatment with such antigen a patient with a known history of brucellosis or suggestive symptoms develops reactions of unusual intensity with or without a systemic response, he may be considered a hypersensitive individual in whom the allergic state might be related to the actual clinical condition. Those who favor allergic desensitization may find the allergic test of some value as a guide in therapeutic attempts.

SKIN TESTS FOR HANSEN'S DISEASE

Lepromin test (Mitsuda test)

This test consists essentially of an intradermal injection of lepromin, an antigen prepared from tissues rich in Hansen bacilli. It is made by boiling lepromatous tissues in isotonic solution of sodium chloride for 1 hr., after which the mass is ground in a mortar, and 20 ml. 0.9% solution of sodium chloride are added for each gm. of ground tissue. After repeated and thorough mixing and grinding, the supernatant fluid is pipetted off, filtered through gauze, and stored in a sterile container.[55]

The liquid is autoclaved at 120° C. for 15 min., 0.5% phenol is added, and the liquid distributed to rubber-capped vials ready for use. It is a cloudy, milky emulsion containing numerous bacilli (globi) and the tissue elements of the leproma. If kept in a dark, cool place, it retains its activity for a long time. Seitz-filtered antigens are inactive.

Procedure:

Inject 0.1-0.15 ml. lepromin intradermally either into the skin of the scapular region or upon the anterior surface of the thigh.

At the end of 24-48 hr. there is a light erythema which is attributed to the presence of foreign protein material and which disappears in a few days, usually in 3 or 4. The site of the test then remains apparently normal until the beginning of the third week when, if the test is positive, a slight papular infiltration is noted, gradually increasing in size until it attains the size of a pea. The infiltration is deep, and its color is bright red. There might be some tenderness on pressure and occasionally formation of a central necrotic focus with ulceration, resulting in a permanent scar.

The test should be evaluated on about the thirtieth day after the injection. If there is no reaction or only a small (less than 5 mm.) infiltration, the test is negative.

---

*M. Ruiz Castañeda.

The test is positive in about 90% of normal individuals, in practically all cases of tuberculoid Hansen's disease, and in about 50% of patients with the simple inflammatory type. It is negative in practically every case of lepromatous Hansen's disease, in about 10% of apparently normal persons, and in about 50% of patients with simple inflammatory Hansen's disease.

It is a **prognostic test.** If the test is negative in a person without symptoms of Hansen's disease, that person is susceptible to the disease. The test is applied to prospective employees of leprosaria; those with negative Mitsuda tests are not permitted to serve in such institutions.

Histamine test

1. Place a drop of 1:1000 solution histamine phosphate on the affected skin to be tested.
2. Place another drop at a point between the suspected area and the adjacent normal skin and a third drop on the normal skin.
3. Lightly prick the epidermis through these drops, using the point of a hypodermic needle, being careful not to cause bleeding.
4. Immediately dry the drops of histamine with cotton and carefully watch the sites of the test.
5. Within 25-40 sec. the **normal skin** shows an area of erythema with irregular outline, usually 5-20 mm. in diameter, later reaching as much as 5 cm.

In 60-100 sec. a wheal forms in the erythematous area, centered by the point where the needle entered the epidermis. After 3 min. a hemorrhagic point may appear at the site of the needle prick. The wheal usually measures 2-5 mm. in diameter.

The reaction persists for approximately 20 min., but at times the erythema and the wheal are still present after 45 min. There are individual variations due to age, room temperature, and local circulatory conditions. The test cannot be made on the skin of Negroes.

Between the affected and the normal skin, the test shows the same succession of phenomena on the normal half of the skin, but on the affected half the erythematous reaction stops abruptly and is absent on that part of the skin, but the wheal is always present without the peripheral erythema.

On the **anesthetic skin,** erythema is wholly lacking, whereas the wheal is present and remains the usual length of time.

The test causes no subjective sensations, either on the normal or the affected skin.

The test is read as normal or abnormal and not as positive or negative.

Any type of degenerative peripheral neuritis may give an abnormal histamine test, and therefore it is not exclusively diagnostic of Hansen's disease. The test is not reliable when performed at a room temperature below 24° C. or when performed on aged persons with slow or impaired peripheral circulation. It is important in the differential diagnosis between Hansen's disease and syringomyelia since in the latter condition the histamine test is normal.

SKIN TEST FOR GLANDERS

Mallein test

A modification of the mallein skin test, permitting its use in human beings, is a valuable aid in the diagnosis of glanders.

One-tenth (0.1) ml. commercial mallein in a dilution of 1:10,000 is injected intradermally into the skin of the forearm. The test is read at 24 and 48 hr. Specific positive tests reach maximum erythema, 10-20 mm. in diameter, after about 18-24 hr. and fade only slightly if at all by the end of 48 hr.

SKIN TEST FOR TULAREMIA

Foshay intradermal test

A successful intradermal reaction was reported by Foshay.[56] This reaction has the appearance of a positive tuberculin reaction. It shows up in about 48 hr. Foshay test solution is made from virulent strains of *Pasteurella tularensis.* This suspension is oxidized for about 5 hr. with nitrous acid and then adjusted to a turbidity equivalent to 100 p.p.m. of Fuller's earth. The standard test dosage of this suspension is 0.05 ml. The proper time to read the response is at the forty-eighth hour after administration. Hypersensitivity of the skin is a notable feature of tularemia; therefore, caution must be used in selecting an antigen that affects the toxicity of heat-killed organisms for skin testing.

SKIN TESTS IN FUNGAL INFECTIONS
